Low urine output (800 to 1500 mL) in the first 24 hours after surgery may be expected, regardless of fluid intake. This low output is caused by increased aldosterone and ADH secretion resulting from the stress of surgery; fluid restriction before surgery; and fluid loss through surgery, drainage, and diaphoresis. By the second or third day, after fluid has been mobilized and the immediate stress reaction subsides, the patient will begin to have increasing urine output.

Acute urinary retention can occur in the postoperative period for a variety of reasons. Anesthesia depresses the nervous system, including the micturition reflex arc and the higher centers that influence it. This allows the bladder to fill more completely than normal before the urge to void is felt. Anesthesia also impedes voluntary micturition. Anticholinergic and opioid drugs may also interfere with the ability to initiate voiding or to empty the bladder completely.

Urinary retention is more likely to occur after lower abdominal or pelvic surgery because spasms or guarding of the abdominal and pelvic muscles interferes with their normal function in micturition. Pain may alter perception and interfere with the patient's awareness of bladder filling. Voiding ability is probably impaired to the greatest extent by immobility and bed rest. The supine position reduces the ability to relax the perineal muscles and external sphincter.

Oliguria (the diminished output of urine) can be a manifestation of renal failure and is a less common, although more serious, problem after surgery. It may result from renal ischemia caused by inadequate renal perfusion.

NURSING MANAGEMENT URINARY PROBLEMS

NURSING ASSESSMENT

Examine the urine for both quantity and quality. Note the color, amount, and odor of the urine. Assess indwelling catheters for patency. Urine output should be at least 0.5 mL/kg/hr. To decrease the risk of catheter-associated urinary tract infection (CAUTI), remove the catheter as soon as possible or within 24 hours, unless there is a reason to continue its use.[29] Most patients urinate within 6 to 8 hours after surgery. If no voiding occurs, scan or percuss the suprapubic area for signs of bladder fullness or distention.

NURSING DIAGNOSES

Nursing diagnoses and collaborative problems related to urinary problems include, but are not limited to, the following:

- Urinary retention *related to* anesthetic agents, pain
- Potential complication: acute kidney injury

NURSING IMPLEMENTATION

You can aid voiding by normal positioning of the patient—sitting for women and standing for men. Reassure the patient regarding the ability to void. Helpful techniques include providing privacy, running water, offering water for the patient to drink, or pouring warm water over the perineum. Walking, preferably to the bathroom, and the use of a bedside commode are additional helpful measures to assist in voiding.

The surgeon often leaves an order to catheterize the patient in 6 to 8 hours if voiding has not occurred. Because of the

possibility of CAUTI, first try to validate that the bladder is actually full. Consider fluid intake during and after surgery and determine bladder fullness (e.g., discomfort when the bladder is palpated). Scan the bladder with a portable ultrasound to assess volume of urine in the bladder and avoid unnecessary catheterization. If catheterization is required, a straight catheterization (as compared to an indwelling catheter) is preferred to limit the possibility of CAUTI.

INTEGUMENTARY PROBLEMS

Etiology

Surgery generally involves an incision through the skin and underlying tissues, disrupting the protective skin barrier. Therefore wound healing is one of the major concerns during the postoperative period.

Wound infection may result from contamination of the wound from three major sources: (1) exogenous flora present in the environment and on the skin, (2) oral flora, and (3) intestinal flora. The incidence of wound sepsis is higher in patients who are malnourished, immunosuppressed, or older, or who have had a long hospital stay or a lengthy surgical procedure (more than 3 hours). Patients needing bowel surgery, particularly after a traumatic injury, are at high risk. Infection may involve the entire incision and may extend downward through deeper tissues. An abscess may form locally, or it may spread throughout entire body cavities, as in peritonitis.

Evidence of wound infection usually does not become apparent before the third to fifth postoperative day. Local manifestations include redness, swelling, and increasing pain and tenderness at the site. Systemic manifestations are fever and leukocytosis.

An accumulation of fluid in a wound may create pressure, impair circulation and wound healing, and predispose the patient to infection. To allow for drainage, the surgeon may place a drain in the incision or make a stab wound adjacent to the incision. These drains may be made of soft rubber and drain into a dressing, or they may be firm catheters attached to a Hemovac or other source of gentle suction.

An adequate nutritional state is essential for wound healing. Obesity affects abdominal wound healing. Wound healing is also a concern for the older adult. The patient who was well nourished preoperatively can tolerate the postoperative delay in nutritional intake for several days. However, the patient with preexisting nutritional deficits that occur with chronic diseases (e.g., diabetes, ulcerative colitis, alcoholism) is more prone to problems of wound healing. The patient who is unable to meet nutritional needs postoperatively may be provided with enteral or parenteral nutrition to promote healing.

NURSING MANAGEMENT SURGICAL WOUNDS

NURSING ASSESSMENT

Nursing assessment of the wound and dressing requires knowledge of the type of wound, the drains inserted, and expected drainage related to the specific type of surgery. A small amount of serous drainage is common from any type of wound. If a drain is in place, a moderate to large amount of drainage may be expected. For example, an abdominal incision with an accompanying drain is expected to have a moderate amount of serosanguineous drainage in the first 24 hours. In contrast, an inguinal herniorrhaphy should have only minimal serous drainage during the postoperative period.

In general, drainage is expected to change from sanguineous (red) to serosanguineous (pink) to serous (clear yellow). The drainage should decrease over hours or days, depending on the type of surgery. Wound infection may be accompanied by purulent drainage. *Wound dehiscence* (separation and disruption of previously joined wound edges) may be preceded by a sudden discharge of brown, pink, or clear drainage. (Wound dehiscence is discussed in Chapter 12.)

NURSING DIAGNOSES

Nursing diagnoses related to surgical wounds include, but are not limited to, the following:

- Impaired skin integrity *related to* surgical incision
- Risk for infection

NURSING IMPLEMENTATION

When drainage appears on the dressing, document the type, amount, color, and odor of drainage. Expected drainage from tubes is outlined in Table 20-7. Also assess the effect of position changes on drainage. Notify the surgeon of any excessive or abnormal drainage or significant changes in vital signs.

TABLE 20-7 DRAINAGE FROM TUBES AND CATHETERS

Substance	Daily Amount	Color	Odor	Consistency
Indwelling Catheter				
Urine	800-1500 mL for first 24 hr Minimum expected output: 0.5 mL/kg/hr	Clear, yellow	Ammonia	Watery
Nasogastric Tube or Gastrostomy Tube				
Gastric contents	<1500 mL/day	Pale, yellow-green Bloody after GI surgery	Sour	Watery
Hemovac				
Wound drainage	Varies with procedure May decrease over hours or days	Varies with procedure Initially, may be sanguineous or serosanguineous, changing to serous	Same as wound dressing	Variable
T Tube				
Bile	500 mL	Bright yellow to dark green	Acid	Thick

The incision may be covered with a dressing immediately after surgery. If there is no drainage after 24 to 48 hours, the dressing may be removed and the incision left open to the air. If the initial operative dressing is saturated, agency policy determines whether you may change the dressing or simply reinforce it.

When a dressing is changed, note the number and type of drains present, and avoid dislodging the drains. Inspect the incision site carefully. The area around the sutures may be slightly reddened and swollen, which is an expected inflammatory response. However, the skin around the incision should be of normal color and temperature. If the wound is healing by primary intention, has little or no drainage, or has no drains in place, a single-layer dressing or no dressing is sufficient. A multilayer dressing is used when drains are in place, when moderate to heavy drainage is occurring, or when healing occurs other than by primary intention. (Wound healing and care are discussed in Chapter 12.)

DISCHARGE FROM THE PACU

The choice of discharge site is based on patient acuity, access to follow-up care, and the potential for postoperative complications. The decision to discharge the patient from the PACU is based on written discharge criteria (Table 20-8). A standardized scoring system, such as the *Modified Aldrete Scoring System,* is often used to determine the patient's general condition and readiness for discharge from the PACU. (The Modified Aldrete Scoring System is presented in eTable 20-1 on the website for this chapter.)

Discharge to the Clinical Unit

Before discharging the patient from the PACU to the clinical unit, provide a verbal report about the patient to the receiving nurse. The report summarizes the operative and postanesthesia period. It should also include information as to where the patient's caregivers are waiting. Nurse-to-nurse communication must be accurate and allow for questions. The use of a standardized communication tool, such as SBAR *(Situation-Background-Assessment-Recommendation),* provides a complete report and enhances a safe transfer of the patient from PACU to the clinical unit (Table 20-9). (Handoff communication is discussed in Chapter 1, and SBAR is presented in Table 1-7.)

If you are the nurse who receives the patient on the clinical unit, assist the PACU transport staff to move the patient from the stretcher to the bed. Take care to protect IV lines, drains, and traction devices. Use a draw sheet, transfer board or sling, and sufficient staff to facilitate the safe transfer of the patient. Obtain vital signs and compare the patient status with the report provided by the PACU nurse. After this, perform a more in-depth assessment and initiate postoperative orders and nursing care as appropriate (Table 20-10).

TABLE 20-8 SURGERY DISCHARGE CRITERIA

PACU Discharge Criteria (Phase I)

- Patient awake (or baseline)
- Vital signs at baseline or stable
- No excess bleeding or drainage
- No respiratory depression
- O_2 saturation >90%
- Pain controlled or acceptable
- Minimal nausea and vomiting
- Report given

Ambulatory Surgery Discharge Criteria (Phase II or Extended Observation)

- All PACU discharge criteria (Phase I) met
- No IV opioid drugs for last 30 min
- Voided if appropriate to surgical procedure or orders
- Able to ambulate if not contraindicated
- Responsible adult present to accompany and drive patient home
- Written discharge instructions given and patient and caregiver understanding confirmed

AMBULATORY SURGERY

Phase II and Extended Observation

Advances in minimally invasive and noninvasive procedures, anesthesia, and analgesia have resulted in an increase in ambulatory surgical procedures.[30] Ambulatory surgery patients include those patients receiving Phase II and extended observation postoperative care (see Table 20-1). Postoperative nausea and vomiting and pain are significant problems after ambulatory surgery. These can lead to delirium, prolonged PACU stay, delayed discharge, readmission, delayed resumption of usual activities, and decreased patient satisfaction.[31,32]

Ambulatory Surgery Discharge

The patient leaving an ambulatory surgery setting must be mobile and alert to provide a degree of self-care when discharged to home (see Table 20-8). Postoperative pain, nausea,

TABLE 20-10 NURSING ASSESSMENT

Care of Patient on Admission to Clinical Unit

1. Record time of patient's return to unit and assess airway, breathing, and circulation.
2. Obtain baseline vital signs, including O_2 saturation.
3. Assess neurologic status, including level of consciousness and movement of extremities.
4. Assess level of pain:
   - Last dose and type of pain control
   - Current pain rating
5. Assess wound, dressing, and drainage tubes:
   - Type and amount of drainage
   - Tubing connected to gravity or suction drainage (per orders)
6. Assess color, temperature, and appearance of skin.
7. Assess urinary status:
   - Time of voiding
   - Presence of catheter, patency, and total output
   - Bladder distention or urge to void
8. Position for airway maintenance, comfort, and safety (bed in low position, side rails up).
9. Check IV infusion:
   - Type of solution
   - Amount of fluid remaining
   - Patency and flow rate
   - Condition of insertion site and size of catheter
10. Position call light within reach, and orient patient to use of call light.
11. Assess for any nausea or vomiting.
    - Availability of emesis basin and tissues
12. Determine emotional state and provide support as needed.
13. Check for presence of caregiver.
    - Patient and caregiver oriented to immediate environment
14. Check and carry out postoperative orders.

and vomiting must be controlled. Overall, the patient must be stable and near the level of preoperative functioning for discharge from the unit. At discharge, provide teaching for the patient and the caregiver specific to the type of anesthesia and surgery, and reinforce with written instructions. The patient may not drive and must be accompanied by a responsible adult at the time of discharge. A follow-up evaluation of the patient's status is made by telephone, and any specific questions and concerns are addressed.

Carefully assess the patient's readiness for discharge and home care needs. Determine availability of caregivers (e.g., family, friends) and access to a (1) pharmacy for prescriptions, (2) phone in the event of an emergency, and (3) follow-up care.

Discuss the patient's expectations regarding activity and assistance needed after discharge. The patient and caregiver must be included in discharge planning and provided with the information and support to make informed decisions about continuing care.

Planning for Discharge and Follow-up Care

Preparation for the patient's discharge is an ongoing process that begins during the preoperative period. The informed patient is prepared as events unfold and gradually assumes more responsibility for self-care during the postoperative period. As discharge approaches, be certain that the patient and any caregivers have the following information:

- Symptoms to be reported (e.g., fever, increased incisional drainage, unrelieved incisional pain, discomfort in other parts of the body)
- When and how to take drugs, and possible side effects

INFORMATICS IN PRACTICE

Discharge Teaching

- If you are discharging a patient who requires a complex dressing change and think that written instructions are not adequate, consider using a video. This may be available on the hospital's television system or the Internet (e.g.,YouTube). You could also take a series of pictures that show how to perform the procedure.
- If using a video from the Internet, check it to ensure that the procedure is properly done.
- The patient and caregiver can view the video or pictures at home as a reference when performing the procedure.

- Care of incision and any dressings, including bathing recommendations
- Activities allowed and prohibited. When various activities can be resumed safely (e.g., driving a car, returning to work, sexual intercourse, leisure activities)
- Dietary restrictions or modifications
- Where and when to return for follow-up care
- Answers to any individual questions or concerns

Common reasons patients seek help after discharge include unrelieved pain, need for advice about medications, and wound issues (e.g., drainage). Attention to complete discharge instructions may prevent needless distress for the patient and the caregiver. Standardized, preprinted discharge instructions that are surgery specific and easy to read ensure that information is complete.[33,34]

Document the discharge instructions in the medical record. For the patient, the postoperative phase of care continues and extends into the recuperative period. Assessment and evaluation of the patient after discharge may be accomplished by a follow-up call or by a visit from a nurse (e.g., home health nurse).

Increasingly, patients are being discharged from the hospital with many care needs. They may be transferred to transitional care facilities, to long-term care facilities, or directly to their homes. When discharged directly to home, the patient is expected to continue self-care, with assistance from family, friends, or home health care personnel. The care may include dressing changes, wound care, catheter or drain care, home antibiotics, or continued physical therapy. Working with the discharge planner or case manager, facilitate the patient's safe transition from hospital-based care to community- or home-based care.

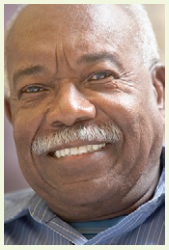
GERONTOLOGIC CONSIDERATIONS

POSTOPERATIVE PATIENT

The older postoperative patient deserves special consideration. The older adult has decreased respiratory function, including decreased ability to cough and decreased thoracic compliance. These alterations lead to an increase in the work of breathing and a decreased ability to eliminate drugs. Carefully monitor reactions to anesthetic drugs. Pneumonia is a common postoperative complication in older adults.

Vascular function in the older adult is altered due to atherosclerosis and decreased elasticity in the blood vessels. Cardiac function is often compromised, and compensatory responses to changes in BP and volume are limited. Circulating blood volume is decreased, and hypertension is common. Cardiovascular parameters must be closely monitored throughout surgery and the postoperative period.

Drug toxicity is a potential problem in the older adult. Renal perfusion in the older adult normally decreases, with a reduction in the ability to eliminate drugs that are excreted by the kidneys. Decreased liver function also leads to decreased drug metabolism and increased drug activity. Carefully assess renal and liver function in the postoperative phase to prevent drug overdose and toxicity.[35]



Observing for changes in mental status is an important part of postoperative care in older adults. Factors such as age, history of alcohol abuse, poor baseline cognition, hypoxia, severe metabolic derangement, hypotension, and polypharmacy can contribute to postoperative delirium. Anesthetics, especially anticholinergic drugs and benzodiazepines, also increase the risk for delirium. Despite knowledge of risk factors, postoperative delirium in older adults is poorly understood.[36] Research suggests that recovery from postoperative delirium is delayed in older patients with high pain levels. This may affect the length of hospital stay and the patient's condition at the time of discharge.[37]

Pain control in the older patient is challenging because of possible preexisting cognitive deficits, impaired communication, and physiologic changes that affect how drugs are metabolized. Older patients may hesitate to request pain medication because they believe that pain is an inevitable result of surgery that should be tolerated. Some older patients may be nervous about using PCA machines.

Thoroughly assess pain in a surgical patient who does not report any pain. Encourage the use of analgesics, and explain to the patient and caregiver that untreated pain has a negative effect on recovery.[35]

CASE STUDY

Postoperative Patient

Stockbyte/Thinkstock

Patient Profile

E.G., a 74-year-old African American retired college professor, has just undergone surgery for a fractured hip. He fell off a ladder while painting his house. The surgery, performed while the patient was under general anesthesia, lasted 3 hours.

Subjective Data

- Was in good health before his fall
- Played tennis three times each week
- Smokes 1 pack of cigarettes per day × 58 years
- Always had problems sleeping
- Difficulty hearing, wears hearing aid
- Upset with injury and its impact on activity
- Is a widower and has no relatives nearby or friends to assist with care
- Reports pain is 8 on a 0-10 scale on arrival to PACU

Objective Data

- Admitted to PACU with abduction pillow between his legs, one peripheral IV catheter, a self-suction drain from the hip dressing, an indwelling urinary catheter
- O_2 saturation 91% on 40% O_2 face mask

Collaborative Care

Postoperative Orders

- Vital signs per PACU routine
- Dextrose 5% in 0.45 normal saline at 100 mL/hr
- Morphine via patient-controlled analgesia 1 mg q10min (20 mg max in 4 hr) for pain
- Advance diet as tolerated
- Incentive spirometry q1hr × 10 while awake
- O_2 therapy to keep O_2 saturation >90%
- Neurovascular checks q1hr × 4 hr
- Empty and measure self-suction drain every shift
- Strict intake and output

Discussion Questions

1. What are the potential postanesthesia problems that you might expect with E.G.?
2. ***Priority Decision:*** What priority nursing interventions would be appropriate to prevent these complications from occurring?
3. ***Delegation Decision:*** Which of these interventions could you delegate to unlicensed assistive personnel (UAP)?
4. What factors may predispose E.G. to the following problems: atelectasis, infection, pulmonary embolism, nausea and vomiting?
5. How can you determine when E.G. is sufficiently recovered from general anesthesia to be discharged to the clinical unit?
6. What potential postoperative problems on the clinical unit might you expect?
7. What are risk factors for this patient developing postoperative delirium? What are the signs and symptoms of delirium?
8. Why is drug toxicity a potential problem for E.G.?
9. ***Priority Decision:*** Based on the assessment data presented, identify two priority nursing diagnoses. Are there any collaborative problems?
10. ***Evidence-Based Practice:*** E.G. asks you why he has to use the incentive spirometer. How would you respond to this question?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. When a patient is admitted to the PACU, what are the priority interventions the nurse performs?
   - **a.** Assess the surgical site, noting presence and character of drainage.
   - **b.** Assess the amount of urine output and the presence of bladder distention.
   - **c.** Assess for airway patency and quality of respirations, and obtain vital signs.
   - **d.** Review results of intraoperative laboratory values and medications received.
2. A patient is admitted to the PACU after major abdominal surgery. During the initial assessment the patient tells the nurse he thinks he is going to "throw up." A priority nursing intervention would be to
   - **a.** increase the rate of the IV fluids.
   - **b.** obtain vital signs, including O_2 saturation.
   - **c.** position patient in lateral recovery position.
   - **d.** administer antiemetic medication as ordered.
3. After admission of the postoperative patient to the clinical unit, which assessment data require the most immediate attention?
   - **a.** Oxygen saturation of 85%
   - **b.** Respiratory rate of 13/min
   - **c.** Temperature of 100.4° F (38° C)
   - **d.** Blood pressure of 90/60 mm Hg

4. A 70-kg postoperative patient has an average urine output of 25 mL/hr during the first 8 hours. The priority nursing intervention(s) given this assessment would be to
   a. perform a straight catheterization to measure the amount of urine in the bladder.
   b. notify the physician and anticipate obtaining blood work to evaluate renal function.
   c. continue to monitor the patient because this is a normal finding during this time period.
   d. evaluate the patient's fluid volume status since surgery and obtain a bladder ultrasound.

5. Discharge criteria for the Phase II patient include *(select all that apply)*
   a. no nausea or vomiting.
   b. ability to drive self home.
   c. no respiratory depression.
   d. written discharge instructions understood.
   e. opioid pain medication given 45 minutes ago.

1. c, 2. c, 3. a, 4. d, 5. c, d, e

CASE STUDY

Managing Multiple Patients

You have been called into work at 10 AM to cover patients for a nurse who had a family emergency. You take over care for the following three patients on an orthopedic surgical unit. You have one UAP available who is assigned to help you and two other RNs.

Patients

Stockbyte/Thinkstock

E.G., a 74-year-old man, underwent surgery for a fractured hip yesterday. He is currently receiving dextrose 5% in 0.45 normal saline at 100 mL/hr, morphine via patient-controlled analgesia at 1 mg q10min (20 mg max in 4 hr) for pain, and O_2 to keep O_2 saturation >93%. He has a self-suction drain in place at the surgical site. He has good respiratory effort when using his incentive spirometer.

Ryan McVay/Photodisc/Thinkstock

F.D., a 72-year-old woman, was admitted to the hospital with compromised circulation of the right lower leg and a necrotic right foot as a complication of her diabetes. She is scheduled for a below-the-knee amputation of the right leg at 1 PM today. She has been NPO since midnight. Her morning capillary blood glucose level was 198 mg/dL. She received 4 units of regular insulin at 8 AM. She has an IV of NSS infusing at 125 mL/hr.

Ryan McVay/Digital Vision/Thinkstock

A.T., a 56-year-old man, is 2 days post lumbar laminectomy. He has been ambulating in the hallway without difficulty and his pain is controlled with the prescribed analgesic medication, last administered at 4 AM. His discharge orders have been written but teaching has yet to be completed.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale for your decision.
2. ***Delegation Decision:*** Which tasks should you delegate to the UAP? *(select all that apply)*
   a. Explain discharge instructions to A.T.
   b. Obtain noon vital signs on E.G. and F.D.
   c. Obtain capillary blood glucose level on F.D.
   d. Remind E.G. and A.T. to use their incentive spirometers every hour.
   e. Confirm E.G.'s understanding of how to use the PCA pump.
3. ***Priority and Delegation Decision:*** When you enter F.D.'s room, you find her somewhat withdrawn and lethargic. Her face is cool and slightly clammy. What initial action would be most appropriate?
   a. Give 1 ampule of D_{50} IV stat
   b. Increase F.D.'s IV rate to 150 mL/hour.
   c. Ask the UAP to give F.D. a glass of orange juice.
   d. Have the UAP obtain a stat capillary blood glucose level.

Case Study Progression

F.D.'s capillary blood glucose reading was 64 mg/dL. You notify her health care provider and administer IV dextrose as ordered. You also change her IV infusion to D5 ½NS and monitor her capillary blood glucose levels on an hourly basis.

4. A preoperative checklist for F.D. is used to ensure completion of *(select all that apply)*
   a. removal of nail polish and jewelry.
   b. signed and witnessed informed consent.
   c. patient understanding of sensory information.
   d. identification of surgical site with indelible marker.
   e. notifying family of where to wait for surgeon postoperatively.
5. F.D. tells you that she is afraid they might amputate the wrong leg. She tells you she has read stories of that happening at other hospitals. Your best response to F.D. would be to
   a. ask her if she would like a sedative to calm her fears.
   b. reassure her that it has never happened in this hospital.
   c. explain the "time-out" procedure for preventing such errors.
   d. offer to go to the operating room with her to ensure the correct leg is amputated.
6. The UAP reports that E.G.'s blood pressure is 92/54 mm Hg, his heart rate is 110 bpm, his respirations are 30 breaths/min, and his O_2 saturation is 90%. On entering E.G.'s room, you find him clutching his chest, complaining of shortness of breath and chest pain. His lungs are clear to auscultation but you note unilateral swelling of his left leg. You suspect that E.G. is likely experiencing
   a. anxiety.
   b. atelectasis.
   c. pulmonary edema.
   d. pulmonary emboli.
7. ***Management Decision:*** When providing discharge instructions to A.T., he tells you that the UAP told him that he could do whatever activity he was comfortable doing—to let pain guide his progress. Your initial reaction to this statement should be to
   a. ask the UAP to clarify what was said to A.T.
   b. report the UAP's actions to the nurse manager.
   c. teach A.T. about the reason for activity restrictions.
   d. clarify the discharge instructions with the health care provider.

LEARNING OUTCOMES

1. Describe the structures and functions of the visual and auditory systems.
2. Explain the physiologic processes involved in normal vision and hearing.
3. Evaluate the significant subjective and objective assessment data related to the visual and auditory systems that should be obtained from a patient.
4. Select the appropriate techniques to use in the physical assessment of the visual and auditory systems.
5. Differentiate normal from common abnormal findings of a physical assessment of the visual and auditory systems.
6. Link the age-related changes in the visual and auditory systems to differences in assessment findings.
7. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the visual and auditory systems.

VISUAL SYSTEM

STRUCTURES AND FUNCTIONS OF VISUAL SYSTEM

The visual system consists of the external tissues and structures surrounding the eye, the external and internal structures of the eye, the refractive media, and the visual pathway. The external structures are the eyebrows, eyelids, eyelashes, lacrimal system, conjunctiva, cornea, sclera, and extraocular muscles. The internal structures are the iris, lens, ciliary body, choroid, and retina. The entire visual system is important for visual function. Light reflected from an object in the field of vision passes through the transparent structures of the eye and, in doing so, is *refracted* (bent) so that a clear image can fall on the retina. From the retina, the visual stimuli travel through the visual pathway to the occipital cortex, where they are perceived as an image.

Reviewed by Sarah Smith, RN, MA, CRNO, COT, Nurse Manager, Department of Ophthalmology, University of Iowa Health Care, Oxford, Iowa; and Helen Stegall, RN, BSN, CORLN, Nurse Manager of Department of Ophthalmology, University of Iowa Hospitals and Clinics, Iowa City, Iowa.

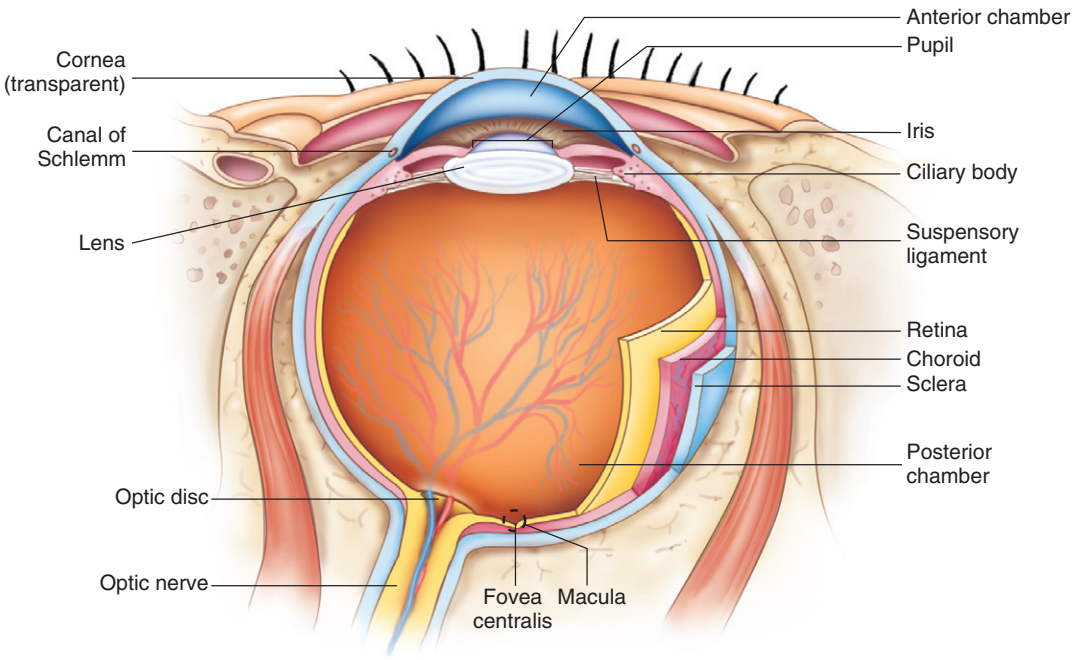

FIG. 21-1 The human eye.

Structures and Functions of Vision

Eyeball. The eyeball, or globe, is composed of three layers (Fig. 21-1). The tough outer layer is composed of the sclera and the transparent cornea. The middle layer consists of the uveal tract (iris, choroid, and ciliary body), and the innermost layer is the retina. The *anterior cavity* is divided into the anterior and posterior chambers. The anterior chamber lies between the iris and the posterior surface of the cornea, and the posterior chamber lies between the anterior surface of the lens and the posterior surface of the iris. The *posterior cavity* lies in the large space behind the lens and in front of the retina.

Refractive Media. For light to reach the retina, it must pass through a number of structures: the cornea, aqueous humor, lens, and vitreous. All these structures must remain clear for light to reach the retina and stimulate the photoreceptor cells. The transparent cornea is the first structure through which light passes. It is responsible for the majority of light refraction necessary for clear vision.

Aqueous humor, a clear watery fluid, fills the anterior and posterior chambers of the anterior cavity of the eye. Aqueous humor is produced from capillary blood in the ciliary body. It is drained away by the scleral veins *(canal of Schlemm),* which enter the circulation of the body. The aqueous humor bathes and nourishes the lens and the endothelium of the cornea. Excess production or decreased outflow can elevate intraocular pressure above the normal 10 to 21 mm Hg, a condition termed *glaucoma.*

The lens is a biconvex structure located behind the iris and supported in place by small fibers collectively called *zonule.* The zonule is a "scaffolding," a series of microscopic wire-like threads that connect the lens to the ciliary body. The primary function of the lens is to bend light rays, allowing the rays to fall onto the retina. The lens shape is modified by action of the ciliary body as part of *accommodation,* a process that allows a person to focus on near objects, such as when reading. Anything altering the clarity of the lens affects light transmission.

Vitreous humor is a transparent gel-like substance that fills the posterior chamber (see Fig. 21-1). Light passing through the vitreous may be blocked by any nontransparent substance within the vitreous. The effect on vision varies, depending on the amount, type, and location of the substance blocking the light.

Refractive Errors. **Refraction** is the eye's ability to bend light rays so that they fall on the retina. In the normal eye, parallel light rays are focused through the lens into a sharp image on the retina. When the light does not focus properly, it is called a *refractive error.*

The individual with **myopia** (nearsightedness) can see near objects clearly, but objects in the distance are blurred. The individual with **hyperopia** (farsightedness) can see distant objects clearly, but close objects are blurred. **Astigmatism** is caused by unevenness in the cornea, which results in visual distortion. **Presbyopia** is a loss of accommodation, causing an inability to focus on near objects. It occurs as a normal process of aging, usually around age 40.

Visual Pathways. Once the image travels through the refractive media, it is focused on the retina (Fig. 21-2). From the retina, the impulses travel through the optic nerve to the optic chiasm where the nasal fibers of each eye cross over to the other side. Fibers from the left field of both eyes form the left optic tract and travel to the left occipital cortex. The fibers from the right field of both eyes form the right optic tract and travel to the right occipital cortex. This arrangement of the nerve fibers in the visual pathways allows determination of the anatomic location of abnormalities.

External Structures and Functions

The eyebrows, eyelids, and eyelashes serve an important role in protecting the eye. They provide a physical barrier to dust and foreign particles (Fig. 21-3). The eye is further protected by the surrounding bony orbit and by fat pads located below and behind the *globe,* or eyeball.

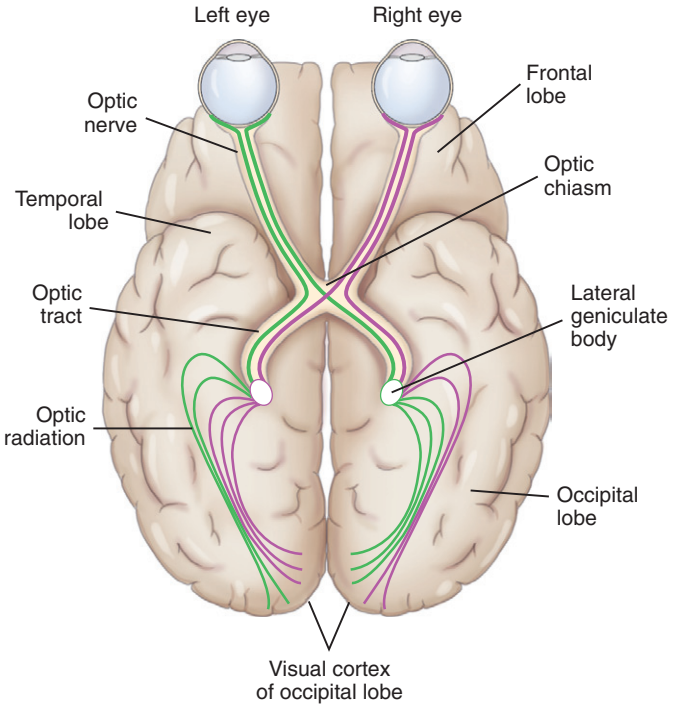

FIG. 21-2 The visual pathway. Fibers from the nasal portion of each retina cross over to the opposite side of the optic chiasma, terminating in the lateral geniculate body of the opposite side. Location of a lesion in the visual pathway determines the resulting visual defect.

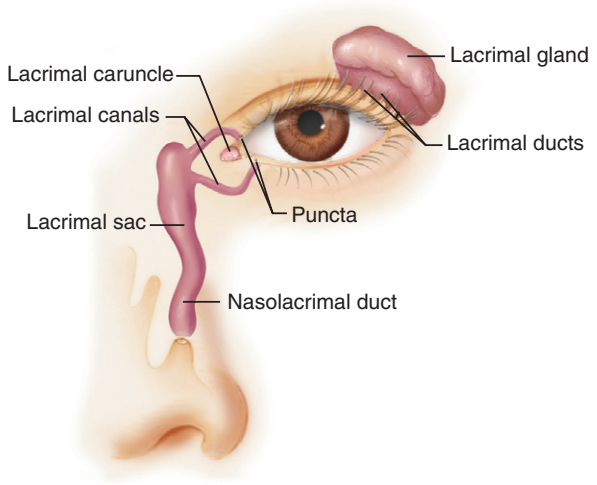

FIG. 21-3 External eye and lacrimal apparatus. Tears produced in the lacrimal gland pass over the surface of the eye and enter the lacrimal canal. From there the tears are carried through the nasolacrimal duct to the nasal cavity.

The upper and lower eyelids join at the medial and lateral canthi. Blinking of the upper eyelid distributes tears over the anterior surface of the eyeball and helps control the amount of light entering the visual pathway. The eyelids open and close through the action of muscles innervated by cranial nerve (CN) VII, the facial nerve.

The **conjunctiva** is a transparent mucous membrane that covers the inner surfaces of the eyelids and also extends over the sclera, forming a "pocket" under each eyelid. Glands in the conjunctiva secrete mucus and tears. The **sclera** is composed of collagen fibers meshed together to form an opaque structure commonly referred to as the "white" of the eye. The sclera forms a tough shell that helps protect the intraocular structures.

The transparent and avascular cornea allows light to enter the eye (see Fig. 21-1). The curved cornea refracts (bends) incoming light rays to help focus them on the retina. The cornea consists of five layers: the epithelium, Bowman's layer, the stroma, Descemet's membrane, and the endothelium. The lacrimal system consists of the lacrimal gland and ducts, lacrimal canals and puncta, lacrimal sac, and nasolacrimal duct (see Fig. 21-3). In addition to the lacrimal gland, other glands provide secretions to make up the mucous, aqueous, and lipid layers of the tear film. The tear film moistens the eye and provides oxygen to the cornea.

Each eye is moved by three pairs of extraocular muscles: (1) superior and inferior rectus muscles, (2) medial and lateral rectus muscles, and (3) superior and inferior oblique muscles. Neuromuscular coordination produces simultaneous movement of the eyes in the same direction.

FOCUSED ASSESSMENT

Visual System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Changes in vision (e.g., acuity, blurred)	Y	N
Eye redness, itching, discomfort	Y	N
Drainage from eyes	Y	N

Objective: Physical Examination

Inspect

Eyes for any discoloration or drainage	✓
Conjunctiva and sclera for color and vascularity	✓
Lens for clarity	✓
Eyelid for ptosis	✓

Assess

Vision based on patient's looking at nurse or Snellen chart	✓
Extraocular movements	✓
Peripheral vision	✓
PERRLA	✓

PERRLA, Pupils equal, round, reactive to light and accommodation.

Internal Structures and Functions

The iris provides the color of the eye. The iris has a small round opening in its center, the *pupil,* which allows light to enter the eye. The pupil constricts via action of the iris sphincter muscle (innervated by CN III [oculomotor nerve]) and dilates via action of the iris dilator muscle (innervated by CN V [trigeminal nerve]) to control the amount of light that enters the eye.

The **lens** is a biconvex, avascular, transparent structure located behind the iris. The primary function of the lens is to bend light rays so that they fall onto the retina. Accommodation occurs when the eye focuses on a near object and is facilitated by contraction of the ciliary body, which changes the shape of the lens. The ciliary body consists of the ciliary muscles, which surround the lens and lie parallel to the sclera. The ciliary processes lie behind the peripheral part of the iris and secrete aqueous humor. The *choroid* is a highly vascular structure that nourishes the ciliary body, the iris, and the outer portion of the retina. It lies inside and parallel to the sclera (see Fig. 21-1).

TABLE 21-1 GERONTOLOGIC ASSESSMENT DIFFERENCES

Visual System

Changes	Differences in Assessment Findings
Eyebrows and Eyelashes	
Loss of pigment in hair	Graying of eyebrows, eyelashes
Eyelids	
Loss of orbital fat, decreased muscle tone	Entropion, ectropion, mild ptosis
Tissue atrophy, prolapse of fat into eyelid tissue	Blepharodermachalasis (excessive upper lid skin)
Conjunctiva	
Tissue damage related to chronic exposure to ultraviolet light or to other chronic environmental exposure	Pinguecula (small yellowish spot usually on medial aspect of conjunctiva)
Sclera	
Lipid deposition	Scleral color yellowish as opposed to bluish
Cornea	
Cholesterol deposits in peripheral cornea	Arcus senilis (milky white-gray ring encircling periphery of cornea) (Fig. 21-4)
Tissue damage related to chronic exposure	Pterygium (thickened, triangular bit of pale tissue that extends from inner canthus of eye to nasal border of cornea)
Decrease in water content, atrophy of nerve fibers	Decreased corneal sensitivity and corneal reflex
Epithelial changes	Loss of corneal luster
Accumulation of lipid deposits	Blurring of vision
Lacrimal Apparatus	
Decreased tear secretion	Dryness
Malposition of eyelid resulting in tears overflowing lid margins instead of draining through puncta	Tearing, irritated eyes
Iris	
Increased rigidity of iris	Decreased pupil size
Dilator muscle atrophy or weakness	Slower recovery of pupil size after light stimulation
Loss of pigment	Change of iris color
Ciliary muscle becoming smaller, stiffer	Decrease in near vision and accommodation
Lens	
Biochemical changes in lens proteins, oxidative damage, chronic exposure to ultraviolet light	Cataracts
Increased rigidity of lens	Presbyopia
Opacities in lens (may also be related to opacities in cornea and vitreous)	Complaints of glare, night vision impaired
Accumulation of yellow substances	Yellow color of lens
Retina	
Retinal vascular changes related to atherosclerosis and hypertension	Narrowed, pale, straighter arterioles. Acute branching
Decrease in cones	Changes in color perception, especially blue and violet
Loss of photoreceptor cells, retinal pigment, epithelial cells, and melanin	Decreased visual acuity
Age-related macular degeneration as a result of vascular changes	Loss of central vision
Vitreous	
Liquefaction and detachment of vitreous	Increased complaints of "floaters"

The **retina** is the innermost layer of the eye that extends and forms the optic nerve. Neurons make up the major portion of the retina. Therefore retinal cells are unable to regenerate if destroyed. The retina lines the inside of the eyeball, extending from the area of the optic nerve to the ciliary body (see Fig. 21-1). It is responsible for converting images into a form that the brain can understand and process as vision. The retina is composed of two types of photoreceptor cells: rods and cones. Rods are stimulated in dim or darkened environments, and cones are receptive to colors in bright environments. The center of the retina is the *fovea centralis,* a pinpoint depression composed only of densely packed cones.[1] This area of the retina provides the sharpest visual acuity. Surrounding the fovea is the *macula*, an area less than 1 mm^2, which has a high concentration of cones and is relatively free of blood vessels.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON VISUAL SYSTEM

Every structure of the visual system is subject to changes as the individual ages. Whereas many of these changes are relatively benign, others may result in severely compromised visual acuity in the older adult. The psychosocial impact of poor vision or blindness can be highly significant. Age-related changes in the visual system and differences in assessment findings are presented in Table 21-1.

ASSESSMENT OF VISUAL SYSTEM

Assessment of the visual system may be as simple as determining a patient's visual acuity or as complex as collecting complete subjective and objective data pertinent to the visual system. To do an appropriate visual evaluation, determine which parts of the data collection are important for each individual patient.

Subjective Data

Important Health Information

Past Health History. Obtain information about the patient's past health history, including both the ocular and nonocular history. Question the patient specifically about systemic diseases, such as diabetes, hypertension, cancer, rheumatoid arthritis, syphilis and other sexually transmitted infections

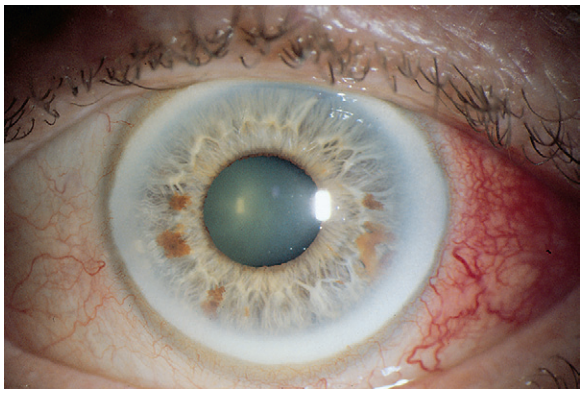

FIG. 21-4 Arcus senilis, or age-related degeneration of the cornea.

CASE STUDY

Patient Introduction

Jack Hollingsworth/ Photodisc/Thinkstock

F.M. is an 81-year-old Hispanic woman who comes to the emergency department with complaints of visual disturbances. F.M. states that her vision "looks like everything is covered with a spider web." She also reports seeing periodic light flashes and small white spots "floating" in the air.

Critical Thinking

As you read through this assessment chapter, think about F.M. with the following questions in mind:

1. What are the possible causes of F.M.'s visual disturbances?
2. What type of assessment would be most appropriate for F.M.: comprehensive, focused, or emergency?
3. What questions would you ask?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies might you expect to be ordered?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

(STIs), acquired immunodeficiency syndrome (AIDS), muscular dystrophy, myasthenia gravis, multiple sclerosis, inflammatory bowel disease, and hypothyroidism or hyperthyroidism; many of these diseases have ocular manifestations. It is particularly important to determine whether the patient has any history of cardiac or pulmonary disease because β-adrenergic blockers are often used to treat glaucoma. These medications can slow heart rate, decrease blood pressure, and exacerbate asthma or chronic obstructive pulmonary disease (COPD).[2]

Obtain a history of tests for visual acuity, including the date of the last examination and change in glasses or contact lenses. Ask the patient about a history of strabismus, amblyopia, cataracts, retinal detachment, refractive surgery, or glaucoma. Note any trauma to the eye, its treatment, and sequelae.

The patient's nonocular history can be significant in assessing or treating the ophthalmic condition. Ask the patient about previous surgeries, treatments, or trauma related to the head.

Medications. If the patient takes medication, obtain a complete list, including dosage and frequency of over-the-counter (OTC) medicines, eyedrops, and herbal therapies or dietary supplements. Many patients do not think of these as "real" drugs and may not mention their use unless specifically questioned. However, many of these drugs have ocular effects. For example, many cold preparations contain a form of epinephrine (e.g., pseudoephedrine) that can dilate the pupil. Note the use of any antihistamine or decongestant, since these drugs can cause ocular dryness. In addition, specifically ask whether the patient uses any prescription drugs such as corticosteroids, thyroid medications, or agents such as oral hypoglycemics and insulin to lower blood glucose levels. Long-term use of corticosteroid preparations can contribute to the development of glaucoma or cataracts. Also note whether the patient is taking any β-adrenergic blockers, since these can be potentiated by the β-adrenergic blockers used to treat glaucoma.

Surgery or Other Treatments. Note any surgical procedures related to the eye or brain. Brain surgery and the subsequent swelling can cause pressure on the optic nerve or tract, resulting in visual alterations. Also document any laser procedures to the eye. The effect of any eye surgery or laser treatment on visual acuity is important information to obtain.

Functional Health Patterns. Ocular problems do not always affect the patient's visual acuity. For example, patients with blepharitis or diabetic retinopathy may not have noticeable visual deficits. The focus of the functional health pattern assessment depends on the presence or absence of vision loss and whether the loss is permanent or temporary. Table 21-2 lists suggested health history questions related to the functional health patterns.

Health Perception–Health Management Pattern. Patient characteristics such as gender, ethnicity, and age are important in assessing ophthalmic conditions. Men are more likely than women to have color blindness. The leading cause of blindness among African Americans is glaucoma.[3] Older individuals are also at greater risk for glaucoma.

The ophthalmic patient in a clinic or office setting is often seeking routine eye care or a change in the prescription of eyewear. However, the patient may have some underlying concerns that he or she does not mention or even recognize. Ask the patient, "Why are you here today?"

The patient's visual health can affect activities at home or at work. It is important to know how the patient perceives the current health problem. As outlined in Table 21-2, guide the patient in describing the current problem. Assess the patient's ability to accomplish necessary self-care, especially any eye care related to the patient's ophthalmic problem.

The patient may not recognize the importance of eye-safety practices such as wearing protective eyewear during potentially hazardous activities or avoiding noxious fumes and other eye irritants. Obtain information about the use of sunglasses in bright light. Prolonged exposure to ultraviolet (UV) light can affect the retina. Ask about night driving habits and any problems encountered. Today, millions of people wear contact lenses, but many do not care for them properly. The type of contact lenses used and the patient's wearing and care habits may provide information for teaching.

Obtain information about allergies. Allergies often cause eye symptoms such as itching, burning, watering, drainage, and blurred vision.

Hereditary systemic diseases (e.g., sickle cell anemia) can significantly affect ocular health. In addition, many refractive errors and other eye problems are hereditary. Specifically, ask whether the patient has a family history of diseases such as atherosclerosis, diabetes, thyroid disease, hypertension, arthritis, or cancer. In addition, determine whether the patient has a family history of ocular problems such as cataracts, tumors,

TABLE 21-2 HEALTH HISTORY

Visual System

Health Perception–Health Management
- Describe the change in your vision. Describe how this affects your daily life.
- Do you wear protective eyewear (sunglasses, safety goggles, hats)?*
- Do you wear contact lenses? If so, how do you take care of them?
- If you use eyedrops, how do you instill them?
- Do you have any allergies that cause eye symptoms?*
- Do you have a family history of cataracts, glaucoma, or macular degeneration?*

Nutritional-Metabolic
- Do you take any nutritional supplements?*
- Does your visual problem affect your ability to obtain and prepare food?*

Elimination
- Do you have to strain to void or defecate?*

Activity-Exercise
- Are your activities limited in any way by your eye problem?*
- Do you participate in any leisure activities that have the potential for eye injury?*

Sleep-Rest
- Is your vision affected by the amount of sleep you get?*
- Does your eye problem affect your sleeping patterns?*

Cognitive-Perceptual
- Does your eye problem affect your ability to read?*
- Do you have any eye pain?* Do you have any eye itching, burning, or foreign body sensation?*

Self-Perception–Self-Concept
- How does your eye problem make you feel about yourself?

Role-Relationship
- Do you have any problems at work or home because of your eyes?*
- Have you made any changes in your social activities because of your eyes?*

Sexuality-Reproductive
- Has your eye problem caused a change in your sex life?*
- For women: Are you pregnant? Do you use birth control pills?*
- For men: Do you use any erectile dysfunction drugs? Any vision problems with their use?*

Coping–Stress Tolerance
- Do you feel able to cope with your eye problem?*
- Are you able to acknowledge the effects of your eye problem on your life?*

Value-Belief
- Do you have any conflicts about the treatment of your eye problem?*

*If yes, describe.

glaucoma, refractive errors (especially myopia and hyperopia), or retinal degenerative conditions (e.g., macular degeneration, retinal detachment).

GENETIC RISK ALERT

Glaucoma
- Certain types of glaucoma have a strong genetic link. Many different glaucoma genes have been discovered.
- People with a family history of glaucoma have a much greater risk of developing it.

Age-Related Macular Degeneration (AMD)
- Some cases of AMD have a genetic link. Multiple genes may be associated with AMD.

Nutritional-Metabolic Pattern. High doses of vitamins containing antioxidants (vitamins C and E and beta-carotene) may be important to ocular health. Some patients with AMD may benefit from supplements of these vitamins.

Elimination Pattern. Straining to defecate (Valsalva maneuver) can raise the intraocular pressure. After eye surgery, many surgeons do not want the patient to strain. Assess the patient's usual pattern of elimination and determine whether there is the potential for constipation in the patient who has had ophthalmic surgical procedures.

Activity-Exercise Pattern. The patient's usual level of activity or exercise may be affected by reduced vision, symptoms accompanying an ocular problem, or activity restrictions after a surgical procedure. Inquire about leisure activities during which the patient may incur an ocular injury. For example, gardening, woodworking, and other craft activities can result in corneal or conjunctival foreign bodies or even penetrating injuries of the globe. Sports activities such as racquetball, baseball, and tennis carry risks for blunt trauma to the eyes. Protection goggles should be worn for these sports.

Sleep-Rest Pattern. In the otherwise healthy person, lack of sleep may cause ocular irritation, especially if the patient wears contact lenses. Normal sleep patterns may be disrupted in the patient with painful eye problems such as corneal abrasions.

Cognitive-Perceptual Pattern. The entire assessment of the ophthalmic patient focuses on the sense of sight, but do not overlook other cognitive or perceptual problems. For example, the functional ability of a patient with a visual deficit will be further compromised if the patient also has hearing problems. The patient who cannot see to read has increased difficulty following postoperative instructions if he or she also has trouble hearing or remembering verbal instructions. Eye pain is always an important symptom to assess. If eye pain is present, question the patient about treatment and response.

Self-Perception–Self-Concept Pattern. The loss of independence that can follow a partial or complete loss of vision, even if the condition is temporary, can have devastating effects on the patient's self-concept. Carefully evaluate the potential effect of vision loss on the patient's self-image. For instance, disabling glare from a cataract may prevent nighttime driving. In today's highly mobile society, the loss of ability to drive can represent a significant loss of independence and self-esteem.

Role-Relationship Pattern. Ocular problems can negatively affect the patient's ability to maintain the necessary or desired roles and responsibilities in the home, work, and social environments. For example, AMD may decrease visual acuity so that the patient can no longer adequately function at work. Many occupations place workers in conditions in which eye injury may occur. For example, factory workers may be at risk from flying metal debris. Eye-safety practices, such as the use of goggles or safety glasses, are now a legal requirement in the workplace. The patient with diabetes may not be able to see well enough to self-administer insulin. This patient may resent dependence on a family member who takes over this function.

CASE STUDY

Subjective Data

Jack Hollingsworth/ Photodisc/Thinkstock

A focused subjective assessment of F.M. revealed the following information:

- ***PMH:*** Extraocular extraction of cataract on R eye with implantation of intraocular lens 2 mo ago. Type 2 diabetes mellitus, hypothyroidism, and hypertension.
- ***Medications:*** Glyburide (DiaBeta) 5 mg/day, levothyroxine (Synthroid) 100 mcg/day, metoprolol (Lopressor) 50 mg PO daily.
- ***Health Perception–Health Management:*** States she was compliant with postoperative antibiotic and corticosteroid eyedrops and with office follow-up with eye surgeon. Recovery from surgery was uneventful, and eyedrops were discontinued 2 wk ago. Does not have allergies. Had excellent eyesight until today. Is afraid she might be having a stroke.
- ***Elimination:*** Has had difficulty moving bowels with increased straining. Trying prune juice to help.
- ***Activity-Exercise:*** Walks in the mall at least ½ mile three times a week. No resistance or isotonic exercises.
- ***Cognitive-Perceptual:*** Denies eye pain, itching, or tearing. Having difficulty reading.
- ***Coping–Stress Tolerance:*** Afraid she is having a stroke.

Sensitively inquire if the ocular problem has affected the patient's preferred roles and responsibilities.

Sexuality-Reproductive Pattern. The patient with severe vision loss may develop such a poor self-image that the ability to be sexually intimate is lost. Assure the patient that low vision or blindness does not affect a person's ability to be sexually expressive. Often touch is more important than vision.

Coping–Stress Tolerance Pattern. The patient with temporary or permanent visual problems may experience emotional stress. Assess the patient's coping level, coping mechanisms, and availability of social and personal support systems.

Value-Belief Pattern. Be sensitive to each patient's individual values and spiritual beliefs, since these may guide the patient's decisions regarding ophthalmic care. It can be difficult to understand why a patient refuses treatment that has potential benefit or wants treatment that may have limited potential benefit.

Objective Data

Physical Examination. Physical examination of the visual system includes inspecting the ocular structures and determining the status of their respective functions. Physiologic functional assessment includes determining the patient's visual acuity, ability to judge closeness and distance, and extraocular muscle (EOM) function; evaluating visual fields; observing pupil function; and measuring the intraocular pressure.[4] Assessment of ocular structures should include examining the ocular adnexa, the external eye, and internal structures. Some structures, such as the retina and blood vessels, must be visualized with the ophthalmoscope.

Assessment of the visual system may include all of the components discussed in the following sections, or it may be as brief as measuring the patient's visual acuity. Assess what is appropriate and necessary for the specific patient. Many of the following assessments are within your scope of practice, but some require special training.

TABLE 21-3 NORMAL PHYSICAL ASSESSMENT OF VISUAL SYSTEM

- Visual acuity 20/20 OU. No diplopia.
- External eye structures symmetric and without lesions or deformities.
- Lacrimal apparatus nontender and without drainage.
- Conjunctiva clear. Sclera white.
- PERRLA.
- Lens clear.
- EOMI.
- Optic nerve margins sharp.
- Retinal vessels normal, with no hemorrhages or spots.

EOMI, Extraocular movements intact; *OU,* both eyes; *PERRLA,* pupils equal, round, reactive to light and accommodation.

Normal physical assessment of the visual system is outlined in Table 21-3. Age-related visual changes and differences in assessment findings are listed in Table 21-1. Assessment techniques related to vision are summarized in Table 21-4, and assessment abnormalities are listed in Table 21-5 on p. 376.

A *focused assessment* is used to evaluate the status of previously identified visual problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the visual system is presented in the box on p. 370.

Initial Observation. Your initial observation of the patient can provide information that will help focus the assessment. When first encountering the patient, you may observe that the patient is dressed in clothing with unusual color combinations. This may indicate a color-vision deficit. Also note an unusual head position. The patient with diplopia may hold the head in a skewed position in an attempt to see a single image. The patient with a corneal abrasion or photophobia will cover the eyes with the hands to try to block out room light. Make a crude estimate of depth perception by extending a hand for the patient to shake.

During the initial observation, observe the patient's overall facial and ophthalmic appearance. The eyes should be symmetric and normally placed on the face. The globes should not have a bulging or sunken appearance.

Assessing Functional Status

Visual Acuity. Always record the patient's visual acuity for medical and legal reasons. Document the patient's visual acuity before the patient receives any ophthalmic care. Position the person on a mark exactly 20 ft (6 m) from the Snellen eye chart. If the person wears glasses or contacts, leave them on. Cover one eye at a time during the test. Ask the person to read down the lines of the chart to the smallest line of letters possible. Record the result using the numeric fraction at the end of the last successful line read. Indicate whether any letters were missed and if corrective lenses were worn (e.g., "Left eye, 20/30-2, with contacts"). Next ask the patient to cover the other eye, and repeat the process. Normal visual acuity is 20/20. The first number indicates the distance the person is standing or sitting from the chart; the second number gives the distance at which a normal eye can read the particular line. *Legal blindness* is defined as the best-corrected vision in the better eye of 20/200 or less.

If the patient reports near vision difficulty or is 40 years of age or older, you would also use a hand-held vision screener with varying print sizes (e.g., a Jaeger chart). Hold the card at

TABLE 21-4 NURSING ASSESSMENT

Assessment Techniques: Visual System

Description	Purpose
Visual Acuity Testing	
Patient reads from Snellen chart at 20 ft (distance vision test) or Jaeger chart at 14 in (near vision test). Examiner notes smallest print patient can read on each chart.	Determines distance and near visual acuity
Confrontation Visual Field Test	
Patient faces examiner, covers one eye, fixates on examiner's face, and counts number of fingers that examiner brings into patient's field of vision.	Determines if patient has a full field of vision, without obvious scotomas
Pupil Function Testing	
Examiner shines light into patient's pupil and observes pupillary response. Each pupil is examined independently. Examiner also checks for consensual and accommodative response.	Determines if patient has normal pupillary response
Intraocular Pressure Testing: Tono-pen	
Covered end of probe is gently touched several times to anesthetized corneal surface. Examiner records several readings to obtain a mean intraocular pressure (see eFig. 21-2).	Measures intraocular pressure (normal pressure is 10-21 mm Hg)
Ophthalmoscopy	
Examiner holds ophthalmoscope close to patient's eye, shining light into back of eye and looking through aperture on ophthalmoscope. Examiner adjusts dial to select one of lenses in ophthalmoscope that produces desired amount of magnification to inspect retina.	Provides magnified view of retina and optic nerve head (see Fig. 21-5)
Color Vision Testing	
In the Ishihara test, a patient identifies numbers or paths formed by pattern of dots in series of color plates.	Determines ability to distinguish colors
Keratometry	
Examiner aligns projection and notes readings of corneal curvature.	Measures corneal curvature. Often done before fitting contact lenses, before refractive surgery, or after corneal transplantation

14 in (35 cm) from the eye in good light to assess near vision. Examine each eye separately with glasses on. A normal result is "14/14" in each eye, read without hesitancy and without the patient moving the card.

Hand motion or light perception may be used for distance vision assessment if a specific vision chart for distance assessment is not available. If you must assess near visual acuity without access to a Jaeger eye chart, an accurate assessment is still possible using newsprint or the label on a container. Record the acuity as "reads newspaper headline at *X* inches."

Extraocular Muscle Functions. Observe the corneal light reflex to evaluate for weakness or imbalance of the extraocular muscles (EOM). In a darkened room, ask the patient to look straight ahead while shining a penlight directly on the cornea. The light reflection should be located in the center of both corneas as the patient faces the light source.

To assess eye movement, hold a finger or an object within 10 to 12 in of the patient's nose. Ask the patient to follow with eyes only the movement of the object or finger in the six cardinal positions of gaze. (This is demonstrated in eFig. 21-1 available on the website for this chapter.) This test can indicate weakness or paralysis in the EOM and cranial nerves (oculomotor nerve [CN III], trochlear nerve [CN IV], and abducens nerve [CN VI]).

Pupil Function and Intraocular Pressure. Pupil function is determined by inspecting the pupils and their reactions to light. The normal finding is commonly abbreviated as PERRL (pupils are equal [in size], round, and reactive to light). To test for accommodation, ask the person to focus on a distant object. This process dilates the eyes. Then have the person shift the focus to a near object (e.g., your finger held about 3 inches from the person's nose). A normal response is constriction of the eyes and convergence (inward movement of both eyes toward each other). When accommodation is assessed in addition to the pupillary light reflex, a normal response is *PERRLA* (pupils are equal, round, and reactive to light and accommodation).

In a small percentage of the population the pupils are unequal in size *(anisocoria)*. The pupils should react to light directly (the pupil constricts when a light shines into the eye) and consensually (the pupil constricts when a light shines into the opposite eye).

Intraocular pressure (see Table 21-4) can be measured by a variety of methods, including the Tono-pen[5] (shown in eFig. 21-2 available on the website for this chapter). Normal intraocular pressure ranges from 10 to 21 mm Hg.

Assessing Structures. The visual system structures are assessed primarily by inspection. The visual system is unique because not only the external structures but also many of the internal structures can be directly inspected. The iris, lens, vitreous, retina, and optic nerve can all be visualized directly through the clear cornea and pupil opening.

This direct inspection requires special observation equipment such as the slit lamp microscope and the ophthalmoscope. This equipment permits examination of the conjunctiva, sclera, cornea, anterior chamber, iris, lens, vitreous, and retina under magnification. The *ophthalmoscope* is a hand-held instrument with a light source and magnifying lenses that is held close to the patient's eye to visualize the posterior part of the eye. Little pain or discomfort is associated with these examinations.

Eyebrows, Eyelashes, and Eyelids. All structures should be present and symmetric, without deformities, redness, or swelling. Eyelashes extend outward from the lid margins. In normal closing the upper and lower eyelid margins just touch. The lacrimal puncta should be open and positioned properly against the globe.

Conjunctiva and Sclera. The conjunctiva and sclera can easily be examined at the same time. Evaluate the color, smoothness, and presence of lesions or foreign bodies. The conjunctiva covering the sclera is normally clear, with fine blood vessels visible. These blood vessels are more common in the periphery.

The sclera is normally white, but it may take on a yellowish hue in the older individual because of lipid deposition. A pale blue cast caused by scleral thinning can also be normal in older adults and in infants (who have naturally thinner sclerae). A

TABLE 21-5 ASSESSMENT ABNORMALITIES

Visual System

Finding	Description	Possible Etiology and Significance
Subjective Data		
Pain	Foreign body sensation	Superficial corneal erosion or abrasion. Can result from contact lens wear or trauma. Conjunctival or corneal foreign body
	Severe, deep, throbbing	Anterior uveitis, acute glaucoma, infection. Acute glaucoma also associated with nausea, vomiting
Photophobia	Persistent abnormal intolerance to light	Inflammation or infection of cornea or anterior uveal tract (iris and ciliary body)
Blurred vision	Gradual or sudden inability to see clearly	Refractive errors, corneal opacities, cataracts, migraine aura, retinal changes (detachment, macular degeneration)
Spots, floaters	Patient describes seeing spots, "spiderwebs," "curtain," or floaters within the field of vision	Most common cause is vitreous liquefaction (benign phenomenon). Other possible causes include hemorrhage into the vitreous humor, retinal holes or tears
Dryness	Discomfort, sandy, gritty, irritation, or burning	Decreased tear formation or changes in tear composition because of aging or various systemic diseases
Diplopia	Double vision	Abnormalities of extraocular muscle action related to muscle or cranial nerve pathologic condition
Objective Data		
Eyelids		
Allergic reactions	Redness, excessive tearing, and itching of lid margins	Many possible allergens. Associated eye trauma can occur from rubbing itchy eyelids
Hordeolum (sty)	Small, superficial white nodule along lid margin	Infection of sebaceous gland of eyelid. Causative organism is usually bacterial (most commonly *Staphylococcus aureus*)
Blepharitis	Redness, swelling, and crusting along lid margins	Bacterial invasion of lid margins. Often chronic
Ptosis	Drooping of upper lid margin, unilateral or bilateral	Mechanical causes as a result of eyelid tumors or excess skin. Myasthenia gravis
Entropion	Inward turning of upper or lower lid margin, unilateral or bilateral	Congenital causes resulting in development abnormalities
Ectropion	Outward turning of lower lid margin	Mechanical causes as a result of eyelid tumors, herniated orbital fat, or extravasation of fluid
Conjunctiva		
Conjunctivitis	Redness, swelling of conjunctiva. May be itchy	Bacterial or viral infection. May be allergic response or inflammatory response to chemical exposure
Subconjunctival hemorrhage	Appearance of blood spot on sclera. May be small or can affect entire sclera	Conjunctival blood vessels rupture, leaking blood into the subconjunctival space
Cornea		
Corneal abrasion	Localized painful disruption of the epithelial layer of cornea. Can be visualized with fluorescein dye	Trauma. Overwear or improper fit of contact lenses
Globe		
Exophthalmos	Protrusion of globe beyond its normal position within bony orbit. Sclera often visible above iris when eyelids are open	Intraocular or periorbital tumors. Hyperthyroidism
Pupil		
Anisocoria	Pupils unequal (constricted)	Central nervous system disorders. Slight difference in pupil size is normal in some people
Abnormal response to light or accommodation	Pupils respond asymmetrically or abnormally to light stimulus or accommodation	Central nervous system disorders, general anesthesia
Extraocular Muscles		
Strabismus	Deviation of eye position in one or more directions	Overaction or underaction of one or more extraocular muscles
Lens		
Cataract	Opacification of lens. Pupil can appear cloudy or white when opacity is visible behind pupil opening	Aging, trauma, diabetes, long-term systemic corticosteroid therapy
Visual Field Defect		
Peripheral	Partial or complete loss of peripheral vision	Glaucoma. Interruption of visual pathway (e.g., tumor). Migraine headache
Central	Loss of central vision	Macular disease

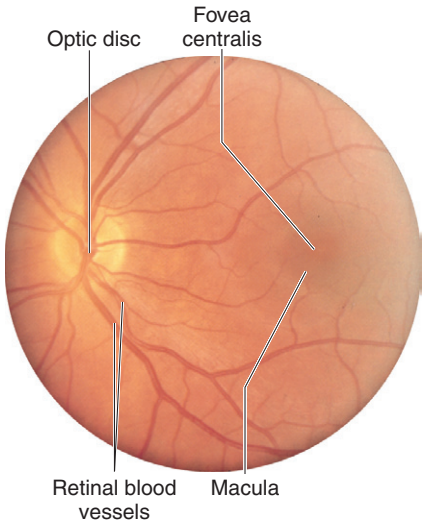

FIG. 21-5 Magnified view of retina through the ophthalmoscope.

slight yellow cast may also be found in some dark-skinned people, such as African Americans and Native Americans.

Cornea. The cornea should be clear, transparent, and shiny. The iris should appear flat and not bulge toward the cornea. The area between the cornea and the iris should be clear, with no blood or purulent material visible in the anterior chamber.

Iris. Both irides should be of similar color and shape. However, a color difference between the irides occurs normally in a small portion of the population.

Retina and Optic Nerve. An ophthalmoscope is used to magnify the retina and optic nerves and bring them into crisp focus (Fig. 21-5). Examine the optic nerve or disc for size, color, and abnormalities. The optic disc is creamy yellow with distinct margins. A central depression in the disc, called the *physiologic cup,* may be seen. This area is the exit site for the optic nerve. The cup should be less than one half the diameter of the disc. Normally, no hemorrhages or exudates are present in the fundus (retinal background). Careful inspection of the fundus can reveal retinal holes, tears, detachments, or lesions. Small hemorrhages can be associated with diabetes or hypertension and can appear in various shapes, such as dots or flames. Finally, examine the macula for shape and appearance. This area of high reflectivity is devoid of any blood vessels.

Important information about the vascular system and the central nervous system (CNS) can be obtained through direct visualization with an ophthalmoscope. Skilled use of this instrument requires practice.

Special Assessment Techniques

Color Vision. Testing the patient's ability to distinguish colors can be an important part of the overall assessment because some occupations may require accurate color discrimination. The Ishihara color test determines the patient's ability to distinguish a pattern of color in a series of color plates.[6]

Stereopsis. *Stereoscopic vision* allows a patient to see objects in three dimensions. Any event that causes a patient to have monocular vision (e.g., enucleation, patching) results in the loss of stereoscopic vision. Without stereopsis, the individual's ability to judge distances or the height of a step is impaired. This disability can have serious consequences if the patient trips over a step when walking or follows too closely behind another vehicle when driving.

CASE STUDY

Objective Data

Jack Hollingsworth/ Photodisc/Thinkstock

Physical Examination

Physical examination findings of F.M. were as follows:

- PERRL. No abnormalities noted on visual examination of external eye structures. EOM intact and symmetric.

As you continue to read this chapter, consider diagnostic studies you would anticipate being performed for F.M.

Diagnostic Studies

The health care provider performs an ophthalmoscopic examination on F.M. and identifies a partial retinal detachment. This diagnosis is confirmed via ultrasonography.

DIAGNOSTIC STUDIES OF VISUAL SYSTEM

Diagnostic studies provide important information in monitoring the patient's condition and planning appropriate interventions. These studies are considered objective data. Table 21-6 presents the most common diagnostic studies of the visual system.

AUDITORY SYSTEM

STRUCTURES AND FUNCTIONS OF AUDITORY SYSTEM

The auditory system is composed of the peripheral auditory system and the central auditory system. The peripheral system includes the structures of the ear itself: the external, middle, and inner ear (Fig. 21-6). This system is concerned with the reception and perception of sound. The inner ear functions in hearing and balance. The central system integrates and assigns meaning to what is heard. This system includes the vestibulocochlear nerve (CN VIII) and the auditory cortex of the brain. The brain and its pathways transmit and process sound and sensations that maintain a person's equilibrium.

The role of the external and middle portion of the ear is to conduct and amplify sound waves from the environment. This portion of sound conduction is termed *air conduction.* Problems in these two parts of the ear may cause *conductive hearing loss,* resulting in a decrease in sound intensity and/or a distortion in sound.

Disturbances in equilibrium can impair coordination, balance, and orientation. Damage to or an abnormality of the inner ear or along the nerve pathways results in *sensorineural hearing loss.* In addition to causing distortion or faintness of sound, sensorineural hearing loss may affect the ability to understand speech or cause complete hearing loss. Impairment within the auditory pathways of the brain causes *central hearing loss.* This type of hearing loss causes difficulty in understanding the meaning of words that are heard. (Types of hearing loss are discussed in Chapter 22 on pp. 406-407.)

External Ear

The external ear consists of the *auricle* (pinna), external auditory canal, and tympanic membrane (TM). The auricle is composed of cartilage and connective tissue covered with epithelium,

TABLE 21-6 DIAGNOSTIC STUDIES

Visual System

Description and Purpose	Nursing Responsibility*
Refractometry	
Subjective measure of refractive error. Multiple lenses are mounted on rotating wheels. Patient sits looking through apertures at Snellen acuity chart, and lenses are changed. Patient chooses lenses that make acuity sharpest. Comprehensive examination requires dilation of eyes to visualize retina and optic nerves.	Procedure is painless. Patient may need help to hold head still. Pupil dilation makes it difficult to focus on near objects. Dilation may last 3-4 hr.
Ultrasonography	
A-scan probe is applanated against patient's anesthetized cornea. Used primarily for axial length measurement for calculating power of intraocular lens implanted after cataract extraction. *B-scan* probe is applied to patient's closed lid. Used more often than A-scan for diagnosis of ocular pathologic conditions such as intraocular foreign bodies or tumors, vitreous opacities, retinal detachments.	Procedure is painless (cornea is anesthetized).
Fluorescein Angiography	
Fluorescein (a nonradioactive, non-iodine dye) injected IV into antecubital or other peripheral vein, followed by serial photographs (over 10-min period) of the retina through dilated pupils. Provides diagnostic information about flow of blood through pigment epithelial and retinal vessels. Often used in diabetic patients to accurately locate areas of diabetic retinopathy before laser destruction of neovascularization.	If extravasation occurs, fluorescein is toxic to tissue. Although systemic allergic reactions are rare, be familiar with emergency equipment and procedures. Tell patient that dye can sometimes cause transient nausea or vomiting. Transient yellow-orange discoloration of urine and skin is normal.
Amsler Grid Test	
Test is self-administered using a hand-held card printed with a grid of lines (similar to graph paper). Patient fixates on center dot and records any abnormalities of the grid lines, such as wavy, missing, or distorted areas. Used to monitor macular problems.	Regular testing is necessary to identify any changes in macular function.

*Patient teaching regarding the purpose and method of testing is a nursing responsibility for all diagnostic procedures.

which also lines the external auditory canal (see Fig. 21-6). The external auditory canal is a slightly S-shaped tube about 1 in (2.5 cm) in length in the adult. The lining of the canal contains fine hairs (cilia), sebaceous (oil) glands, and ceruminous (wax) glands. The oil and wax lubricate the ear canal, keep it free from debris, and kill bacteria.

The function of the external ear and canal is to collect and transmit sound waves to the *tympanic membrane* (eardrum). This shiny, translucent, pearl-gray membrane is composed of epithelial cells, connective tissue, and mucous membrane. It serves as a partition and an instrument of sound transmission between the external auditory canal and the middle ear.

Middle Ear

The middle ear cavity is an air space located in the temporal bone. Mucous membrane lines the middle ear and is continuous from the nasal pharynx via the eustachian (auditory) tube. The eustachian tube functions to equalize atmospheric air pressure between the middle ear and the throat and allows the tympanic membrane to move freely. It opens during yawning and swallowing. Blockage of this tube can occur with allergies, nasopharyngeal infections, or enlarged adenoids.

The middle ear contains the three smallest bones in the body: *malleus, incus,* and *stapes* (ossicles). Vibrations of the TM cause the ossicles to move and transmit sound waves to the oval window. The superior part of the middle ear is called the *epitympanum,* or the attic. It also communicates with air cells within the mastoid bone. The mastoid is the posterior part of the temporal bone. The facial nerve (CN VII) traverses above the oval window of the middle ear. The thin, bony covering of the facial nerve can become damaged by chronic ear infection, skull fracture, or trauma during ear surgery. Problems may occur related to voluntary facial movements, eyelid closure, and taste discrimination. Permanent damage to the facial nerve can also result.

Inner Ear

The inner ear is composed of a bony labyrinth (maze) surrounding a membrane. Perilymphatic fluid lies between the bone and the membrane. The fluid inside the membrane is called *endolymph.* The inner ear contains the functional organs for hearing and balance. The receptor organ for hearing is the *cochlea,* which is a coiled structure. It contains the *organ of Corti,* whose tiny hair cells respond to stimulation of selected portions of the basilar membrane according to pitch. This stimulus is converted into an electrochemical impulse and then transmitted by the acoustic portion of the vestibulocochlear nerve (CN VIII) to the temporal lobe of the brain to process and interpret the sound.

Three semicircular canals and the vestibule make up the organ of balance. These structures comprise the membranous labyrinth, which is housed within the bony labyrinth. The membranous labyrinth is filled with endolymphatic fluid, and the bony labyrinth is filled with perilymphatic fluid. Nervous stimuli are communicated by the vestibular portion of CN VIII. Debris such as loose crystals of calcium or excessive pressure within the lymphatic fluid can produce disorders such as benign paroxysmal positional vertigo (BPPV).

Transmission of Sound. Sound waves are conducted by air (air conduction) and picked up by the auricles and auditory canal. The TM is struck by the sound waves, causing it to vibrate. The central area of the TM is connected to the malleus, which also starts to vibrate. The malleus transmits the vibration to the incus and then the stapes. As the stapes moves back and forth, it pushes the membrane of the oval window in and out. Movement of the oval window produces waves in the perilymph.

Once sound has been transmitted to the liquid medium of the inner ear, the vibration is picked up by the tiny sensory hair cells of the cochlea, which initiate nerve impulses. These impulses are carried by nerve fibers to the main branch of the acoustic portion of CN VIII and then to the brain.

The bones of the skull can also transmit sound directly to the inner ear (bone conduction). This can be demonstrated by placing the stem of a vibrating tuning fork on the skull.

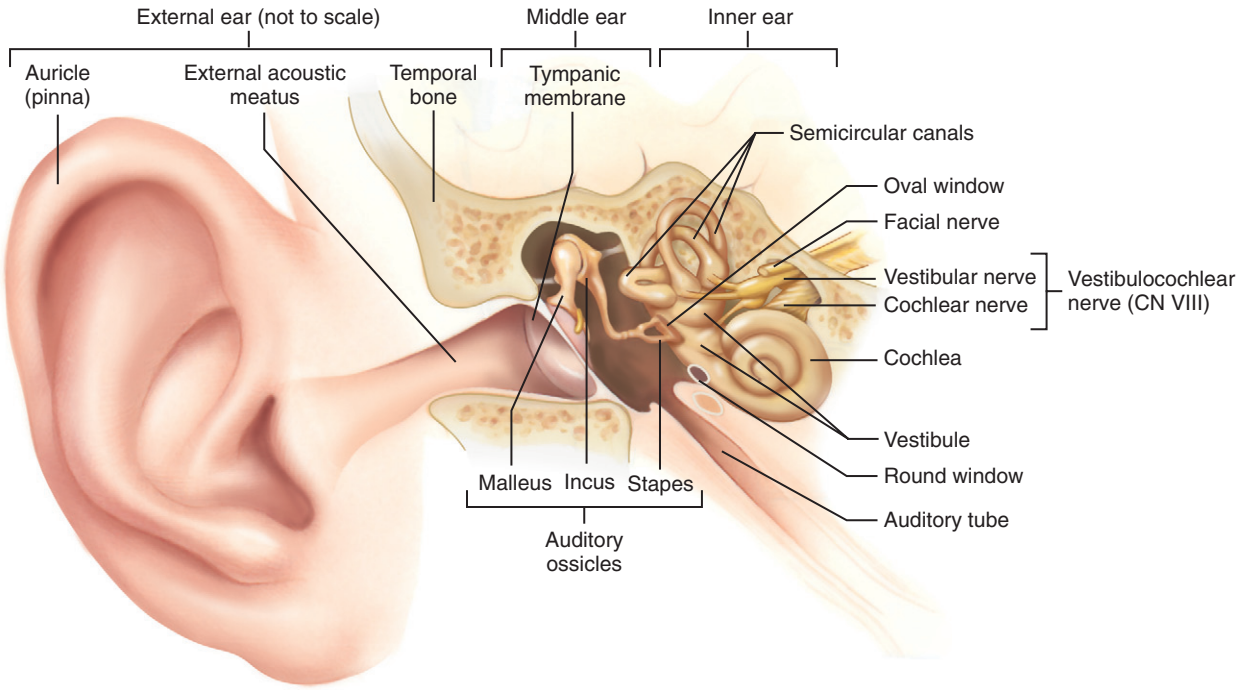

FIG. 21-6 External, middle, and inner ear.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON AUDITORY SYSTEM

Approximately 36 million American adults report some degree of hearing loss, with aging being the primary cause.[7] **Presbycusis,** or hearing loss due to aging, can result from a variety of sources. Noise exposure, systemic diseases, poor nutrition, ototoxic drugs, and pollution exposure over the life span can damage the delicate hair cells of the organ of Corti or atrophy lymph-producing cells. Sound transmission is also diminished by calcification of the ossicles. The loss associated with presbycusis is usually greater for high-pitched sounds. Accumulation of dry cerumen (earwax) in the external canal can also interfere with the transmission of sound.[8] **Tinnitus,** or ringing in the ears, may accompany the hearing loss that results from the aging process. As the average life span increases, the number of people with hearing loss will also increase. Prevention and early identification of problems will ensure a more active and healthy aging population.

Age-related changes in the auditory system and differences in assessment findings are presented in Table 21-7.

FOCUSED ASSESSMENT

Auditory System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Changes in hearing	Y	N
Ear pain	Y	N
Ear drainage	Y	N

Objective: Physical Examination

Inspect

Alignment and position of ears on head	✓
Size, shape, symmetry, color, and skin intactness	✓
External auditory meatus for discharge or lesions	✓

Assess

Hearing based on ability to respond to conversation, respond to a whisper, or hear a ticking watch	✓

ASSESSMENT OF AUDITORY SYSTEM

Assessment of the auditory system should include assessment of hearing and equilibrium because the auditory and *vestibular* (balance) systems are closely related. It is often difficult to separate symptoms related to these two systems. Help the patient describe symptoms and problems to differentiate the source of the problems. Health history questions to ask a patient with an auditory problem are listed in Table 21-8.

Problems with balance may manifest as vertigo or nystagmus. **Vertigo** is a sense that the person or objects around the person are moving or spinning and is usually stimulated by movement of the head. *Dizziness* is a sensation of being off-balance that occurs when standing or walking. **Nystagmus** is an abnormal eye movement that may be observed as a twitching of the eyeball or described by the patient as a blurring of vision with head or eye movement.

Initially try to categorize symptoms related to balance and separate them from symptoms related to hearing loss or tinnitus. The symptoms can be combined later in the assessment to help make the diagnosis and plan for the patient.

Subjective Data

Important Health Information

Past Health History. Many problems related to the ear may result from childhood illnesses or problems of adjacent organs.

TABLE 21-7 GERONTOLOGIC ASSESSMENT DIFFERENCES

Auditory System

Changes	Differences in Assessment Findings
External Ear	
Increased production of and drier cerumen	Impacted cerumen, potential hearing loss
Increased hair growth	Visible hair, especially in men
Loss of elasticity in cartilage	Collapsed ear canal
Middle Ear	
Atrophic changes of tympanic membrane	Conductive hearing loss
Inner Ear	
Hair cell degeneration, neuron degeneration in auditory nerve and central pathways, reduced blood supply to cochlea, calcification of ossicles	Presbycusis, diminished sensitivity to high-pitched sounds, impaired speech reception, tinnitus
Less effective vestibular apparatus in semicircular canals	Alterations in balance and body orientation
Brain	
Decline in ability to filter out unwanted and unnecessary sound	Difficulty hearing in a noisy environment, heightened sensitivity to loud sounds

Consequently, a careful assessment of past health problems is important.

Ask the patient about previous problems regarding the ears, especially during childhood. Record the frequency of acute middle ear infections (otitis media); surgical procedures (e.g., myringotomy); perforations of the eardrum; drainage; and a history of mumps, measles, or scarlet fever. Congenital hearing loss can result from infectious diseases (e.g., rubella, influenza, syphilis), teratogenic medications, or hypoxia in the first trimester of pregnancy. Document head injury because it may result in hearing loss. Information about food and environmental allergies is important because they can cause the eustachian tube to become edematous and prevent aeration of the middle ear.

Record symptoms such as vertigo, tinnitus, and hearing loss in the patient's words. Guide the description by asking for specific details of the sensations and situations that may cause them or make them worse. Information regarding family members with hearing loss and type of hearing loss is important. Some congenital hearing loss is hereditary. The age of onset of presbycusis also follows a familial pattern.

Medications. Obtain information about present or past medications that are *ototoxic* (cause damage to CN VIII) and can produce hearing loss, tinnitus, and vertigo. The amount and frequency of aspirin use are important because tinnitus can result from high aspirin intake. Aminoglycosides, any other antibiotics, salicylates, antimalarial agents, chemotherapeutic drugs, diuretics, and nonsteroidal antiinflammatory drugs

TABLE 21-8 HEALTH HISTORY

Auditory System

Health Perception–Health Management

Hearing

- Have you had a change in your hearing?* If yes, how does this change affect your daily life?
- Do you use any devices to improve your hearing (e.g., hearing aid, special volume control, headphones for television or stereo)?*
- How do you protect your hearing?
- Do you have any allergies that result in ear problems?*

Equilibrium

- When did the dizziness or spinning sensation first occur?
- Does this sensation occur when you first stand up, when you are lying down, or both?
- Have you ever fallen because of the dizziness?*
- Can you drive or walk alone? If no, elaborate.
- Are there any times of the day when your symptoms are worse?*

Tinnitus

- How long have you experienced ringing in your ears? Has it changed?* Describe the ringing (e.g., buzzing, ringing, roaring). Do you also have a feeling of fullness or pressure?*
- When does it bother you the most?
- What things have you tried that help or have not helped?
- What medications are you taking?

Nutritional-Metabolic

- Do you notice any differences in symptoms with changes in diet?*
- Does your ear problem cause nausea that interferes with your food intake?*
- Does chewing or swallowing cause you any ear discomfort?*

Elimination

- Does straining during a bowel movement cause ear pain?*

Activity-Exercise

- Do you need help with certain activities (e.g., lifting, bending, climbing stairs, driving, speaking) because of symptoms?*

Sleep-Rest

- Is your sleep disturbed by noises or ringing in the ears or by a sensation of spinning?*

Cognitive-Perceptual

- Do you experience ear pain?* What relieves the pain? What makes it worse? Does the pain affect your hearing or balance?
- Have you noticed any problem with communicating or understanding what people are saying?*

Self-Perception–Self-Concept

- Have changes in your hearing affected how you feel about yourself or your feeling of independence?*

Role-Relationship

- What effect has your ear problem had on your work, family, or social life?
- Are you able to recognize the effects of your ear problems on your life?*

Sexuality-Reproductive

- Has your ear problem caused a change in your sex life?*

Coping–Stress Tolerance

- Do you consider your ear problem a source of stress?*
- How do you cope when you are experiencing symptoms?

Value-Belief

- Do you have a conflict between what your health care provider would like you to do and what you believe you should do?

*If yes, describe.

(NSAIDs) are groups of drugs that are potentially ototoxic. Monitor for hearing and balance problems in patients receiving these drugs. Many drugs produce hearing loss that may be reversible if treatment is stopped.

Surgery or Other Treatments. Document previous hospitalizations for ear surgery, including *myringotomy* (ventilation holes placed in the TM with or without tubes), *tympanoplasty* (surgical repair of TM), tonsillectomy, and adenoidectomy (removal of tonsils and adenoids). Record the use of and satisfaction with a hearing aid. Also note any problems with impacted cerumen.

Functional Health Patterns. Hearing and balance problems can affect all aspects of a person's life. To assess the impact of hearing loss, ask health history questions based on a functional health patterns approach (see Table 21-8).

Health Perception–Health Management Pattern. Note the onset of hearing loss, whether sudden or gradual, and who noted the onset (e.g., patient, family, significant others). Gradual hearing losses are most often noted by those who communicate with the patient. Sudden losses and those exacerbated by some other condition are most often reported by the patient.

Assess the patient for personal measures used to preserve hearing. The use of protective ear covers or earplugs is good practice for people in high-noise environments. Document if the patient is a swimmer and the frequency and duration of swimming and use of ear protection. Note the type of water (pool, lake, or ocean) in which the swimming takes place to help identify contact with contaminated water. Assess for the placement of any item in the ear, including hearing aids, which can cause trauma to the canal and TM.

Nutritional-Metabolic Pattern. Alcohol, sodium, and dietary supplements affect the amount of endolymph in the inner ear system. Patients with Ménière's disease may notice some improvement in their symptoms with alcohol restriction and a low-sodium diet.[9] Note changes in symptoms with food intake. Question the patient about any ear pain (otalgia) or discomfort associated with chewing or swallowing that might decrease nutritional intake. This situation is often associated with a problem in the middle ear.

Assessment of clenching or grinding of the teeth helps differentiate problems of the ear from referred pain of the temporomandibular joint (TMJ). Ask about dental problems and dentures.

Elimination Pattern. Elimination patterns are mainly of interest in the patient with perilymph fistula and after surgical procedures. Frequent constipation or straining with bowel or bladder elimination may interfere with healing or repair of a perilymph fistula. After middle ear surgery (stapedectomy) the patient needs to prevent increased intracranial (and consequent inner ear) pressure associated with straining during bowel movements. Stool softeners may be ordered postoperatively for the patient who reports chronic problems with constipation.

Activity-Exercise Pattern. A review of the patient's activity-exercise pattern is essential when assessing for equilibrium problems. Question the patient specifically about the onset, duration, and frequency of symptoms. Identify activities that relieve or worsen symptoms and how they relate to the time of the day. For example, patients with Ménière's disease are less able to compensate for environmental input as the day progresses.

Sleep-Rest Pattern. Ask the patient with chronic tinnitus about sleep problems. Find out if the patient has tried any techniques to drown out the tinnitus (e.g., having fan on, using white noise devices). Also assess for snoring because it can be caused by swelling or hypertrophy of tissue in the nasopharynx. This excessive tissue can impair the functioning of the eustachian tube and cause the sensation of ear fullness or pain.

Cognitive-Perceptual Pattern. Pain is associated with some ear problems, particularly those involving the middle ear and auditory canal. If pain is present, ask the patient to describe the pain, presence of drainage (otorrhea), history of teeth grinding, and the treatments used for relief. Note the effect on the pain level when the auricle is moved or the tragus is palpated.

Note the patient's ability to pay attention and follow directions. Problems with these tasks may be an early indicator of hearing loss. The patient may not recognize a gradual hearing loss. Ask significant others if they have noted any change in the patient's hearing.

Self-Perception–Self-Concept Pattern. Ask the patient to describe how the ear problem has affected his or her personal life and feelings about himself or herself. Hearing loss and chronic vertigo are particularly distressing for the patient. Hearing loss can result in embarrassing social situations that affect the patient's self-concept. Sensitively question the patient about such situations.

At times the patient with chronic vertigo may be accused of acting intoxicated. Clarify the symptom history with the patient and consider an evaluation with a hearing specialist.

Role-Relationship Pattern. Question the patient about the effect that the ear problem has had on family life, work responsibilities, and social relationships. Hearing loss can result in strained family relations and misunderstandings.

Also ask about employment or contact with environments that have excessive noise levels, such as work with jet engines and machinery and electronically amplified music. Document the use of preventive devices worn in noisy environments. Many jobs rely on the ability to hear accurately and respond appropriately. If a hearing loss is present, gather detailed information on the effect this has on the patient's job.

The unpredictability of vertigo attacks can have devastating effects on all aspects of a patient's life. Ordinary activities such as driving or cooking and work that requires balance all have an element of danger. Assess the effect of the vertigo on the patient's many roles and responsibilities.

Sexuality-Reproductive Pattern. Determine whether hearing loss or vertigo has interfered with the establishment of a satisfactory sex life. Although intimacy does not depend on the ability to hear, a hearing loss could interfere with establishing or maintaining a relationship.

Coping–Stress Tolerance Pattern. Ask the patient about his or her usual coping style, stress-reducing techniques, and available support. If the patient seems unable to manage the situation, outside intervention may be required. Denial is a common response to a hearing problem and should be assessed.

Value-Belief Pattern. Question the patient about any conflicts produced by the problem or treatment related to values or beliefs. Every effort should be made to resolve the problem so the patient does not experience additional stress. Ask about the use of home remedies such as hot oil in the ear.

Objective Data

Physical Examination. During the health-history interview, collect objective data regarding the patient's ability to hear. Note clues such as posturing of the head and appropriateness of

TABLE 21-9 NORMAL PHYSICAL ASSESSMENT OF AUDITORY SYSTEM

- Ears symmetric in location and shape.
- Auricles and tragus nontender, without lesions.
- Canal clear, tympanic membrane intact, landmarks and light reflex intact.
- Able to hear low whisper at 30 cm. Weber test results, no lateralization. Rinne test results AC > BC.

AC, Air conduction; *BC,* bone conduction.

responses. Does the patient ask to have certain words repeated? Does the patient intently watch the examiner but miss comments when *not* looking at the examiner? Is the patient lip reading? Record these significant observations. This is also important because the patient is often unaware of hearing loss or does not admit to changes in hearing until moderate losses have occurred.

A normal assessment of the auditory system is listed in Table 21-9. Age-related changes of the auditory system and differences in assessment findings are listed in Table 21-7.

A *focused assessment* is used to evaluate the status of previously identified auditory problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the auditory system is presented in the box on p. 379.

External Ear. Inspect and palpate the external ear before examining the external canal and tympanum.[4] Observe the auricle, preauricular area, and mastoid area for symmetry, color of skin, swelling, redness, and lesions. Then palpate the auricle and mastoid areas for tenderness and nodules. Grasping the auricle or pressing on the tragus may elicit pain, especially if the external ear or canal is inflamed.

External Auditory Canal and Tympanum. Before inserting an otoscope, inspect the canal opening for patency, palpate the tragus, and gently move the auricle to check for discomfort. Select a speculum slightly smaller than the size of the ear canal. Tip the patient's head to the opposite shoulder. Grasp the top of the auricle and gently pull up and backward to straighten the canal. Hold the otoscope while stabilizing it with your fingers on the patient's cheek, and then insert it slowly. A pneumatic otoscope creates negative pressure to pull at the TM and is helpful in confirming TM retraction or fluid behind the membrane (see eFig. 21-3 available on the website for this chapter). A tight seal of the speculum is essential during this step of the examination. Observe the canal for size and shape and the color, amount, and type of cerumen. Be careful when clearing the canal of cerumen. Damage can occur to the middle ear if the TM is perforated.

Inspect the TM for color, fluid behind the membrane, landmarks, contour, and intactness (Fig. 21-7). The TM is normally pearl gray, white, or pink; shiny; and translucent. The handle *(manubrium)* of the malleus and its short process *(umbo)* should be visible through the membrane. The position and dome (concave) shape of the TM causes the light from the otoscope to reflect back in a cone shape with crisp edges. If the TM is bulging or retracted, the edges of the light reflex will be fuzzy (diffuse) and may spread over the TM. The middle and inner ear cannot be examined with the otoscope because of the TM.

Table 21-10 summarizes assessment abnormalities of the auditory system.

DIAGNOSTIC STUDIES OF AUDITORY SYSTEM

Table 21-11 describes diagnostic studies commonly used to assess the auditory system.

Tests for Hearing Acuity

Tests involving the whispered and spoken voice can provide general screening information about the patient's ability to hear. Audiometric testing provides more detailed information that can be used for diagnosis and treatment.

In the *whisper test,* stand 12 to 24 in (30.5 to 61 cm) to the side of the patient and, after exhaling, speak in a low whisper. Ask the patient to repeat numbers or words or answer questions. Use a louder whisper if the patient does not respond correctly. Test each ear separately. The ear not being tested is covered by the patient.

Tuning Fork Tests. Tuning fork tests aid in differentiating between conductive and sensorineural hearing loss. Tuning forks of 512 Hz are generally used for this examination. Both skill and experience are required to ensure accurate results. If a problem is suspected, further evaluation by pure-tone audiometry is needed. The most common tuning fork tests are the *Weber test* and the *Rinne test*[10] (described in eTable 21-1 available on the website for this chapter). These tests measure hearing by bone conduction or by air conduction. Results of tuning fork tests are subjective. The patient with inconsistent or questionable test results should be referred for more objective audiometric evaluation.

Audiometry. *Audiometry* is beneficial as a screening test for hearing acuity and as a diagnostic test for determining the degree and type of hearing loss. The audiometer produces pure tones at varying intensities to which the patient can respond. Sound is characterized by the number of vibrations or cycles that occur each second. *Hertz* (Hz) is the unit of measurement used to classify the frequency of a tone; the higher the fre-

TABLE 21-10 ASSESSMENT ABNORMALITIES

Auditory System

Finding	Description	Possible Etiology and Significance
External Ear and Canal		
Sebaceous cyst behind ear	Usually within skin, possible presence of black dot (opening to sebaceous gland)	Removal or incision and drainage if painful
Tophi	Hard nodules in the helix or antihelix consisting of uric acid crystals	Associated with gout, metabolic disorder. Further diagnosis needed
Impacted cerumen	Wax that has not normally been excreted from the ear. No visualization of eardrum	Decreased hearing possible, pain, sensation of fullness in auditory canal, removal necessary before otoscopic examination
Discharge in canal	Infection of external ear, usually painful	Swimmer's ear, infection of external ear. Possibly caused by ruptured eardrum and otitis media
Swelling of pinna, pain	Infection of glands of skin, hematoma caused by trauma	Aspiration (for hematoma)
Scaling or lesions	Change in usual appearance of skin	Seborrheic dermatitis, actinic keratosis, basal or squamous cell carcinoma
Exostosis	Bony growth extending into canal causing narrowing of canal	Possible interference with visualization of tympanum. Usually asymptomatic
Tympanum		
Retracted eardrum	Appearance of shorter, more horizontal malleus. Absent or bent cone of light	Vacuum in middle ear, blockage of eustachian tube, negative pressure in middle ear
Hairline fluid level, yellow-amber bubbles above fluid level	Caused by transudate of blood and serum, meniscus of fluid producing hairline appearance	Serous otitis media
Bulging red or blue eardrum, lack of landmarks	Fluid-filled middle ear, pus, blood	Acute otitis media, perforation possible
Perforation of eardrum (see Fig. 21-7)	Previous perforations of the eardrum that have failed to heal. Thin, transparent layer of epithelium surrounding eardrum	Chronic otitis media, mastoiditis, drainage
Recruitment	Disproportionate loudness of sound from malfunction of inner ear	Hearing aid difficult to use

TABLE 21-11 DIAGNOSTIC STUDIES

Auditory System

Study	Description and Purpose	Nursing Responsibility
Auditory		
Pure-tone audiometry	Sounds are presented through earphones in soundproof room. Patient responds nonverbally when sound is heard. Response is recorded on an audiogram. Purpose is to determine patient's hearing range in terms of decibels (dB) and Hertz (Hz) for diagnosing conductive and sensorineural hearing loss. Tinnitus can cause inconsistent results.	Nurse does not usually participate in examination.
One- and two-syllable word lists	Words are presented and recorded at comfortable level of hearing to determine percentage correct and word understanding.	Nurse may perform test.
Auditory evoked potential (AEP)	Procedure is similar to electroencephalogram (see Chapter 56 and Table 56-8). Electrodes are attached to patient in a darkened room. Electrodes are placed typically at vertex, mastoid process, or earlobes and forehead. A computer is used to isolate auditory from other electrical activity of brain.	Explain procedure to patient. Do not leave patient alone in darkened room.
Electrocochleography	Test is useful for uncooperative patient or patient who cannot volunteer useful information. Test records electrical activity in cochlea and auditory nerve.	Nurse does not usually participate in examination.
Auditory brainstem response (ABR)	Study measures electrical peaks along auditory pathway of inner ear to brain and provides diagnostic information related to acoustic neuromas, brainstem problems, and stroke.	Nurse does not usually participate in examination.
Tympanometry (impedance audiometry)	Useful in diagnosis of middle ear effusions. A probe is placed snugly in external ear canal, and positive and negative pressures are then applied. Compliance of middle ear is then noted in response to pressures.	Nurse does not usually participate in examination.

TABLE 21-11 DIAGNOSTIC STUDIES—cont'd

Auditory System

Study	Description and Purpose	Nursing Responsibility
Vestibular		
Caloric test stimulus	Endolymph of semicircular canals is stimulated by irrigation of cold (68° F [20° C]) or warm (97° F [36° C]) solution into ear. Patient is seated or in supine position. Observation of type of nystagmus, nausea and vomiting, falling, or vertigo is helpful in diagnosing disease of labyrinth. Decreased function is indicated by decreased response and indicates disease of vestibular system. Other ear is tested similarly and results are compared.	Instruct patient to eat light meal before test to avoid nausea. Observe patient for vomiting. Assist if necessary. Ensure patient safety.
Electronystagmography (ENG)	Electrodes are placed near patient's eyes, and movement of eyes (nystagmus) is recorded on graph during specific eye movements and when ear is irrigated. Used to diagnose diseases of vestibular system.	Instruct patient to eat light meal before test to avoid nausea. Observe patient for vomiting. Assist if necessary. Ensure patient safety.
Posturography	Balance test that can isolate one semicircular canal from others to determine site of lesion. Test is done in a boxlike device in which floor moves in response to a correction in balance by patient.	Inform patient that test is time consuming and uncomfortable. Test can be discontinued at any time at patient's request.
Rotary chair testing	Evaluates peripheral vestibular system. Patient is seated in a chair driven by a motor under computer control. Test is usually done in the dark.	Instruct patient to eat light meal before test to avoid nausea. Observe patient for vomiting. Assist if necessary. Ensure patient safety.

quency, the higher the pitch. Hearing loss can affect certain sound frequencies. The specific pattern produced on the audiogram by these losses can assist in the diagnosis of the type of hearing loss. The intensity or strength of a sound wave is expressed in terms of decibels (dB), ranging from 0 to 110 dB. The intensity of a sound required to make any frequency barely audible to the average normal ear is 0 dB. *Threshold* refers to the signal level at which pure tones are detected (pure-tone thresholds) or the signal level at which the patient correctly hears 50% of the signals (speech detection thresholds).

Normal speech is approximately 40 to 65 dB; a soft whisper is 20 dB. Normally, a child and a young adult can hear frequencies from about 16 to 20,000 Hz, but hearing is most sensitive between 500 and 4000 Hz. This is similar to the frequencies of normal speech. A 40- to 45-dB loss in these frequencies causes moderate difficulty in hearing normal speech. A hearing aid may be helpful because it makes sound information louder but not clearer. A hearing aid may not be helpful to the patient who has problems with discrimination of sounds or sound information because the consonants are still not heard enough to make speech understandable.

Screening Audiometry. Screening audiometry is the testing of large numbers of people with a fast, simple test to detect possible hearing problems. A pass-fail criterion is used to screen people who will or will not be given additional diagnostic testing. People who fail the screening should be referred to an audiologist for pure-tone (threshold) audiometry.

Specialized Tests

The more specialized tests of the auditory system are frequently performed in an outpatient setting by an audiologist. An audiologist can perform many additional tests with the use of audiometers and computers that record electrical activity from the middle ear, inner ear, and brain (see Table 21-11). The most common test performed by the audiologist is pure-tone audiometry. A pure-tone audiometer produces pure tones at varied frequencies (pitch) and intensity (volume). Testing determines the patient's hearing range in decibels and Hertz.

More sophisticated tests are available to determine the origin of certain hearing losses. These include evoked potential studies (also called auditory brainstem response) and electrocochleography. Computed tomography (CT) and magnetic resonance imaging (MRI) scans are used to diagnose the site of a lesion, such as a tumor of the auditory nerve.

Test for Vestibular Function

Table 21-11 describes diagnostic studies commonly used to assess vestibular function.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a patient who has a hemorrhage in the posterior cavity of the eye, the nurse knows that blood is accumulating
   - **a.** in the aqueous humor.
   - **b.** between the lens and the retina.
   - **c.** between the cornea and the lens.
   - **d.** in the space between the iris and the lens.
2. Increased intraocular pressure may occur as a result of
   - **a.** edema of the corneal stroma.
   - **b.** dilation of the retinal arterioles.
   - **c.** blockage of the lacrimal canals and ducts.
   - **d.** increased production of aqueous humor by the ciliary process.

3. Question patients using eyedrops to treat their glaucoma about
   a. use of corrective lenses.
   b. their usual sleep pattern.
   c. a history of heart or lung disease.
   d. sensitivity to opioids or depressants.
4. Always assess the patient with an ophthalmic problem for
   a. visual acuity.
   b. pupillary reactions.
   c. intraocular pressure.
   d. confrontation visual fields.
5. During an assessment of hearing, the nurse would expect to find normal finding of
   a. absent cone of light.
   b. bluish purple tympanic membrane.
   c. midline tone heard equally in both ears.
   d. fluid level at hairline in the tympanum.
6. Age-related changes in the auditory system commonly include *(select all that apply)*
   a. drier cerumen.
   b. tinnitus in both ears.
   c. auditory nerve degeneration.
   d. atrophy of the tympanic membrane.
   e. greater ability to hear high-pitched sounds.
7. Before injecting fluorescein for angiography, it is important for the nurse to *(select all that apply)*
   a. obtain an emesis basin.
   b. ask if the patient is fatigued.
   c. administer a topical anesthetic.
   d. inform patient that skin may turn yellow.
   e. assess for allergies to iodine-based contrast media.

1. b, 2. d, 3. c, 4. a, 5. c, 6. a, c, d, 7. a, d

LEARNING OUTCOMES

1. Compare and contrast the types of refractive errors and appropriate corrections.
2. Describe the etiology and collaborative care of extraocular disorders.
3. Explain the pathophysiology, clinical manifestations, and nursing management and collaborative care of the patient with selected intraocular disorders.
4. Discuss the nursing measures that promote the health of the eyes and ears.
5. Elaborate on the general preoperative and postoperative care of patients undergoing surgery of the eye or ear.
6. Summarize the action and uses of drug therapy for treating problems of the eyes and ears.
7. Explain the pathophysiology, clinical manifestations, and nursing and collaborative management of common ear problems.
8. Compare the causes, management, and rehabilitative potential of conductive and sensorineural hearing loss.
9. Explain the use, care, and patient teaching related to assistive devices for eye and ear problems.
10. Describe the common causes and assistive measures for uncorrectable visual impairment and deafness.
11. Describe the measures used to assist the patient in adapting psychologically to decreased vision and hearing.

The chapter describes visual and auditory problems, with an emphasis on their pathophysiology, clinical manifestations, collaborative care, and nursing management. Discussion of assistive devices for visual and hearing impairment is also included.

VISUAL PROBLEMS

CORRECTABLE REFRACTIVE ERRORS

The most common visual problem is **refractive error.** This defect prevents light rays from converging into a single focus on the retina. Defects are a result of irregularities of the corneal curvature, the focusing power of the lens, or the length of the eye. The major symptom is blurred vision. In some cases the patient may also complain of ocular discomfort, eyestrain, or headaches. The principal refractive errors of the eye can be corrected by the use of lenses in the form of eyeglasses or contact lenses, refractive surgery, or surgical implantation of an artificial lens. Contrary to popular belief, failure to correct refractive errors does not worsen the error, nor does it cause any further pathologic conditions after age 6.

Myopia (nearsightedness) is an inability to accommodate for objects at a distance. It causes light rays to be focused in front of the retina. Myopia may occur because of excessive light refraction by the cornea or lens or because of an abnormally long eye. (Refractive errors are depicted in eFig. 22-1 available on the website for this chapter.) Myopia is the most common refractive error, with approximately 25% of Americans having this disorder.

Hyperopia (farsightedness) is an inability to accommodate for near objects. It causes the light rays to focus behind the retina and requires the patient to use accommodation to focus the light rays on the retina for near objects. This type of refractive error occurs when the cornea or lens does not have adequate focusing power or when the eyeball is too short.

Presbyopia is the loss of accommodation associated with age. This condition generally appears at about age 40. As the eye ages, the lens becomes larger, firmer, and less elastic. These changes, which progress with aging, result in an inability to focus on near objects.[1]

Astigmatism is caused by an irregular corneal curvature. This irregularity causes the incoming light rays to be bent unequally. Consequently, the light rays do not come to a single point of focus on the retina. Astigmatism can occur in conjunction with any of the other refractive errors.

Aphakia is the absence of the lens. Rarely, the lens may be absent congenitally, or it may be removed during cataract surgery. A lens that is traumatically injured is removed and replaced with an intraocular lens (IOL) implant. The lens accounts for approximately 30% of ocular refractive power. The absence of the lens results in a significant refractive error. Without the focusing ability of the lens, images are projected behind the retina.

Nonsurgical Corrections

Corrective Glasses. Myopia, hyperopia, presbyopia, and astigmatism can be modified by using the appropriate corrective lenses. Glasses for presbyopia are often called "reading glasses" because they are usually worn for close work only. The presbyopic correction may also be combined with a correction for another refractive error, such as myopia or astigmatism. In these combined glasses the presbyopic correction is in the lower portion of the spectacle lens. A traditional bifocal or trifocal has visible lines. However, most lenses today that correct vision at various distances do not have visible lines. The prescription varies throughout the lens, allowing distance focusing in the top two thirds and near focus in the bottom one third of the lens.

Contact Lenses. Contact lenses are another way to correct refractive errors. Contact lenses are made from various plastic and silicone substances that are highly permeable to oxygen and have a high water content. These features allow for increased wearing time with greater comfort. If the oxygen supply to the cornea is decreased, it becomes swollen, visual acuity decreases, and the patient experiences severe discomfort.

Altered or decreased tear formation can make wearing contact lenses difficult. Tear production can be decreased by medications such as antihistamines, decongestants, diuretics, and birth control pills, as well as the hormones produced during pregnancy. Environmental factors such as wind, fans, and dust may also decrease the tear film. Allergic conjunctivitis with itching, tearing, and redness can also affect contact lens wear.

In general, you need to know whether the patient wears contact lenses, the pattern of wear (daily versus extended), and care practices. Shining a light obliquely on the eyeball can help visualize a contact lens. Contact lenses are associated with microbial keratitis, a severe sight-threatening complication. Risk factors for keratitis include poor hand cleaning, poor lens case hygiene, and inadequate lens cleaning.[2] Teach the patient the importance of following recommended cleaning practices and reporting redness, sensitivity, vision problems, and pain to the eye care professional. Instruct the patient to remove contact lenses immediately if any of these problems occur.

Surgical Therapy

Surgical procedures are designed to eliminate or reduce the need for eyeglasses or contact lenses and correct refractive errors by changing the focus of the eye. Surgical management for refractive errors includes laser surgery and IOL implantation.

Laser. *Laser-assisted in situ keratomileusis* (LASIK) may be considered for patients with low to moderately high amounts of myopia or hyperopia, with or without astigmatism. The procedure first involves using a laser or surgical blade to create a flap in the cornea. The flap is folded back on the middle section, or stroma, of the cornea.[3] Pulses from a computer-controlled laser vaporize a part of the stroma. The flap is then repositioned, adhering on its own without sutures in a few minutes.

Photorefractive keratectomy (PRK) is indicated for low to moderate amounts of myopia or hyperopia, with or without astigmatism and is a good option for a patient with insufficient corneal thickness for a LASIK flap. In PRK only the epithelium is removed, and the laser sculpts the cornea to correct the refractive error. *Laser-assisted subepithelial keratomileusis* (LASEK) is similar to PRK except that the epithelium is replaced after surgery.

Implant. *Refractive intraocular lens* (refractive IOL) implantation is an option for patients with a high degree of myopia or hyperopia. Like cataract surgery, it involves removal of the patient's natural lens and implantation of an IOL, which is a small plastic lens to correct a patient's refractive error. Since this requires entering the eye, the risk of complications is higher. New accommodating IOLs correct both myopia and presbyopia.

CULTURAL & ETHNIC HEALTH DISPARITIES

Visual and Auditory Problems

- Whites have a higher incidence of hearing impairment than African Americans or Asian Americans.
- Glaucoma has an increased incidence and severity among African Americans compared with whites.
- Hispanic Americans have an increased incidence of diabetic retinopathy.
- Native Americans have an increased incidence of otitis media when compared with whites.
- Whites have a higher incidence of macular degeneration than Hispanics, African Americans, and Asian Americans.

Phakic intraocular lenses (phakic IOLs) are sometimes referred to as implantable contact lenses. They are implanted into the eye without removing the eye's natural lens. They are used for patients with high degrees of myopia or hyperopia. Unlike refractive IOLs, the phakic IOL is placed in front of the eye's natural lens. Leaving the natural lens in the eye preserves the eye's ability to focus for reading vision. Artisan is one type of phakic IOL used for moderate to severe myopia.

UNCORRECTABLE VISUAL IMPAIRMENT

In the United States, 6.5 million people over age 65 have *severe visual impairment,* which is defined as the inability to read newsprint even with glasses.[4] Of those individuals, 9% have no useful vision, and the remaining 91% are considered partially sighted. The *partially sighted* individual may still have significant visual abilities.

A patient with visual impairment may be categorized by the level of visual loss. *Total blindness* is defined as no light perception and no usable vision. *Functional blindness* is present when the patient has some light perception but no usable vision.

The patient with either total or functional blindness is considered legally blind. *Legal blindness* refers to central visual acuity of 20/200 or less in the better eye with correction, or a peripheral visual field of 20 degrees or less. It is estimated that about 1.3 million people in the United States are legally blind. Almost all blindness in the United States is the result of common eye diseases, including cataracts, glaucoma, age-related macular degeneration, and diabetic retinopathy. Less than 4% of blindness is the result of injuries.[4]

NURSING MANAGEMENT VISUAL IMPAIRMENT

NURSING ASSESSMENT

It is important to assess how long the patient has had a visual impairment, since recent loss of vision has different implications for nursing care. Determine how the patient's visual impairment affects normal functioning. Question the patient about the level of difficulty involved in doing certain tasks. For example, ask how much difficulty the patient has when reading a newspaper, writing a check, moving from one room to the next, or viewing television. Other questions can help determine the personal meaning that the patient attaches to the visual impairment. Ask how the vision loss has affected specific aspects of the patient's life, whether the patient has lost a job, or what activities the patient does not engage in because of the visual impairment. The patient may attach many negative meanings to the impairment because of societal views of blindness. For example, the patient may view the impairment as punishment or view himself or herself as useless and burdensome. Determine the patient's primary coping strategies, the patient's emotional reactions, and the availability and strength of the patient's support systems.

PLANNING

The overall goals are that the patient with recently impaired vision or the patient with poor adjustment to long-standing visual impairment will (1) make a successful adjustment to the impairment, (2) verbalize feelings related to the loss, (3) identify personal strengths and external support systems, and (4) use appropriate coping strategies. If the patient has been functioning at an appropriate or acceptable level, the goal is to maintain the current level of function.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Encourage the partially sighted patient with preventable causes of further visual impairment to seek appropriate health care. For example, the patient with vision loss from glaucoma may prevent further visual impairment by complying with prescribed therapies and suggested ophthalmic evaluations.

ACUTE INTERVENTION. Provide emotional support and direct care to the patient with recent visual impairment. Allow the patient to express anger and grief, and help the patient identify fears and successful coping strategies. The family is intimately involved in the experiences that follow vision loss. With the patient's knowledge and permission, include family members in discussions and encourage them to express their concerns.

Many people are uncomfortable around a blind or partially sighted individual because they are not sure what behaviors are appropriate. Being sensitive to the patient's feelings without being overly worried or smothering the patient's independence is vital in creating a therapeutic nursing presence. Always communicate in a normal conversational tone and manner with the patient, and address the patient, not the caregiver. Common courtesy dictates introducing oneself and any other people who approach the blind or partially sighted patient and saying goodbye on leaving. Making eye contact with the partially sighted patient accomplishes several objectives. It ensures that you are speaking while facing the patient so the patient has no difficulty hearing. Your head position validates that you are attentive to the patient. In addition, establishing eye contact ensures that you can observe the patient's facial expressions and reactions.

Assist the patient using a *sighted-guide technique*. Stand slightly in front and to one side of the patient, and offer an elbow for the patient to hold. Serve as the sighted guide, walking slightly ahead of the patient with the patient holding the back of your arm. As you walk, describe the environment to help orient the patient. For example, "We're going through an open doorway and approaching two steps down." Help the patient sit by placing one of his or her hands on the seat of the chair.

AMBULATORY AND HOME CARE. In working with the visually impaired patient, remember that a person classified as legally blind may have some useful vision. Rehabilitation after partial or total loss of vision can foster independence, self-esteem, and productivity. Know what services and devices are available for the partially sighted or blind patient, and make appropriate referrals. For the legally blind patient the primary resource for services is the state agency for rehabilitation of the blind. Legally

blind individuals are eligible for federal and state assistance and income tax benefits. A list of agencies that serve the partially sighted or blind patient is available from the American Foundation for the Blind *(www.afb.org)*. Many of these agencies are listed in the resources section at the end of the chapter.

Braille or audio books for reading and a cane or guide dog for ambulation are examples of vision substitution techniques. These are usually most appropriate for the patient with no functional vision. For most patients who have some remaining vision, vision enhancement techniques can provide help in learning to ambulate, read printed material, and accomplish activities of daily living (ADLs).

Optical Devices for Vision Enhancement. A wide range of newer technologies are available to assist people with low vision.[5] These devices include desktop video magnification/closed circuit units, electronic hand-held magnifiers, text-to-speech scanners (material read aloud to you), E-readers, and computer tablets (material read aloud, magnification, image zooming, brighter screen, voice recognition). Many of these devices require some training by an assistive technology professional. Encourage patients to practice with the technologic device to ensure they can use it successfully.

Nonoptical Methods for Vision Enhancement. *Approach magnification* is a simple way to enhance the patient's residual vision. Recommend that the patient sit closer to the television or hold books closer to the eyes. Contrast enhancement techniques include watching television in black and white, using a black felt-tip marker, and using contrasting colors (e.g., a red stripe at the edge of steps or curbs). Increased lighting can be provided by halogen lamps, direct sunlight, or gooseneck lamps that can be aimed directly at the reading material or other near objects.[6] Large type is often helpful, especially in conjunction with other optical or nonoptical vision enhancements.

EVALUATION

The overall expected outcomes are that the patient with severe visual impairment will

- Have no further loss of vision
- Be able to use adaptive coping strategies
- Not experience a decrease in self-esteem or social interactions
- Function safely within her or his own environment

GERONTOLOGIC CONSIDERATIONS

VISUAL IMPAIRMENT

The older adult is at an increased risk for vision loss caused by eye disease. This older person may have other deficits, such as cognitive impairment or limited mobility, that further affect the ability to function in usual ways. Societal devaluation of the elderly may compound the self-esteem or isolation issues associated with the older patient's visual impairment. Financial resources may meet normal needs but can be inadequate to meet the increased demands of vision services or assistive devices.

The older patient may become confused or disoriented when visually compromised. The combination of decreased vision and confusion increases the risk of falls, which have potentially serious consequences for the older adult. Decreased vision may compromise the older patient's ability to function, resulting in concerns about maintaining independence and a diminished self-image. Decreased manual dexterity may make the instillation of prescribed eyedrops difficult for some older adults.

HEALTHY PEOPLE

Health Impact of Responsible Eye Care

- Regular hand washing prevents the spread of disease from one eye to the other.
- Seeking appropriate health care can lead to early detection of disease and prevent further loss of vision in patients with certain types of partial vision loss.
- Wearing sunglasses and practicing proper nutrition may help prevent cataract development and age-related macular degeneration.
- Wearing eye protection during potentially hazardous work, hobby, and sport activities reduces the risk of eye injuries.

EYE TRAUMA

Although the eyes are well protected by the bony orbit and fat pads, everyday activities can result in ocular trauma. In the United States an estimated 2.5 million eye injuries occur each year. Of those injured, more than 10% will lose useful vision in the affected eye. Table 22-1 outlines emergency management of the patient with an eye injury. The most common ocular injuries in the United States occur in the home due to gardening, power tool use, and home repair work.[7] Sport and work-related injuries are additional causes of eye trauma.

Trauma is often a preventable cause of visual impairment. Many eye injuries could be prevented by wearing protective eyewear. Your role in individual and community education is extremely important in reducing the incidence of ocular trauma.

EXTRAOCULAR DISORDERS

INFLAMMATION AND INFECTION

One of the most common conditions encountered by the ophthalmologist is inflammation or infection of the external eye. Many external irritants or microorganisms can affect the eye, conjunctiva, and avascular cornea. It is your responsibility to teach the patient appropriate interventions related to the specific disorder.

An external **hordeolum** (commonly called a *sty*) is an infection of the sebaceous glands in the lid margin (Fig. 22-1). The most common bacterial infective agent is *Staphylococcus aureus*. A red, swollen, circumscribed, and acutely tender area develops rapidly. Instruct the patient to apply warm, moist compresses at least four times a day until it improves. This may be the only treatment necessary. If it tends to recur, teach the patient to perform lid scrubs daily. In addition, appropriate antibiotic ointments or drops may be indicated.

A *chalazion* is a chronic inflammatory granuloma of the meibomian (sebaceous) glands in the lid. It may evolve from a hordeolum or occur in response to the material released into the lid when a blocked gland ruptures. The chalazion usually appears on the upper lid as a swollen, tender, reddened area that may be painful. Initial treatment is similar to that for a hordeolum. If warm, moist compresses are ineffective in promoting spontaneous drainage, the ophthalmologist may surgically remove the lesion (this is normally an office procedure) or inject the lesion with corticosteroids.

Blepharitis is a common chronic bilateral inflammation of the lid margins.[8] The lids are red rimmed with many scales or

TABLE 22-1 EMERGENCY MANAGEMENT

Eye Injury

Etiology	Assessment Findings	Interventions
Trauma • Blunt (e.g., fist) • Penetrating (e.g., glass, metal, or wood fragments. Knife, stick, or other object) **Chemical Burn** • Alkaline • Acid **Thermal Burn** • Direct burn from hot surface • Indirect burn from UV light (e.g., welding torch, looking directly at sun) **Foreign Bodies** • Glass • Metal • Wood • Plastic • Ceramics	• Pain • Photophobia • Redness—diffuse or localized • Swelling • Ecchymosis • Tearing • Blood in the anterior chamber • Absent eye movements • Fluid drainage from eye (e.g., blood, CSF, aqueous humor) • Abnormal or decreased vision • Visible foreign body • Prolapsed globe • Abnormal intraocular pressure • Visual field defect	**Initial** • Determine mechanism of injury. • Ensure airway, breathing, circulation. • Assess for other injuries. • Assess for chemical exposure. • Begin ocular irrigation *immediately* in case of chemical exposure. Do not stop until emergency personnel arrive to continue irrigation. Use sterile saline or water if saline is unavailable. • Assess visual acuity. • Do not put pressure on the eye. • Instruct patient not to blow nose. • Do not attempt to treat the injury (except as noted above for chemical exposure). • Stabilize foreign objects. • Cover the eye(s) with dry, sterile patches and a protective shield. • Do not give the patient food or fluids. • Elevate head of bed 45 degrees. • Do not put medication or solutions in the eye unless ordered by physician. • Administer analgesia as appropriate. **Ongoing Monitoring** • Reassure the patient. • Monitor pain. • Anticipate surgical repair for penetrating injury, globe rupture, or globe avulsion.

CSF, Cerebrospinal fluid; *UV,* ultraviolet.

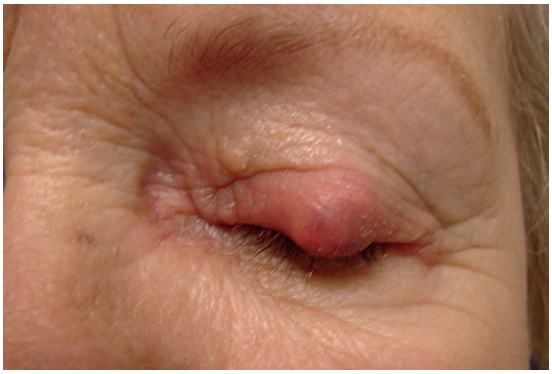

FIG. 22-1 Hordeolum (sty) on the upper eyelid caused by staphylococcal infection.

crusts on the lid margins and lashes. The patient may primarily complain of itching but may also experience burning, irritation, and photophobia. Conjunctivitis may occur simultaneously.

If the blepharitis is caused by a staphylococcal infection, collaborative care includes the use of an appropriate ophthalmic antibiotic ointment. Often blepharitis is caused by both staphylococcal and seborrheal microorganisms, and the treatment must be more vigorous to avoid hordeolum, *keratitis* (inflammation of the cornea), and other eye infections. Emphasize thorough cleaning practices of the skin and scalp. Gentle cleansing of the lid margins with baby shampoo can effectively soften and remove crusting.

Conjunctivitis

Conjunctivitis is an infection or inflammation of the conjunctiva. These infections may be caused by bacteria or viruses. Conjunctival inflammation may result from exposure to allergens or chemical irritants. The tarsal conjunctiva (lining the interior surface of the lids) may become inflamed as a result of a chronic foreign body in the eye, such as a contact lens. Careful hand washing and use of individual or disposable towels help prevent spreading the condition.

Bacterial Infections. Acute bacterial conjunctivitis *(pinkeye)* is a common infection. Although it occurs in every age-group, epidemics are common among children because of their poor hygienic habits. *S. aureus* is the most common cause. The patient with bacterial conjunctivitis may complain of discomfort, pruritus, redness, and a mucopurulent drainage.[9] Although this typically occurs initially in one eye, it generally spreads to the unaffected eye. It is usually self-limiting, but treatment with antibiotic drops (e.g., besifloxacin [Besivance]) shortens the course of the disorder.

Viral Infections. Conjunctival infections may be caused by many different viruses. The patient with viral conjunctivitis may complain of tearing, foreign body sensation, redness, and mild photophobia. This condition is usually mild and self-limiting. However, it can be severe, with increased discomfort and subconjunctival hemorrhaging. Adenovirus conjunctivitis may be contracted in contaminated swimming pools and through direct contact with an infected patient. Treatment is usually palliative. If the patient is severely symptomatic, topical corticosteroids can provide temporary relief but have no effect on the final outcome. Antiviral drops are ineffective and therefore not indicated.

Chlamydial Infections. Trachoma is a chronic conjunctivitis caused by *Chlamydia trachomatis* (serotypes A through C). It is a major cause of blindness worldwide. An estimated 84 million people have active disease in need of treatment if blindness is to be prevented, with 8 million people already living with irreversible vision loss.[10]

This preventable eye disease is transmitted mainly by the hands and by flies. Adult inclusion conjunctivitis (AIC) is

caused by *C. trachomatis* (serotypes D through K). AIC is becoming more prevalent in the United States because of the increase in sexually transmitted chlamydial infection.

Manifestations of both trachoma and AIC are mucopurulent ocular discharge, irritation, redness, and lid swelling. For unknown reasons, AIC does not carry the long-term consequences of trachoma. AIC also differs from trachoma in that it is common in economically developed countries, whereas trachoma is most commonly seen in underdeveloped countries. Antibiotic therapy is usually effective for trachoma and AIC.

Although antibiotic treatment may be successful, patients with AIC have a high risk of concurrent chlamydial genital infection, as well as other sexually transmitted infections. In your teaching plan for these patients, include the sexual implications of AIC.

Allergic Conjunctivitis. Conjunctivitis caused by exposure to an allergen can be mild and transitory, or it can be severe enough to cause significant swelling, sometimes ballooning the conjunctiva beyond the eyelids. The defining symptom of allergic conjunctivitis is itching. The patient may also complain of burning, redness, and tearing. In addition to pollens, the patient may develop allergic conjunctivitis in response to animal dander, ocular solutions, and medications. Instruct the patient to avoid the allergen if it is known. Artificial tears can be effective in diluting the allergen and washing it from the eye. Effective topical medications include antihistamines and corticosteroids.

Keratitis

Keratitis is an inflammation or infection of the cornea that can be caused by a variety of microorganisms or by other factors. The condition may involve the conjunctiva and/or the cornea. When it involves both, the disorder is termed *keratoconjunctivitis.*

Bacterial Infections. The cornea can become infected by a variety of bacteria. Topical antibiotics are generally effective, but eradicating the infection may require subconjunctival antibiotic injection or, in severe cases, IV antibiotics. Risk factors include mechanical or chemical corneal epithelial damage, contact lens wear, nutritional deficiencies, immunosuppressed states, and contaminated products (e.g., lens care solutions and cases, topical medications, cosmetics).

Viral Infections. Herpes simplex virus (HSV) keratitis is the most frequently occurring infectious cause of corneal blindness in the Western hemisphere. It is a growing problem, especially with immunosuppressed patients. The corneal ulcer has a characteristic dendritic (tree-branching) appearance. Pain and photophobia are common. Up to 40% of patients with herpetic keratitis heal spontaneously.

Antiviral treatments include trifluridine drops (Viroptic), oral acyclovir (Zovirax), and topical vidarabine (Vira-A) ointment.[11] Therapy may also involve corneal debridement. Topical corticosteroids are usually contraindicated because they contribute to a longer course and possible deeper ulceration of the cornea.

The varicella-zoster virus (VZV) causes both chickenpox and herpes zoster ophthalmicus (HZO). HZO may occur by reactivation of an endogenous infection that has persisted in a latent form after an earlier attack of varicella or by contact with a patient with chickenpox or herpes zoster. It occurs most frequently in the older adult and in the immunosuppressed patient. Collaborative care of the patient with acute HZO may include analgesics for the pain, topical corticosteroids to reduce inflammation, antiviral agents such as acyclovir to reduce viral replication, mydriatic agents to dilate the pupil and relieve pain, and topical antibiotics to combat secondary infection. The patient may apply warm compresses and povidone-iodine gel to the affected skin (gel should not be applied near the eye).

Epidemic keratoconjunctivitis (EKC) is the most serious ocular adenoviral disease. EKC is spread by direct contact, including sexual activity. In the medical setting, contaminated hands and instruments can be the source of spread. The patient may complain of tearing, redness, photophobia, and foreign body sensation. In most patients the disease involves only one eye. Treatment is primarily palliative and includes ice packs and dark glasses. In severe cases therapy can include mild topical corticosteroids to temporarily relieve symptoms and topical antibiotic ointment. Teach the patient and the caregiver the importance of good hygiene practices to avoid spreading the disease.

Other Causes of Keratitis. Keratitis may also be caused by fungi (most commonly *Aspergillus, Candida,* and *Fusarium* species), especially in the case of ocular trauma in an outdoor setting where fungi are prevalent in the soil and moist organic matter.

Acanthamoeba keratitis is caused by a parasite that is associated with contact lens wear, probably as a result of contaminated lens care solutions or cases. Homemade saline solution is particularly susceptible to *Acanthamoeba* contamination. Instruct the patient who wears contact lenses about good lens care practices. Medical treatment of *Acanthamoeba* keratitis is difficult, since the organism is resistant to most drugs. Only one antifungal eyedrop (natamycin [Natacyn]) is approved by the U.S. Food and Drug Administration (FDA). If antimicrobial therapy fails, the patient may require a corneal transplant.

Exposure keratitis occurs when the patient cannot adequately close the eyelids. The patient with *exophthalmos* (protruding eyeball) from thyroid eye disease or masses posterior to the globe is susceptible to exposure keratitis.

Corneal Ulcer. Tissue loss caused by infection of the cornea produces a *corneal ulcer* (infectious keratitis) (Fig. 22-2). The infection can be due to bacteria, viruses, or fungi. Corneal ulcers are often painful, and patients may feel as if there is a foreign body in their eye. Other symptoms can include tearing, purulent or watery discharge, redness, and photophobia. Treatment is generally aggressive to avoid permanent loss of vision.

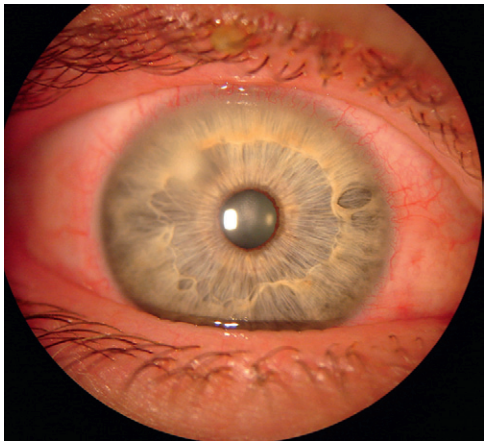

FIG. 22-2 Corneal ulcer. Infection associated with poor contact lens care.

Antibiotic, antiviral, or antifungal eyedrops may be prescribed as frequently as every hour night and day for the first 24 hours. An untreated corneal ulcer can result in corneal scarring and perforation (hole in the cornea). A corneal transplant may be indicated.

NURSING MANAGEMENT INFLAMMATION AND INFECTION

Assess ocular changes, such as edema, redness, decreased visual acuity, feelings that a foreign body is present, or discomfort. Document the findings in the patient's record. Also consider the psychosocial aspects of the patient's condition, especially when vision is impaired.

Careful asepsis and frequent, thorough hand washing are essential to prevent spreading organisms from one eye to the other, to other patients, to family members, and to health care professionals. Teach the patient and the family about avoiding sources of ocular irritation or infection and responding appropriately if an ocular problem occurs. Inform the patient about appropriate use and care of lenses and lens care products. The patient with infective disorders that may have a sexual mode of transmission needs specific information about those disorders.

Apply warm or cool compresses if indicated for the patient's condition. Darkening the room and providing an appropriate analgesic are other comfort measures. If the patient's visual acuity is decreased, modify the patient's environment or activities for safety.

The patient may require eyedrops as frequently as every hour. If the patient receives two or more different drops, stagger the eyedrops to promote maximum absorption. For example, if two different eyedrops are ordered hourly, administer one drop on the hour and one drop on the half hour (unless otherwise prescribed). The patient who needs frequent eyedrop administration may experience sleep deprivation.

The patient's primary need in the home environment is for information about required care and how to accomplish that care. Also instruct the patient and the caregiver about the proper techniques for medication administration. If the patient's vision is compromised, suggest alternative ways to accomplish necessary daily activities and self-care. Inform the patient who wears contact lenses and develops infections to discard all opened or used lens care products and cosmetics to decrease the risk of reinfection from contaminated products (a common problem and a probable source of infection for many patients).

DRY EYE DISORDERS

Keratoconjunctivitis sicca (dry eyes) is a common complaint, particularly of older adults and individuals with certain systemic diseases such as scleroderma and systemic lupus erythematosus. Patients with dry eyes complain of irritation or "sand in my eye" and that the sensation typically worsens through the day. This condition is caused by a decrease in the quality or quantity of the tear film, and treatment is directed at the underlying cause. With decreased tear secretion, the patient may use artificial tears or ointments. In severe cases, closure of the lacrimal puncta may be necessary. Patients with dry eyes associated with dry mouth may have Sjögren's syndrome (see Chapter 65).

STRABISMUS

Strabismus is a condition in which the patient cannot consistently focus two eyes simultaneously on the same object. One eye may deviate in *(esotropia),* out *(exotropia),* up *(hypertropia),* or down *(hypotropia)* (see eFig. 22-2 available on the website for this chapter). Strabismus in the adult may be caused by thyroid disease, neuromuscular problems of the eye muscles, retinal detachment repair, or cerebral lesions. In the adult the primary complaint with strabismus is double vision.

CORNEAL DISORDERS

Corneal Scars and Opacities

The cornea is an optically transparent tissue that allows light rays to enter the eye and focus on the retina, thus producing a visual image. Any wound causes the cornea to become abnormally hydrated and decreases the normal transparency. The treatment for corneal scars or opacities is *penetrating keratoplasty* (corneal transplant). The ophthalmic surgeon removes the full thickness of the patient's cornea and replaces it with a donor cornea that is sutured into place (Fig. 22-3). Vision may not be restored for up to 12 months. Newer procedures in which only the damaged cornea epithelial layer is replaced are Descemet's stripping endothelial keratoplasty (DSEK) and Descemet's membrane endothelial keratoplasty (DMEK).[12] Patients report faster visual recovery with less astigmatism and changes in their glass lens prescription with these surgeries.

Approximately 40,000 corneal transplants are performed in the United States each year. The surgery is one of the fastest and safest of all tissue or organ transplant surgeries. The time between the donor's death and the removal of the tissue should be as short as possible. The eye banks test donors for human immunodeficiency virus (HIV) and hepatitis B and C. The tissue is preserved in a special nutritive solution. Improved methods of tissue procurement and preservation, postoperative topical corticosteroids, and careful follow-up have decreased graft rejection. Matching the blood type of the donor and the recipient may also improve the success rate.

Keratoconus

Keratoconus is a noninflammatory, usually bilateral disease that has a familial tendency. Keratoconus usually appears during adolescence and slowly progresses between ages 20 and 60

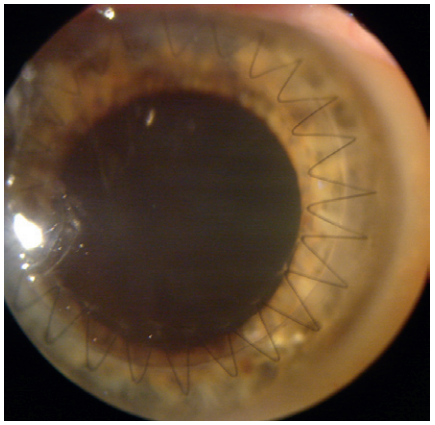

FIG. 22-3 Sutures on a donated cornea after penetrating keratoplasty (corneal transplant).

years. The anterior cornea thins and protrudes forward, taking on a cone shape. The only symptom is blurred vision. The astigmatism may be corrected with glasses or rigid contact lenses.

Intacs inserts are two clear plastic lenses surgically inserted on the cornea perimeter to reduce astigmatism and myopia. Intacs are generally used to delay the need for a corneal transplant when contact lenses or glasses no longer help a patient achieve adequate vision.

The cornea can perforate as central corneal thinning progresses. In advanced cases a penetrating keratoplasty is indicated before perforation.

INTRAOCULAR DISORDERS

CATARACT

A **cataract** is an opacity within the lens. The patient may have a cataract in one or both eyes. If cataracts are present in both eyes, one may affect the patient's vision more than the other. Almost 22 million Americans ages 40 years and older have cataracts, and by age 80 more than 50% have cataracts. Direct medical costs for cataract treatment are estimated at $6.8 billion annually. Cataract removal is the most common surgical procedure in the United States.[13]

Etiology and Pathophysiology

Although most cataracts are age related *(senile cataracts),* they can be associated with other factors. These include blunt or penetrating trauma, congenital factors such as maternal rubella, radiation or ultraviolet (UV) light exposure, certain drugs such as systemic corticosteroids or long-term topical corticosteroids, and ocular inflammation. The patient with diabetes mellitus tends to develop cataracts at a younger age.

Cataract development is mediated by a number of factors. In senile cataract formation it appears that altered metabolic processes within the lens cause an accumulation of water and alterations in the lens fiber structure. These changes affect lens transparency, causing vision changes.

Clinical Manifestations and Diagnostic Studies

The patient with cataracts may complain of a decrease in vision, abnormal color perception, and glare. Glare is due to light scatter caused by the lens opacities, and it may be significantly worse at night when the pupil dilates. The visual decline is gradual, but the rate of cataract development varies from patient to patient. Diagnosis is based on decreased visual acuity or other complaints of visual dysfunction. The opacity is directly observable by ophthalmoscopic or slit lamp microscopic examination. As noted earlier, a totally opaque lens creates the appearance of a white pupil. Table 22-2 lists other diagnostic studies that may be helpful in evaluation of a cataract.

Collaborative Care

The presence of a cataract does not necessarily indicate a need for surgery. For many patients the diagnosis is made long before they actually decide to have surgery. Nonsurgical therapy may postpone the need for surgery. Collaborative care for cataracts is presented in Table 22-2.

Nonsurgical Therapy. Currently, no treatment is available to "cure" cataracts other than surgical removal. Often changing the patient's eyewear prescription can improve visual acuity, at least temporarily. Other visual aids, such as strong reading glasses or magnifiers of some type, may help the patient with close vision. Increasing the amount of light to read or accomplish other near-vision tasks is another useful measure. The patient may be willing to adjust his or her lifestyle to adjust to visual decline. For example, if glare makes it difficult to drive at night, a patient may elect to drive only during daylight hours or to have a family member drive at night. Sometimes informing and reassuring the patient about the disease process makes the patient comfortable about choosing nonsurgical measures, at least temporarily.

Surgical Therapy. When palliative measures no longer provide an acceptable level of visual function, the patient is an appropriate candidate for surgery. The patient's occupational needs and lifestyle changes are also factors affecting the decision to have surgery. In some instances, factors other than the patient's visual needs may influence the need for surgery. Lens-induced problems such as increased intraocular pressure (IOP) may require lens removal. Opacities may prevent the ophthalmologist from obtaining a clear view of the retina in the patient with diabetic retinopathy or other sight-threatening pathologic conditions. In those cases the cataract may be removed to allow visualization of the retina and adequate management of the problem.

Preoperative Phase. The patient's preoperative preparation should include an appropriate history and physical examination. Because almost all patients have local anesthesia, many physicians and surgical facilities do not require an extensive preoperative physical assessment. However, most patients with cataracts are older adults who may have several medical problems that should be evaluated and controlled before surgery. Almost all patients with cataracts are admitted to a surgical facility on an outpatient basis. The patient is normally admitted several hours before surgery to allow time for preoperative procedures.

The patient receives dilating drops and a nonsteroidal anti-inflammatory eyedrop to reduce inflammation. One type of

TABLE 22-2 COLLABORATIVE CARE

Cataract

Diagnostic
- History and physical examination
- Visual acuity measurement
- Ophthalmoscopy (direct and indirect)
- Slit lamp microscopy
- Glare testing, potential acuity testing in selected patients
- Keratometry and A-scan ultrasound (if surgery is planned)
- Other tests (e.g., visual field perimetry) to determine cause of visual loss

Collaborative Therapy

Nonsurgical
- Change in glasses prescription
- Strong reading glasses or magnifiers
- Increased lighting
- Lifestyle adjustment

Acute Care: Surgical Therapy

Preoperative
- Mydriatic, cycloplegic agents
- Nonsteroidal antiinflammatory drugs
- Topical antibiotics
- Antianxiety medications

Surgery
- Removal of lens
  - Phacoemulsification
  - Extracapsular extraction
- Correction of surgical aphakia
- Intraocular lens implantation (most frequent type of correction)
- Contact lens

Postoperative
- Topical antibiotic
- Topical corticosteroid or other antiinflammatory agent
- Mild analgesia if necessary
- Eye shield and activity as preferred by patient's surgeon

drug used for dilation is a *mydriatic,* an α-adrenergic agonist that produces pupillary dilation by contraction of the iris dilator muscle. Another type of drug is a *cycloplegic,* an anticholinergic agent that produces paralysis of accommodation (cycloplegia) by blocking the effect of acetylcholine on the ciliary body muscles. Cycloplegics (tropicamide [Mydriacyl, Tropicacyl]) produce pupillary dilation (mydriasis) by blocking the effect of acetylcholine on the iris sphincter muscle. The patient often receives preoperative antianxiety medication before the local anesthesia injection.

DRUG ALERT: Cycloplegics and Mydriatics

- Instruct patient to wear dark glasses to minimize photophobia.
- Monitor for signs of systemic toxicity (e.g., tachycardia, central nervous system [CNS] effects).

Intraoperative Phase. Cataract extraction is an intraocular procedure. The anterior capsule is opened and the lens nucleus and cortex are removed, leaving the remaining capsular bag intact. In extracapsular extraction the surgeon removes the lens nucleus by *phacoemulsification,* in which the nucleus is fragmented by ultrasonic vibration and aspirated from inside the capsular bag.[14] The remaining cortex is aspirated with an irrigation and aspiration instrument. Larger incisions require closure with sutures, whereas smaller incisions are self-sealing and may require no closing suture.

Almost all patients now have an IOL implanted at the time of cataract extraction surgery (Fig. 22-4). The lens of choice is a posterior chamber lens that is implanted in the capsular bag behind the iris. At the end of the procedure, additional medications such as antibiotics and corticosteroids may be administered. Depending on the type of anesthesia, the patient's eye may be covered with a patch or protective shield, which is usually worn overnight and removed during the first postoperative visit.

Postoperative Phase. Unless complications occur, the patient is usually ready to go home as soon as the effects of sedative agents have worn off. Postoperative medications usually include antibiotic drops to prevent infection and corticosteroid drops to decrease the postoperative inflammatory response. Although postoperative activity restrictions and nighttime eye shielding are probably unnecessary, many ophthalmologists still prefer that the patient avoid activities that increase the IOP, such as bending or stooping, coughing, or lifting.

During each postoperative examination the surgeon measures the patient's visual acuity, checks anterior chamber depth, assesses corneal clarity, and measures IOP. Even on the operative day the patient's uncorrected visual acuity in the operative eye may be good. However, it is not unusual or indicative of any problem if the patient's visual acuity is reduced immediately after surgery.

The postoperative eyedrops are gradually reduced in frequency and finally discontinued when the eye has healed. When the eye is fully recovered, the patient receives a final prescription for glasses. The newest innovation is a multifocal IOL that corrects for both near and far vision. Regardless of the type of IOL used, patients may still need glasses to achieve their best visual acuity.

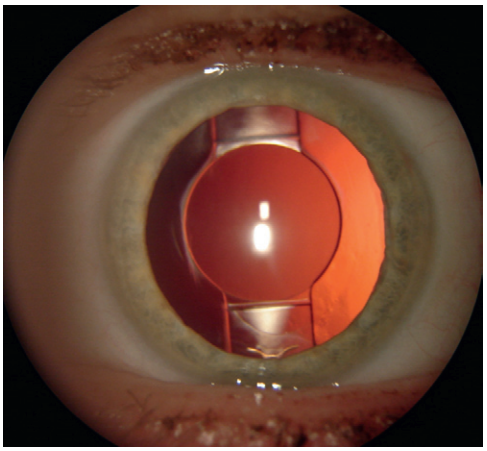

FIG. 22-4 Intraocular lens implant after cataract surgery.

NURSING MANAGEMENT CATARACTS

NURSING ASSESSMENT

Assess the patient's distance and near visual acuity. If the patient is going to have surgery, especially note the visual acuity in the patient's unoperated eye. Use this information to determine how visually compromised the patient may be while the operative eye is healing. In addition, assess the psychosocial impact of the patient's visual disability and the level of knowledge regarding the disease process and therapeutic options. Postoperatively, assess the patient's level of comfort and ability to follow the postoperative regimen.

NURSING DIAGNOSES

Nursing diagnoses for the patient with a cataract include, but are not limited to, the following:

- Self-care deficits *related to* visual deficit
- Anxiety *related to* lack of knowledge about the surgical and postoperative experience

PLANNING

Preoperatively, the overall goals are that the patient with a cataract will (1) make informed decisions regarding therapeutic options and (2) experience minimal anxiety. Postoperatively, the overall goals are that the patient with a cataract will (1) understand and comply with postoperative therapy, (2) maintain an acceptable level of physical and emotional comfort, and (3) remain free of infection and other complications.

NURSING IMPLEMENTATION

HEALTH PROMOTION. There are no proven measures to prevent cataract development. However, it is probably wise (and certainly does no harm) to suggest that the patient wear sunglasses, avoid extraneous or unnecessary radiation, and maintain appropriate intake of antioxidant vitamins (e.g., vitamins C and E) and good nutrition. Also provide information about vision enhancement techniques for the patient who chooses not to have surgery.

ACUTE INTERVENTION. Preoperatively, the patient with cataracts needs accurate information about the disease process and the treatment options, especially because cataract surgery is considered an elective procedure. Be available to give the patient and the family information to help them make an informed decision about appropriate treatment. For the patient who elects to have surgery, provide information, support, and reassurance about the surgical and postoperative experience to reduce or alleviate anxiety.

TABLE 22-3 PATIENT & CAREGIVER TEACHING GUIDE

After Eye Surgery

Include the following information in the teaching plan for the patient and the caregiver after eye surgery.

- Proper hygiene and eye care techniques to ensure that medications, dressings, and/or surgical wound is not contaminated during eye care
- Signs and symptoms of infection and when and how to report these to allow for early recognition and treatment of possible infection
- Importance of complying with postoperative restrictions on head positioning, bending, coughing, and Valsalva maneuver to optimize visual outcomes and prevent increased intraocular pressure
- How to instill eye medications using aseptic techniques and adherence with prescribed eye medication routine to prevent infection
- How to monitor pain, take pain medication, and report pain not relieved by medication
- Importance of continued follow-up as recommended to maximize potential visual outcomes

Source: Lamb P, Simms-Eaton S: *Core curriculum for ophthalmic nursing,* ed 3, Dubuque, 2008, Kendall-Hunt.

Photophobia is common when administering pupil dilation medications. Therefore decreasing the room lighting is helpful. These medications produce transient stinging and burning. Table 22-3 outlines patient and caregiver teaching after eye surgery. Inform patients with a patch that they will not have depth perception until the patch is removed. This necessitates special considerations to avoid falls or other injuries. The patient with significant visual impairment in the unoperated eye requires more assistance while the operative eye is patched. Some patients may require 1 or 2 weeks for the visual acuity in the operated eye to reach an adequate level for most visual needs. These patients also need some special assistance until the vision improves.

After cataract surgery the patient usually experiences little or no pain but may have some scratchiness in the operative eye. Mild analgesics are usually sufficient to relieve any pain. If the pain is intense, the patient should notify the surgeon because this may indicate hemorrhage, infection, or increased IOP. Also instruct the patient to notify the surgeon if there is increased or purulent drainage, increased redness, or any decrease in visual acuity. A nursing care plan for the patient after eye surgery (eNursing Care Plan 22-1) is available on the website for this chapter.

AMBULATORY AND HOME CARE. Patients with cataracts who have surgery remain in the surgical facility for only a few hours. The patient and caregiver are responsible for almost all postoperative care. Give them written and verbal instructions before discharge, including information about postoperative eye care, activity restrictions, medications, follow-up visit schedule, and signs and symptoms of possible complications. Include the patient's caregiver in the instruction because some patients may have difficulty with self-care activities, especially if the vision in the unoperated eye is poor. Provide an opportunity for the patient and the caregiver to perform return demonstrations of any self-care activities.

Most patients experience little visual impairment after surgery.[15] IOL implants provide immediate visual rehabilitation, and many patients achieve a usable level of visual acuity within a few days after surgery.

A few patients may have significant visual impairment postoperatively. These include patients who do not have an IOL implanted at the time of surgery, those who require several weeks to achieve a usable level of visual acuity following surgery, or those with poor vision in their unoperated eye. For those patients the time between surgery and receiving glasses or contacts can be a period of significant visual disability. Suggest ways the patient and caregiver can modify activities and the environment to maintain an adequate level of safe functioning. Suggestions may include getting assistance with steps, removing area rugs and other potential obstacles, preparing meals for freezing before surgery, or obtaining audio books for diversion until visual acuity improves.

EVALUATION

The overall expected outcomes are that the patient following cataract surgery will

- Have improved vision
- Be better able to take care of self
- Have minimal to no pain
- Be optimistic about expected outcomes

GERONTOLOGIC CONSIDERATIONS

CATARACTS

Most patients with cataracts are older. When the older patient is visually impaired, even temporarily, the patient may experience a loss of independence, lack of control over her or his life, and a significant change in self-perception. Societal devaluation of the older individual complicates these experiences. The older patient often needs emotional support and encouragement, as well as specific suggestions to allow a maximum level of independent function. Assure the older patient that cataract surgery can be accomplished safely and comfortably with minimal sedation.

RETINOPATHY

Retinopathy is a process of microvascular damage to the retina. It can develop slowly or rapidly and lead to blurred vision and progressive vision loss. Retinopathy occurs most often in adults with diabetes mellitus or hypertension.

Diabetic retinopathy is a common complication of diabetes mellitus, especially in patients with long-standing uncontrolled diabetes. It is estimated that 40% of patients with diabetes over the age of 40 years have some evidence of retinopathy. (Diabetes is discussed in Chapter 49.) *Nonproliferative retinopathy* is the most common form of diabetic retinopathy and is characterized by capillary microaneurysms, retinal swelling, and hard exudates. Macular edema represents a worsening of the retinopathy as plasma leaks from macular blood vessels. As capillary walls weaken, they can rupture, leading to intraretinal "dot or blot" hemorrhaging (Fig. 22-5). A severe loss in central vision can result. As the disease advances, *proliferative retinopathy* may occur. New blood vessels grow, but they are abnormal, fragile, and predisposed to leak, thus causing severe vision loss. Fluorescein angiography is used to detect retinopathy, which may be treated with laser photocoagulation.[16]

Hypertensive retinopathy is caused by high blood pressure creating blockages in retinal blood vessels. (Hypertension is

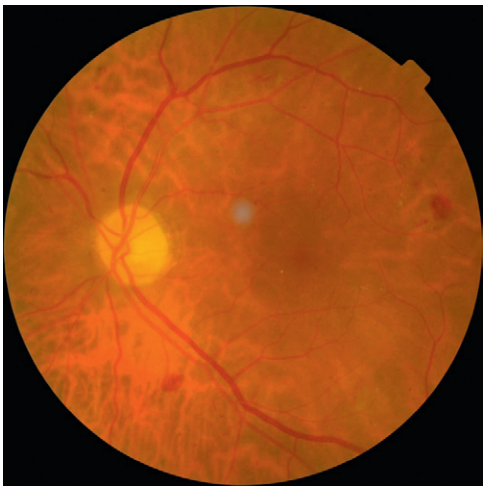

FIG. 22-5 Diabetic retinopathy. Intraretinal dot or blot hemorrhages.

discussed in Chapter 33.) These changes may not initially affect a person's vision. On a routine eye examination, retinal hemorrhages, anoxic cotton-wool spots, and macular swelling can be noted. Sustained, severe hypertension can cause sudden visual loss from swelling of the optic disc and nerve *(papilledema)*. Treatment, which may be an emergency, focuses on lowering the blood pressure. Normal vision is restored in most patients with treatment of the underlying cause of the hypertension.

RETINAL DETACHMENT

A **retinal detachment** is a separation of the sensory retina and the underlying pigment epithelium, with fluid accumulation between the two layers. The incidence of retinal detachment is approximately 1 out of every 15,000 individuals each year. In the patient with no other risk factors who has had a retinal detachment in one eye, the risk of detachment in the second eye is 2% to 25%. Almost all patients with an untreated, symptomatic retinal detachment become blind in the involved eye.

Etiology and Pathophysiology

Retinal detachment has many causes, the most common of which is a retinal break. *Retinal breaks* are an interruption in the full thickness of the retinal tissue, and they can be classified as tears or holes. *Retinal holes* are atrophic retinal breaks that occur spontaneously. *Retinal tears* can occur as the vitreous humor shrinks during aging and pulls on the retina. The retina tears when the traction force exceeds the strength of the retina. Once the retina has a break, liquid vitreous can enter the subretinal space between the sensory layer and the retinal pigment epithelium layer, causing a *rhegmatogenous* retinal detachment. Risk factors for retinal detachment are listed in Table 22-4.

Clinical Manifestations and Diagnostic Studies

Patients with a detaching retina describe symptoms that include *photopsia* (light flashes); floaters; and a "cobweb," "hairnet," or ring in the field of vision. Once the retina has detached, the patient describes a painless loss of peripheral or central vision, "like a curtain" coming across the field of vision. The area of visual loss corresponds to the area of detachment. If the detachment is small or develops slowly, the patient may not be aware of a visual problem. Visual acuity measurements should be the first diagnostic procedure with any complaint of vision loss

TABLE 22-4 RISK FACTORS FOR RETINAL DETACHMENT

- Increasing age
- Severe myopia
- Eye trauma
- Cataract surgery
- Family or personal history of retinal detachment

TABLE 22-5 COLLABORATIVE CARE

Retinal Detachment

Diagnostic
- History and physical examination
- Visual acuity measurement
- Ophthalmoscopy (direct and indirect)
- Slit lamp microscopy
- Ultrasound if cornea, lens, or vitreous is hazy or opaque

Collaborative Therapy

Preoperative
- Mydriatic, cycloplegic agents
- Photocoagulation of retinal break that has not progressed to detachment

Surgery
- Laser photocoagulation
- Cryotherapy (cryopexy)
- Scleral buckling procedure
- Vitrectomy
- Intravitreal bubble

Postoperative
- Topical antibiotic
- Topical corticosteroid
- Analgesia
- Mydriatics
- Positioning and activity as preferred by patient's surgeon

(Table 22-5). The retinal detachment can be directly visualized using direct and indirect ophthalmoscopy or slit lamp microscopy in conjunction with a special lens to view the far periphery of the retina. Ultrasound may be useful in identifying a retinal detachment if the retina cannot be directly visualized (e.g., when the cornea, lens, or vitreous is hazy or opaque).

Collaborative Care

Some retinal breaks are not likely to progress to detachment. In these situations the ophthalmologist simply monitors the patient, giving precise information about the warning signs and symptoms of impending detachment and instructing the patient to seek immediate evaluation if any of those signs or symptoms is recognized. The ophthalmologist usually refers the patient with a detachment to a retinal specialist. Treatment objectives are to seal any retinal breaks and to relieve inward traction on the retina. Several techniques are used to accomplish these objectives.[17]

Surgical Therapy

Laser Photocoagulation and Cryopexy. These techniques seal retinal breaks by creating an inflammatory reaction that causes a chorioretinal adhesion or scar. *Laser photocoagulation* involves using an intense, precisely focused light beam to create an inflammatory reaction. The light is directed at the area of the retinal break. For retinal breaks accompanied by significant detachment, the retinal specialist may use photocoagulation intraoperatively in conjunction with scleral buckling. Tears or holes without accompanying retinal detachment may be treated prophylactically with laser photocoagulation if there is a high risk of progression to a retinal detachment. When used alone, laser therapy is an outpatient procedure that usually requires only topical anesthesia. The patient may experience minimal adverse symptoms during or after the procedure.

Another method used to seal retinal breaks is cryotherapy (also called *cryopexy*). This procedure involves using extreme cold to create the inflammatory reaction that produces the sealing scar. The ophthalmologist applies the cryoprobe instrument to the external globe in the area over the tear. This is usually done on an outpatient basis and using local anesthesia. As with photocoagulation, cryotherapy may be used alone or during scleral buckling surgery. The patient may experience significant discomfort and eye pain after cryotherapy. Encourage the patient to take the prescribed pain medication.

Scleral Buckling. *Scleral buckling* is an extraocular surgical procedure that involves indenting the globe so that the pigment epithelium, the choroid, and the sclera move toward the detached retina. The retinal surgeon sutures a silicone implant against the sclera, causing the sclera to buckle inward. The surgeon may place an encircling band over the implant if there are multiple retinal breaks, if suspected breaks cannot be located, or if there is widespread inward traction on the retina (Fig. 22-6). If present, subretinal fluid may be drained by inserting a small-gauge needle to facilitate contact between the retina and the buckled sclera. Scleral buckling is usually done with the patient under local anesthesia as an outpatient procedure.

Intraocular Procedures. In addition to the extraocular procedures described, retinal surgeons may also use one or more intraocular procedures in treating some retinal detachments. *Pneumatic retinopexy* is the intravitreal injection of a gas to form a temporary bubble in the vitreous that closes retinal breaks and provides apposition of the separated retinal layers.

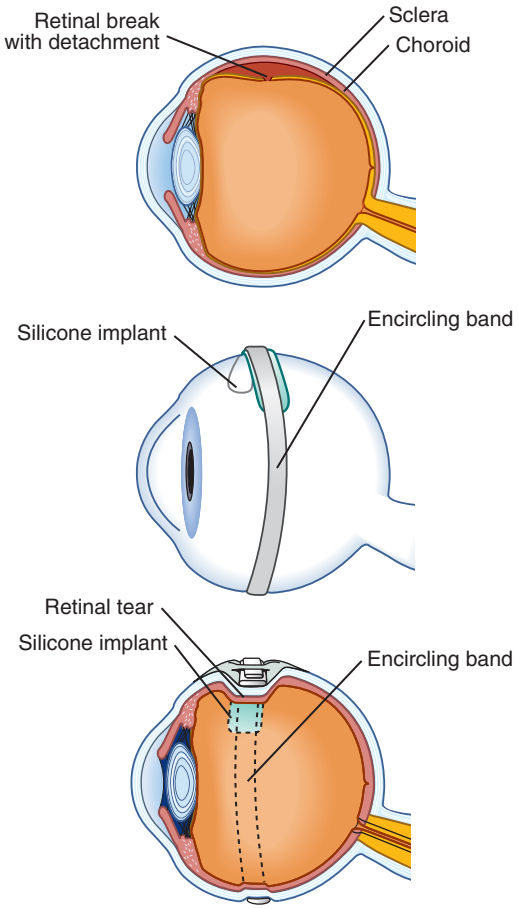

FIG. 22-6 Retinal break with detachment and surgical repair by scleral buckling technique.

Because the intravitreal bubble is temporary, this technique is combined with laser photocoagulation or cryotherapy (also called cryopexy). The patient with an intravitreal bubble must position the head so that the bubble is in contact with the retinal break. The patient may need to maintain this position as much as possible for up to several weeks.

Vitrectomy (surgical removal of the vitreous) may be used to relieve traction on the retina, especially when the traction results from proliferative diabetic retinopathy. Vitrectomy may be combined with scleral buckling to provide a dual effect in relieving traction.

Postoperative Considerations. Reattachment is successful in 90% of retinal detachments.[17] Visual prognosis varies, depending on the extent, length, and area of detachment. Postoperatively, the patient may be on bed rest and may require special positioning to maintain proper position of an intravitreal bubble. The patient may need multiple topical medications, including antibiotics, antiinflammatory agents, or dilating agents. The level of activity restriction after retinal detachment surgery varies greatly. Verify the prescribed level of activity with each patient's surgeon, and help the patient plan for any necessary assistance related to activity restrictions.

In most cases, retinal detachment is an urgent situation, and the patient is confronted suddenly with the need for surgery. The patient needs emotional support, especially during the immediate preoperative period when preparations for surgery can lead to additional anxiety. When the patient experiences postoperative pain, administer prescribed pain medications and teach the patient to take the medication as necessary after discharge. The patient may go home within a few hours of surgery or may remain in the hospital for several days, depending on the surgeon and the type of repair.

Discharge planning and teaching are important and should begin as early as possible because the patient does not remain hospitalized long. Patient and caregiver teaching after eye surgery is discussed in Table 22-5. The patient is at risk for retinal detachment in the other eye. Therefore teach the patient the signs and symptoms of retinal detachment. Also promote the use of proper protective eyewear to help avoid retinal detachments related to trauma.

AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration (AMD) is the most common cause of irreversible central vision loss in people over age 60 in the United States. AMD is divided into two forms: dry (nonexudative) and wet (exudative). People with *dry AMD,* which is the more common form (90% of all cases), often notice that close vision tasks are becoming more difficult. In this form the macular cells start to atrophy, leading to a slowly progressive and painless vision loss.

Wet AMD is the more severe form. Wet AMD accounts for 90% of the cases of AMD-related blindness. Wet AMD has a more rapid onset and is characterized by the development of abnormal blood vessels in or near the macula. Patients with wet AMD had dry AMD first.[18]

Etiology and Pathophysiology

AMD is related to retinal aging. Genetic factors also play a major role, and family history is a major risk factor for AMD. A gene responsible for some cases of AMD has been recently identified.

Long-term exposure to UV light, hyperopia, cigarette smoking, and light-colored eyes may be additional risk factors. Nutritional factors may play a role in the progression of AMD. A dietary supplement of vitamin C, vitamin E, beta-carotene, and zinc decreases the progression of advanced AMD but has no effect on people with minimal AMD or those with no evidence of AMD.[19] Eating lots of dark green, leafy vegetables containing lutein (e.g., kale and spinach) may help reduce the risk of AMD *(www.nei.nih.gov/health/maculardegen/armd_facts.asp)*.

The dry form of AMD starts with the abnormal accumulation of yellowish extracellular deposits called *drusen* in the retinal pigment epithelium. The atrophy and degeneration of macular cells then result. Wet AMD is characterized by the growth of new blood vessels from their normal location in the choroids to an abnormal location in the retinal epithelium. As the new blood vessels leak, scar tissue gradually forms. Acute vision loss may occur in some cases with bleeding from subretinal neovascular membranes.

Clinical Manifestations and Diagnostic Studies

The patient may complain of blurred and darkened vision, *scotomas* (blind spots in the visual field), and *metamorphopsia* (distortion of vision). If patients have only one eye affected, they may not notice early changes in their vision. In addition to visual acuity measurement, the primary diagnostic procedure is ophthalmoscopy. The examiner looks for drusen and other fundus changes associated with AMD. The Amsler grid test may help define the involved area, and it provides a baseline for future comparison. Fundus photography and IV angiography with fluorescein and/or indocyanine green dyes may help to further determine the extent and type of AMD.

Collaborative Care

Vision does not improve for most people with AMD. Limited treatment options for patients with wet AMD include several medications that are injected directly into the vitreous cavity. Ranibizumab (Lucentis), bevacizumab (Avastin), aflibercept (Eylea), and pegaptanib (Macugen) are selective inhibitors of endothelial growth factor, thus helping to slow vision loss in wet AMD. Side effects can include blurred vision, eye irritation, eye pain, and photosensitivity. The injections are given at 4- to 6-week intervals, depending on which drug is used. Retinal stability is determined by ocular coherence tomography (OCT). OCT allows the physician to identify fluid in the central retina that determines the need for continued intravitreal injections.

Photodynamic therapy (PDT) uses verteporfin (Visudyne) IV and a "cold" laser to excite the dye. This procedure is used in wet AMD and destroys the abnormal blood vessels without permanent damage to the retinal pigment epithelium and photoreceptor cells. Verteporfin is a photosensitizing drug that becomes active when exposed to the low-level laser light wave. Until the drug is completely excreted by the body, it can be activated by exposure to sunlight or other high-intensity light such as halogen. Therefore caution patients to avoid direct exposure to sunlight and other intense forms of light for 5 days after treatment. After receiving therapy, patients must be completely covered because any exposure of the skin to sunlight could activate the drug in that area, resulting in a thermal burn.

People at risk for developing advanced AMD should consider supplements of vitamins and minerals (in consultation with their health care provider). The cessation of smoking may also help in halting the progression of dry AMD to a more advanced stage.

Many patients with low-vision assistive devices can continue reading and retain a license to drive during the daytime and at lowered speeds. The permanent loss of central vision has significant psychosocial implications for nursing care. Management of the patient with uncorrectable visual impairment is discussed on p. 388 and is appropriate for the patient with AMD. Avoid giving the impression that "nothing can be done" about the problem when caring for the patient with AMD. Although therapy will not recover lost vision, much can be done to augment the remaining vision.

GLAUCOMA

Glaucoma is a group of disorders characterized by increased IOP and the consequences of elevated pressure, optic nerve atrophy, and peripheral visual field loss. Glaucoma is the second leading cause of permanent blindness in the United States and the leading cause of blindness among African Americans. At least 2 million people have glaucoma, and, of these, more than 50% are unaware of their condition. Another 10 million people have elevated IOP, placing them at increased risk of developing the disease. The incidence of glaucoma increases with age. Blindness from glaucoma is largely preventable with early detection and appropriate treatment. Genetic factors have been identified in some types of glaucoma.[20]

Etiology and Pathophysiology

A proper balance between the rate of aqueous production (referred to as *inflow*) and the rate of aqueous reabsorption (referred to as *outflow*) is essential to maintain the IOP within normal limits. The place where the outflow occurs is called the *angle* because it is the angle where the iris meets the cornea. When the rate of inflow is greater than the rate of outflow, IOP can rise above the normal limits. If IOP remains elevated, permanent vision loss may occur.

Primary open-angle glaucoma (POAG) is the most common type of glaucoma. In POAG the outflow of aqueous humor is decreased in the trabecular meshwork. The drainage channels become clogged, like a clogged kitchen sink. Damage to the optic nerve can then result.

Primary angle-closure glaucoma (PACG) is due to a reduction in the outflow of aqueous humor that results from angle closure. Usually this is caused by the lens bulging forward as a result of the aging process. Angle closure may also occur as a result of pupil dilation in the patient with anatomically narrow angles. An acute attack may be precipitated by situations in which the pupil remains partially dilated long enough to cause an acute and significant rise in the IOP. This may occur because of drug-induced mydriasis, emotional excitement, or darkness. Drug-induced mydriasis may occur not only from topical ophthalmic preparations but also from many systemic medications (both prescription and over-the-counter [OTC] drugs). Check drug records and documentation before administering medications to the patient with angle-closure glaucoma, and instruct the patient not to take any mydriatic medications.

Clinical Manifestations

POAG develops slowly and without symptoms of pain or pressure. The patient usually does not notice the gradual visual field loss until peripheral vision has been severely compromised.

Eventually the patient with untreated glaucoma has "tunnel vision" in which only a small center field can be seen, and all peripheral vision is absent.

Acute angle-closure glaucoma causes definite symptoms, including sudden, excruciating pain in or around the eye. This is often accompanied by nausea and vomiting. Visual symptoms include seeing colored halos around lights, blurred vision, and ocular redness.

Manifestations of subacute or chronic angle-closure glaucoma appear more gradually. The patient who has had a previous, unrecognized episode of subacute angle-closure glaucoma may report a history of blurred vision, seeing colored halos around lights, ocular redness, or eye or brow pain.

Diagnostic Studies

IOP is usually elevated in glaucoma (normal is 10 to 21 mm Hg). In the patient with elevated pressures, the ophthalmologist usually repeats the measurements over time to verify the elevation. In open-angle glaucoma, IOP is usually between 22 and 32 mm Hg. In acute angle-closure glaucoma, IOP may be over 50 mm Hg.

In open-angle glaucoma, slit lamp microscopy reveals a normal angle. In angle-closure glaucoma the examiner may note a markedly narrow or flat anterior chamber angle, an edematous cornea, a fixed and moderately dilated pupil, and ciliary injection (hyperemia of the ciliary blood vessels produces a red color).

Measures of peripheral and central vision provide other diagnostic information. Whereas central acuity may remain 20/20 even in the presence of severe peripheral visual field loss, visual field perimetry may reveal subtle changes in the peripheral retina early in the disease process, long before actual scotomas develop. In acute angle-closure glaucoma, central visual acuity is reduced if the patient has corneal edema, and the visual fields may be markedly decreased. As glaucoma progresses, *optic disc cupping* may be one of the first signs of chronic open-angle glaucoma. The optic disc becomes wider, deeper, and paler (light gray or white), which is visible with direct or indirect ophthalmoscopy (Fig. 22-7).

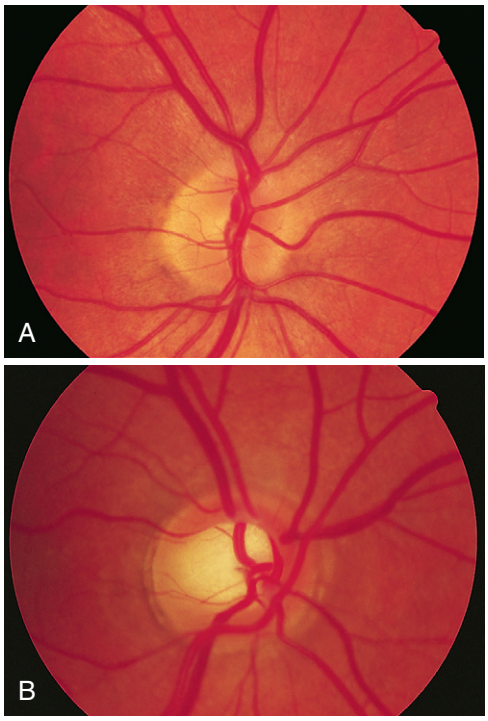

FIG. 22-7 **A,** In the normal eye the optic cup is pink with little cupping. **B,** In glaucoma the optic cup is bleached and optic cupping is present. (Note the appearance of the retinal vessels, which travel over the edge of the optic cup and appear to dip into it.)

Collaborative Care

The primary focus of glaucoma therapy is to keep the IOP low enough to prevent the patient from developing optic nerve damage. Therapy varies with the type of glaucoma. The diagnostic and collaborative care of glaucoma is summarized in Table 22-6.

Chronic Open-Angle Glaucoma

Initial treatment in chronic open-angle glaucoma is with drugs (Table 22-7). The patient must understand that continued treatment and supervision are necessary because the drugs control, but do not cure, glaucoma.

Argon laser trabeculoplasty (ALT) is a noninvasive option to lower IOP when medications are not successful or when the patient either cannot or will not use the drug therapy as recommended. ALT is an outpatient procedure that requires only topical anesthetic. The laser stimulates scarring and contraction of the trabecular meshwork, which opens the outflow channels. ALT reduces IOP approximately 75% of the time. The patient uses topical corticosteroids for 3 to 5 days after the procedure. The most common postoperative complication is an acute rise in IOP. The ophthalmologist examines the patient 1 week and again at 4 to 6 weeks after surgery.

TABLE 22-6 COLLABORATIVE CARE

Glaucoma

Diagnostic
- History and physical examination
- Visual acuity measurement
- Tonometry
- Ophthalmoscopy (direct and indirect)
- Slit lamp microscopy
- Gonioscopy
- Visual field perimetry

Collaborative Therapy

Chronic Open-Angle Glaucoma

Drug Therapy (see Table 22-7)
- β-Adrenergic blockers
- α-Adrenergic agonists
- Cholinergic agents (miotics)
- Carbonic anhydrase inhibitors

Surgical Therapy
- Argon laser trabeculoplasty (ALT)
- Trabeculectomy with or without filtering implant

Acute Angle-Closure Glaucoma
- Topical cholinergic agent
- Hyperosmotic agent
- Laser peripheral iridotomy
- Surgical iridectomy

Filtration surgery, also called a *trabeculectomy,* may be indicated if medical management and laser therapy are not successful. The success rate of this surgery is 75% to 85%.

Acute Angle-Closure Glaucoma. Acute angle-closure glaucoma is an ocular emergency that requires immediate intervention. Miotics (see Table 22-7) and oral or IV hyperosmotic agents, including glycerin liquid (Ophthalgan), isosorbide solution (Ismotic), and mannitol solution (Osmitrol), are usually successful in immediately lowering the IOP. A laser peripheral iridotomy or surgical iridectomy is necessary for long-term treatment and prevention of subsequent episodes. These procedures allow the aqueous humor to flow through a newly created opening in the iris and into normal outflow channels. One of these procedures may also be performed on the other eye as a

TABLE 22-7 DRUG THERAPY

Acute and Chronic Glaucoma

Drug	Action	Side Effects	Nursing Considerations
β-Adrenergic Blockers			
betaxolol (Betoptic)	β_1 Cardioselective blocker. ↓ IOP, ↓ aqueous humor production	Transient discomfort. Systemic reactions rarely reported but include bradycardia, heart block, pulmonary distress, headache, depression	Topical drugs. Minimal effect on pulmonary and cardiovascular parameters. Contraindicated in patient with bradycardia, cardiogenic shock, or overt cardiac failure. Systemic absorption can have additive effect with systemic β_1-blocking agents.
carteolol (Ocupress) levobunolol (Betagan) metipranolol (OptiPranolol) timolol maleate (Timoptic, Istalol)	β_1 and β_2 noncardioselective blockers. ↓ IOP, ↓ aqueous humor production	Transient ocular discomfort, blurred vision, photophobia, bradycardia, decreased BP, bronchospasm, headache, depression	Topical drops. Same as betaxolol. These noncardioselective β_2-blockers are also contraindicated in patients with asthma or COPD.
α-Adrenergic Agonists			
dipivefrin (Propine)	α- and β-adrenergic agonist. Converted to epinephrine inside the eye. ↓ aqueous humor production, enhances outflow facility	Ocular discomfort and redness, tachycardia, hypertension	Topical drops. Contraindicated in patient with narrow-angle glaucoma. Teach punctal occlusion if patient at risk of systemic reactions.
epinephrine (Epifrin, Eppy, Glaucon, Epitrate, Epinal, Eppy/N)	Same as dipivefrin	Same as dipivefrin, but can be more pronounced	Topical drops. Same as dipivefrin.
apraclonidine (Iopidine) brimonidine (Alphagan)	α-Adrenergic agonists. ↓ aqueous humor production	Ocular redness. Irregular heart rate	Topical drops. Used to control or prevent acute postlaser IOP rise (used before and immediately after ALT and iridotomy, Nd:YAG laser capsulotomy). Teach patient at risk of systemic reactions to occlude puncta.
latanoprost (Xalatan) travoprost (Travatan) bimatoprost (Lumigan)	Prostaglandin F analogs	Increased brown iris pigmentation, ocular discomfort and redness, dryness, itching, and foreign body sensation	Topical drops. Teach patient to not exceed 1 drop per evening. Have patient remove contact lens 15 min before instilling.
Cholinergic Agents (Miotics)			
carbachol (Isopto Carbachol)	Parasympathomimetic. Stimulates iris sphincter contraction, causing miosis and opening of trabecular meshwork, facilitating aqueous outflow. Also partially inhibits cholinesterase	Transient ocular discomfort, headache, blurred vision, decreased adaptation to the dark, syncope, salivation, dysrhythmias, vomiting, diarrhea, hypotension	Topical drops. Caution patient about ↓ visual acuity caused by miosis, particularly in dim light.
pilocarpine (Akarpine, Isopto Carpine, Pilocar, Pilopine-HS, Piloptic, Pilostat)	Parasympathomimetic. Stimulates iris sphincter contraction, causing miosis and opening of trabecular meshwork, facilitating aqueous humor outflow	Same as carbachol	Topical drops. Same as carbachol.
Carbonic Anhydrase Inhibitors			
Systemic			
acetazolamide (Diamox) dichlorphenamide (Daranide) methazolamide (Neptazane)	↓ Aqueous humor production	Paresthesias, especially "tingling" in extremities. Hearing dysfunction or tinnitus. Loss of appetite, taste alteration, GI disturbances. Drowsiness, confusion	Oral nonbacteriostatic sulfonamides. Anaphylaxis and other sulfa-type allergic reactions may occur in patient allergic to sulfa. Diuretic effect can ↓ electrolyte levels. Should not be given to patient on high-dose aspirin therapy.
Topical			
brinzolamide (Azopt) dorzolamide (Trusopt)	—	Transient stinging, blurred vision, redness	Same as above.

ALT, Argon laser trabeculoplasty; *IOP,* intraocular pressure.

precaution because many patients often experience an acute attack in the other eye.

DRUG ALERT: Miotics

- Warn patients about decreased visual acuity, especially in dim light.

NURSING MANAGEMENT GLAUCOMA

NURSING ASSESSMENT

Because glaucoma is a chronic condition requiring long-term management, assess the patient's ability to understand and adhere to the rationale and regimen of the prescribed therapy. In addition, assess the patient's psychologic reaction to the diagnosis of a potentially sight-threatening chronic disorder. Include the patient's caregiver in the assessment process because the chronic nature of this disorder affects the family in many ways. Some families may become the primary providers of necessary care, such as eyedrop administration, if the patient is unwilling or unable to accomplish these self-care activities.

NURSING DIAGNOSES

Nursing diagnoses for the patient with glaucoma include, but are not limited to, the following:

- Risk for injury *related to* visual acuity deficits
- Self-care deficits *related to* visual acuity deficits
- Acute pain *related to* pathophysiologic process and surgical correction
- Noncompliance *related to* the inconvenience and side effects of glaucoma medications

PLANNING

The overall goals are that the patient with glaucoma will (1) have no progression of visual impairment, (2) understand the disease process and rationale for therapy, (3) comply with all aspects of therapy (including medication administration and follow-up care), and (4) have no postoperative complications.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Loss of vision as a result of glaucoma is a preventable problem. Teach the patient and the caregiver about the risk of glaucoma and that it increases with age. Stress the importance of early detection and treatment in preventing visual impairment. A comprehensive ophthalmic examination is important in identifying people with glaucoma or those at risk of developing glaucoma. The current recommendation is for an ophthalmologic examination every 2 to 4 years for people between ages 40 and 64 years, and every 1 to 2 years for people age 65 years or older. African Americans in every age category should have examinations more often because of the increased incidence and more aggressive course of glaucoma in these individuals.[21]

ACUTE INTERVENTION. Acute nursing interventions are directed primarily toward the patient with acute angle-closure glaucoma and the surgical patient. The patient with acute angle-closure glaucoma requires immediate medication to lower the IOP. It must be administered in a timely and appropriate manner according to the ophthalmologist's prescription. Most surgical procedures for glaucoma are outpatient procedures. Acutely, the patient needs postoperative instructions and may require nursing measures to relieve discomfort related to the procedure. Patient and caregiver teaching after eye surgery is discussed in Table 22-3.

AMBULATORY AND HOME CARE. Because of the chronic nature of glaucoma, remind the patient to follow the therapeutic regimen and follow-up recommendations prescribed by the ophthalmologist. Provide accurate information about the disease process and treatment options, including the rationale underlying each option. In addition, the patient needs information about the purpose, frequency, and technique for administration of antiglaucoma drugs. Encourage adherence by helping the patient identify the most convenient and appropriate times for medication administration or advocating a change in therapy if the patient reports unacceptable side effects.

EVALUATION

The overall expected outcomes are that the patient with glaucoma will

- Have no further loss of vision
- Adhere to the recommended therapy
- Safely function within own environment
- Obtain relief from pain associated with the disease and surgery

GERONTOLOGIC CONSIDERATIONS

GLAUCOMA

Many older patients with glaucoma have systemic illnesses or take systemic medications that may affect their therapy. In particular, the patient using a β-adrenergic blocking glaucoma agent may experience an additive effect if a systemic β-adrenergic blocking drug is also being taken. All β-adrenergic blocking glaucoma agents are contraindicated in the patient with bradycardia, heart block greater than first-degree heart block, cardiogenic shock, and overt cardiac failure. The noncardioselective β-adrenergic blocking glaucoma agents are also contraindicated in the patient with chronic obstructive pulmonary disease (COPD) or asthma. The hyperosmolar agents may precipitate heart failure or pulmonary edema in the susceptible patient. The older patient on high-dose aspirin therapy for rheumatoid arthritis should not take carbonic anhydrase inhibitors. The α-adrenergic agonists can cause tachycardia or hypertension, which may have serious consequences in the older patient. Teach the older patient to occlude the puncta to limit the systemic absorption of glaucoma medications.

INTRAOCULAR INFLAMMATION AND INFECTION

The term *uveitis* is used to describe inflammation of the uveal tract, retina, vitreous body, or optic nerve. This inflammation may be caused by bacteria, viruses, fungi, or parasites. *Cytomegalovirus retinitis* (CMV retinitis) is an opportunistic infection that occurs in patients with acquired immunodeficiency syndrome (AIDS) and in other immunosuppressed patients. The etiology of sterile intraocular inflammation includes autoimmune disorders, AIDS, malignancies, or those disorders associated with systemic diseases such as inflammatory bowel disease. Pain and photophobia are common symptoms.

Endophthalmitis is an extensive intraocular inflammation of the vitreous cavity. Bacteria, viruses, fungi, or parasites can all induce this serious inflammatory response. The mechanism of infection may be endogenous, in which the infecting agent arrives at the eye through the bloodstream, or exogenous, in which the infecting agent is introduced through a surgical wound or a penetrating injury. Although rare, endophthalmitis

is a devastating complication of intraocular surgery or penetrating ocular injury. It can lead to irreversible blindness within hours or days. Manifestations include ocular pain, photophobia, decreased visual acuity, headaches, reddened and swollen conjunctiva, and corneal edema.

Treatment of intraocular inflammation depends on the underlying cause. Intraocular infections require antimicrobial agents, which may be delivered topically, subconjunctivally, intravitreally, systemically, or in some combination. Sterile inflammatory responses require antiinflammatory medications such as corticosteroids. The patient with intraocular inflammation is usually uncomfortable and may be noticeably anxious and frightened. Provide accurate information and emotional support to the patient and family. In severe cases, enucleation may be necessary. When the patient has lost visual function or even the entire eye, the patient will grieve the loss. Your role includes helping the patient through the grieving process.

OCULAR TUMORS

Benign and malignant tumors can occur in many areas of the eye, including the conjunctiva, retina, and orbit. Malignancies of the eyelid include basal cell and squamous cell carcinomas (see Chapter 24).

Uveal melanoma is a cancerous neoplasm of the iris, choroid, or ciliary body. It is the most common primary intraocular malignancy in adults with an incidence of 2610 new cases diagnosed annually in the United States.[22] It is more frequently found in light-skinned people over age 60 with chronic UV exposure. Genetic factors such as a mutated gene may also increase a person's risk. Uveal melanoma can arise from preexisting nevi in the eye. Tumors may be asymptomatic or associated with vision loss depending on their size and location and presence of hemorrhage and retinal detachment. As with other cancers, cancer stage and cell type are important variables in the patient's prognosis. Diagnostic testing may include ultrasonography, magnetic resonance imaging (MRI), and fine-needle aspiration biopsy. Uveal melanoma commonly appears as a dome-shaped, well-circumscribed, solid brown to golden colored pigment in the iris, choroid, or ciliary body (Fig. 22-8). Many patients do not lose their eye, and some may experience good vision after treatment in the affected eye.

FIG. 22-8 Uveal melanoma. A large tumor in the choroid, the most common location in the eye for melanoma.

Depending on the status of the involved eye, treatment options can include enucleation, plaque radiation therapy (brachytherapy), external beam radiation, transpupillary photocoagulation, eye wall resection, and exenteration. Within 15 years, about 50% of all patients with uveal melanoma will develop metastases, with the liver the most common site.

ENUCLEATION

Enucleation is the removal of the eye. The primary indication for enucleation is a blind, painful eye. This may result from glaucoma, infection, or trauma. Enucleation may also be indicated in ocular malignancies. The surgical procedure includes severing the extraocular muscles close to their insertion on the globe, inserting an implant to maintain the intraorbital anatomy, and suturing the ends of the extraocular muscles over the implant. The conjunctiva covers the joined muscles, and a clear conformer is placed over the conjunctiva until the permanent prosthesis is fitted. A pressure dressing helps prevent postoperative bleeding.

Postoperatively, observe the patient for signs of complications, including excessive bleeding or swelling, increased pain, displacement of the implant, or temperature elevation. Patient teaching should include the instillation of topical ointments or drops and wound cleansing. Instruct the patient in the method of inserting the conformer into the socket in case it falls out. The patient is often devastated by the loss of an eye, even when enucleation occurs after a lengthy period of painful blindness. Recognize and validate the patient's emotional response and provide support to the patient and the family.

Approximately 6 weeks after surgery the wound is sufficiently healed for the permanent prosthesis. The prosthesis is fitted by an ocularist and designed to match the remaining eye. Teach the patient how to remove, cleanse, and insert the prosthesis. Special polishing is required periodically to remove dried protein secretions.

OCULAR MANIFESTATIONS OF SYSTEMIC DISEASES

Many systemic diseases have significant ocular manifestations. Ocular signs and symptoms may be the first finding or complaint in the patient with a systemic disease. One example is the patient with undiagnosed diabetes who seeks ophthalmic care for blurred vision. A careful history and examination of the patient can reveal that the underlying cause of the blurred vision is lens swelling caused by hyperglycemia. Another example is the patient who seeks care for a conjunctival lesion. The ophthalmologist may be the first health care professional to make the diagnosis of AIDS based on the presence of a conjunctival Kaposi sarcoma (KS). eTable 22-1 (available on the website for this chapter) lists some systemic diseases and disorders and the associated ophthalmic manifestations.

AUDITORY PROBLEMS EXTERNAL EAR AND CANAL

TRAUMA

Trauma to the external ear can cause injury to the subcutaneous tissue that may result in a hematoma. If the hematoma is not

aspirated, inflammation of the membranes of the ear cartilage (perichondritis) can result. Blows to the ear can also cause conductive hearing loss if the ossicles in the middle ear are damaged or the tympanic membrane (TM) is perforated. Head trauma that injures the temporal lobe of the cerebral cortex can impair the ability to understand the meaning of sounds.

EXTERNAL OTITIS

The skin of the external ear and canal is subject to the same problems as skin anywhere on the body. **External otitis** involves inflammation or infection of the epithelium of the auricle and ear canal. Swimming may alter the flora of the external canal because of chemicals and contaminated water. This can result in an infection often referred to as "swimmer's ear." Trauma from picking the ear or using sharp objects (e.g., hairpins) frequently causes the initial break in the skin. Piercing of cartilage in the upper part of the auricle also places the patient at higher risk for infection.

Infections and skin conditions may cause external otitis. Bacteria or fungi may be the cause. *Pseudomonas aeruginosa* is the most common bacterial cause. Fungi, including *Candida albicans* and *Aspergillus,* especially thrive in warm, moist climates. The warm, dark environment of the ear canal provides a good growth medium for microorganisms.

Malignant external otitis is a serious infection caused by *P. aeruginosa.* It occurs mainly in older patients with diabetes. The infection, which can spread from the external ear to the parotid gland and temporal bone (osteomyelitis), is usually treated with antibiotics.

Ear pain *(otalgia)* is one of the first signs of external otitis. Even in mild cases, the patient may experience significant discomfort with chewing, moving the auricle, or pressing on the tragus. Swelling of the ear canal can muffle hearing. There may be serosanguineous (blood-tinged fluid) or purulent (white to green thick fluid) drainage. Fever occurs when the infection spreads to surrounding tissue.

NURSING AND COLLABORATIVE MANAGEMENT
EXTERNAL OTITIS

Diagnosis of external otitis is made by otoscopic examination of the ear canal. Care must be taken to avoid pain when pulling on the pinna to straighten out the canal or when inserting the otoscope speculum. The eardrum may be difficult to see due to swelling in the canal. Culture and sensitivity studies of the drainage may be done. Moist heat, mild analgesics, and topical anesthetic drops usually control the pain. Topical treatments may include antibiotics for infection and corticosteroids for inflammation. If the surrounding tissue is involved, systemic antibiotics are prescribed.[23] Improvement should occur in 48 hours, but the patient needs to adhere to the prescribed therapy for 7 to 14 days for complete resolution.

Hands should be washed before and after administration of otic drops (eardrops). The drops should be administered at room temperature. Cold drops can cause vertigo due to stimulation of the semicircular canals, and heated drops can burn the tympanum. The tip of the dropper should not touch the ear during administration to prevent contamination of the entire bottle of drops. The ear is positioned so that the drops can run into the canal. The patient should maintain this position for 2 minutes to allow the drops to spread. Sometimes the drops are placed onto a wick of cotton that is placed in the canal. Instruct the patient not to push the cotton farther into the ear. Careful handling and disposal of material saturated with drainage are important. Instruct the patient on methods to reduce the risk of external otitis (Table 22-8).

TABLE 22-8 PATIENT & CAREGIVER TEACHING GUIDE

Prevention of External Otitis

Include the following instructions when teaching the patient and caregiver.

1. Do not put anything in your ear canal unless requested by your health care provider.
2. Report itching if it becomes a problem.
3. Earwax is normal.
   - It lubricates and protects the canal.
   - Report chronic excessive cerumen if it impairs your hearing.
4. Keep your ears as dry as possible.
   - Use earplugs if you are prone to swimmer's ear.
   - Turn your head to each side for 30 seconds at a time to help water run out of the ears.
   - Do not dry with cotton-tipped applicators.
   - A hair dryer set to low and held at least 6 in from the ear can speed water evaporation.

CERUMEN AND FOREIGN BODIES IN EXTERNAL EAR CANAL

Impacted cerumen (earwax) can cause discomfort and decreased hearing. In the older person the cerumen becomes dense and drier. The hair in the ear becomes thicker and coarser, entrapping the hard, dry cerumen in the canal. Symptoms of cerumen impaction include hearing loss, otalgia, tinnitus, and vertigo.

Management involves irrigation of the canal with body-temperature solutions to soften the cerumen. Special syringes can be used and vary from a simple bulb syringe to special irrigating equipment. Place the patient in a sitting position with an emesis basin under the ear. Pull the auricle up and back, and direct the flow of solution above or below the impaction. It is important that the ear canal not be completely occluded with the syringe tip. If irrigation does not remove the wax, mild lubricant drops may be used to soften the earwax. Severe impactions may need to be removed by the health care provider.

Attempts to remove a foreign object from the ear may result in pushing it farther into the canal. Vegetable matter in the ear tends to swell and may create a secondary inflammation, making removal more difficult. Mineral oil or lidocaine drops can be used to kill an insect before removal with microscope guidance. Removal of impacted objects should be performed by the health care provider.

Ears should be cleaned with a washcloth and finger. Cotton-tipped applicators should be avoided. Penetration of the middle ear by a cotton-tipped applicator can cause serious injury to the TM and ossicles. The use of cotton-tipped applicators can also cause cerumen to become impacted against the TM and impair hearing.

MALIGNANCY OF EXTERNAL EAR

Skin cancers are the only common malignancies of the ear. Rough sandpaper-like changes to the upper border of the auricle

are premalignant lesions (actinic keratoses) associated with chronic sun exposure. They are often removed with liquid nitrogen. Malignancies in the external ear canal include basal cell carcinoma in the pinna and squamous cell carcinoma in the ear canal. If left untreated, they can invade underlying tissue. Teach the patient about the dangers of sun exposure and the importance of using hats and sunscreen when outdoors.

MIDDLE EAR AND MASTOID

OTITIS MEDIA

Acute Otitis Media

Acute otitis media is an infection of the tympanum, ossicles, and space of the middle ear. Swelling of the auditory tube from colds or allergies can trap bacteria, causing a middle ear infection. Pressure from the inflammation pushes on the TM, causing it to become red, bulging, and painful. Acute otitis media is usually a childhood disease because, in children, the auditory tube that normally drains fluid and mucus from the middle ear is shorter and narrower and its position is flatter than in adults. Infection can be due to viruses or bacteria. Pain, fever, malaise, and reduced hearing are signs and symptoms of infection. Referred pain from the temporomandibular joint, teeth, gums, sinuses, or throat may also cause ear pain.

Collaborative care involves the use of antibiotics if an infection is present.[24] Surgical intervention is generally reserved for the patient who does not respond to medical treatment. A *myringotomy* involves an incision in the tympanum to release the increased pressure and exudate from the middle ear. A tympanostomy tube may be placed for short- or long-term use. Prompt treatment of an episode of acute otitis media generally prevents spontaneous perforation of the TM. If allergies are a causative factor, antihistamines may also be prescribed.

Otitis Media With Effusion

Otitis media with effusion is an inflammation of the middle ear with a collection of fluid in the middle ear space. The fluid may be thin, mucoid, or purulent. If the auditory tube does not open and allow equalization of atmospheric pressure, negative pressure within the middle ear pulls fluid from surrounding tissues. This problem commonly follows upper respiratory tract or chronic sinus infections, barotrauma (caused by pressure change), or otitis media.

Complaints include a feeling of fullness of the ear, a "plugged" feeling or popping, and decreased hearing. The patient does not experience pain, fever, or discharge from the ear. It is common to have otitis media with effusion for weeks to months after an episode of acute otitis media. It usually resolves without treatment but may recur.

Chronic Otitis Media and Mastoiditis

Repeated attacks of otitis media may lead to chronic otitis media, especially in adults who have a history of recurrent otitis in childhood. Because the mucous membrane of the middle ear is continuous with the air cells of the mastoid bone, both can be involved in the chronic infectious process.

Chronic otitis media is characterized by a purulent exudate and inflammation that can involve the ossicles, the auditory tube, and the mastoid bone. It is often painless. Hearing loss, nausea, and episodes of dizziness can occur. Hearing loss is a complication from inflammatory destruction of the ossicles, a TM perforation, or accumulation of fluid in the middle ear space. A mass of epithelial cells and cholesterol in the middle ear *(cholesteatoma)* may also develop. The cholesteatoma enlarges and can destroy the adjacent bones. Unless removed surgically, it can cause extensive damage to the ossicles and impair hearing.

Otoscopic examination of the TM may reveal changes in color and mobility or a perforation (Fig. 22-9). Culture and sensitivity tests of the drainage are necessary to identify the organisms involved so that appropriate antibiotic therapy can be prescribed. The audiogram may demonstrate a hearing loss as great as 50 to 60 dB if the ossicles have been damaged or separated. Sinus x-rays, MRI, or a computed tomography (CT) scan of the temporal bone is done to assess for bone destruction and the presence of a mass.

NURSING AND COLLABORATIVE MANAGEMENT CHRONIC OTITIS MEDIA

The aims of treatment are to clear the middle ear of infection, repair any perforations, and preserve hearing (Table 22-9). Otic and systemic (oral and IV) antibiotic therapy is started based on the culture and sensitivity results. In many cases of chronic otitis media, antibiotic resistance is present. The patient may need to undergo frequent evacuation of drainage and debris in an outpatient setting.

Often chronic TM perforations do not heal with conservative treatment, and surgery is necessary. *Tympanoplasty (myringoplasty)* involves reconstruction of the TM and/or the ossicles. A *mastoidectomy* is often performed with a tympanoplasty to

remove infected portions of the mastoid bone. Removal of tissue stops at the middle ear structures that appear capable of conducting sound. Sudden pressure changes in the ear and postoperative infections can disrupt the surgical repair during the healing phase or cause facial nerve paralysis.

Impaired hearing is expected during the postoperative period if there is packing in the ear. A cotton ball dressing is used for the incision made through the external auditory canal (endaural). Instruct the patient to change the cotton packing as needed. If a postauricle (behind the ear) incision is used and a drain is in place, place a dressing over the mastoid area. A small gauze pad is cut to fit behind the ear, and soft dressing material is applied over the ear to prevent the outer circular head dressing from placing pressure on the auricle. Monitor the tightness of the dressing to prevent tissue necrosis and assess the amount and type of drainage. Keep the suture line dry. Postoperative teaching is presented in eTable 22-2, available on the website for this chapter.

OTOSCLEROSIS

Otosclerosis is a hereditary autosomal dominant disease. It is the most common cause of hearing loss in young adults.[25] Spongy bone develops from the bony labyrinth, preventing movement of the footplate of the stapes in the oval window. This reduces the transmission of vibrations to the inner ear fluids and results in conductive hearing loss. Although otosclerosis is typically bilateral, one ear may show faster progression of hearing loss. The patient is often unaware of the problem until the loss becomes so severe that communication is difficult.

Otoscopic examination may reveal a reddish blush of the tympanum (Schwartz's sign) caused by the vascular and bony changes within the middle ear. Tuning fork tests and an audiogram demonstrate good hearing by bone conduction but poor hearing by air conduction (air-bone gap). Usually a difference of at least 20 to 25 dB between air and bone conduction levels of hearing is seen in otosclerosis.

The hearing loss associated with otosclerosis may be stabilized by the oral administration of sodium fluoride with vitamin D and calcium carbonate. These medications retard bone resorption and encourage the calcification of bony lesions. Amplification of sound by a hearing aid can be effective because the inner ear function is normal.

Collaborative care of otosclerosis is shown in Table 22-10. Microdrill or laser surgical treatment involves opening the footplate (stapedotomy) or replacing the stapes with a metal or Teflon substitute (prosthesis). These procedures are usually performed with the patient under conscious sedation. The ear with poorer hearing is repaired first, and the other ear may be operated on within a year. Immediately after surgery the patient often reports a significant improvement in hearing in the operative ear. Because of the accumulation of blood and fluid in the middle ear during the postoperative period, the hearing level decreases initially, but it improves gradually with healing.

Nursing management of the patient undergoing surgery to correct otosclerosis is similar to that for the patient having a tympanoplasty. Use Gelfoam on the incision flap to limit bleeding. Place a cotton ball in the ear canal, and cover the ear with a small dressing. The patient may experience dizziness, nausea, and vomiting as a result of stimulation of the labyrinth during surgery. Some patients demonstrate nystagmus because of disturbance of the perilymph fluid. The patient should take care to avoid sudden movements that may bring on or exacerbate vertigo. Actions that increase inner ear pressure, such as coughing, sneezing, lifting, bending, and straining during bowel movements, should be avoided.

INNER EAR PROBLEMS

Three symptoms that indicate disease of the inner ear are vertigo, sensorineural hearing loss, and tinnitus. Symptoms of vertigo arise from the vestibular labyrinth, whereas hearing loss and tinnitus arise from the auditory labyrinth. There is an overlap between manifestations of inner ear problems and CNS disorders.

MÉNIÈRE'S DISEASE

Ménière's disease (endolymphatic hydrops) is characterized by symptoms caused by inner ear disease, including episodic vertigo, tinnitus, fluctuating sensorineural hearing loss, and aural fullness. The patient experiences significant disability because of sudden, severe attacks of vertigo with nausea, vomiting, sweating, and pallor. Symptoms usually begin between 30 and 60 years of age.

The cause of the disease is unknown, but it results in an excessive accumulation of endolymph in the membranous labyrinth. The volume of endolymph increases until the membranous labyrinth ruptures. Attacks may be preceded by a sense of fullness in the ear, increasing tinnitus, and muffled hearing. The patient may experience the feeling of being pulled to the ground ("drop attacks"). Some patients report that they feel like they are whirling in space. Attacks may last hours or days and may occur several times a year. The clinical course of the disease is highly variable.

NURSING AND COLLABORATIVE MANAGEMENT MÉNIÈRE'S DISEASE

Collaborative care of Ménière's disease (Table 22-11) includes diagnostic tests to rule out other causes of the symptoms, including CNS disease. Results that suggest Ménière's disease include a mild, low-frequency sensorineural hearing loss on audiogram and abnormalities with vestibular tests. A glycerol test may aid in diagnosis. An oral dose of glycerol is given, followed by serial audiograms over 3 hours. Improvement in hearing or speech discrimination supports a diagnosis of Ménière's disease. The improvement is attributed to the osmotic effect of glycerol that pulls fluid from the inner ear.

During the acute attack, antihistamines (e.g., diphenhydramine [Benadryl]), anticholinergics (e.g., atropine), and benzodiazepines (e.g., lorazepam [Ativan]) can be used to decrease

Surgical Therapy
- Endolymphatic sac decompression
- Endolymphatic shunt
- Vestibular nerve section
- Labyrinthectomy

Ambulatory or Home Care
- Diuretics
- Antihistamines
- Calcium channel blockers
- Sedatives
- Hydrops diet: restriction of sodium, caffeine, nicotine, alcohol, and foods with monosodium glutamate (MSG)

the abnormal sensation and lessen nausea and vomiting. Acute vertigo is treated symptomatically with bed rest, sedation, and antiemetics (e.g., prochlorperazine [Compazine]) or antivertigo drugs (e.g., meclizine [Antivert]) for motion sickness. The patient requires reassurance and counseling that the condition is not life threatening. Management between attacks may include diuretics, antihistamines, calcium channel blockers, and a low-sodium diet. Diazepam (Valium), meclizine, and fentanyl with droperidol (Innovar) may be used to reduce the vertigo. Over time, most patients respond to the prescribed medications but must learn to live with the unpredictability of the attacks and the loss of hearing.

Frequent and incapacitating attacks are indications for surgical intervention. Decompression of the endolymphatic sac and shunting are performed to reduce the pressure on the cochlear hair cells and to prevent further damage and hearing loss. If relief is not achieved, vestibular nerve section (cutting the nerve) may be performed. When involvement is unilateral, surgical ablation of the labyrinth, resulting in loss of the vestibular and hearing cochlear function, is performed. Some patients with severe attacks of vertigo have shown improvement with the injection of gentamicin through the TM.[26] This results in inner ear damage and a reduction in endolymph production.

Plan nursing interventions to minimize vertigo and provide for patient safety. During an acute attack keep the patient in a quiet, darkened room in a comfortable position. Teach the patient to avoid sudden head movements or position changes. Fluorescent or flickering lights or a television may exacerbate symptoms and should be avoided. Make an emesis basin available because vomiting is common. To minimize the risk of falling, keep the side rails up and the bed in a low position when the patient is in bed. Instruct the patient to call for assistance when getting out of bed. Medications and fluids are administered parenterally, and intake and output are monitored. When the attack subsides, assist the patient with ambulation because unsteadiness may remain.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

Benign paroxysmal positional vertigo (BPPV) is a common cause of vertigo. Approximately 50% of the cases of vertigo may be due to BPPV. In BBPV, free-floating debris in the semicircular canal causes vertigo with specific head movements, such as getting out of bed, rolling over in bed, and sitting up from lying down. The debris ("ear rocks") is composed of small crystals of calcium carbonate that derive from the utricle in the inner ear. The utricle may be injured by head trauma, infection, or degeneration from the aging process. However, for many patients a cause cannot be found.

Symptoms include nystagmus, vertigo, light-headedness, loss of balance, and nausea. There is no hearing loss, and symptoms tend to be intermittent. The symptoms of BPPV may be confused with those of Ménière's disease. Diagnosis is based on the results of auditory and vestibular tests.

Although BPPV is bothersome, it is rarely serious unless a person falls. The Epley maneuver, or canalith repositioning procedure, is effective in providing symptom relief for many patients.[27] In this maneuver the ear debris is moved from areas in the inner ear that cause symptoms and repositioned into less sensitive areas where they do not cause these problems. The Epley maneuver does not address the actual presence of debris but rather changes their location. A trained health care provider can instruct the patient in how to perform the maneuver.

ACOUSTIC NEUROMA

An **acoustic neuroma** is a unilateral benign tumor that occurs where the vestibulocochlear nerve (cranial nerve [CN] VIII) enters the internal auditory canal. Early diagnosis is important because the tumor can compress the trigeminal and facial nerves and arteries within the internal auditory canal. Symptoms usually begin between 40 and 60 years of age.

Early symptoms are associated with CN VIII compression and destruction. They include unilateral, progressive, sensorineural hearing loss; reduced touch sensation in the posterior ear canal; unilateral tinnitus; and mild, intermittent vertigo. Diagnostic tests include neurologic, audiometric, and vestibular tests; CT scans; and MRI.

Surgery to remove small tumors generally preserves hearing and vestibular function. Large tumors (larger than 3 cm) and the surgery required to remove them can leave the patient with permanent hearing loss and facial paralysis. Stereotactic radiosurgery may slow tumor growth and preserve the facial nerve. Instruct the patient to report any clear, colorless discharge from the nose. This may be cerebrospinal fluid (CSF), which increases the risk of infection. Teach the importance of follow-up care after surgery to monitor hearing and for recurrence of the tumor.

HEARING LOSS AND DEAFNESS

Hearing disorders are a common cause of disability in the United States. Nearly half of the people who need assistance with hearing disorders are 65 years of age or older. With the aging of the population, the incidence of hearing loss is increasing. Causes of hearing loss are shown in Fig. 22-10.

Types of Hearing Loss

Conductive Hearing Loss. *Conductive hearing loss* occurs when conditions in the outer or middle ear impair the transmission of sound through air to the inner ear. A common cause is otitis media with effusion. Other causes are impacted cerumen,

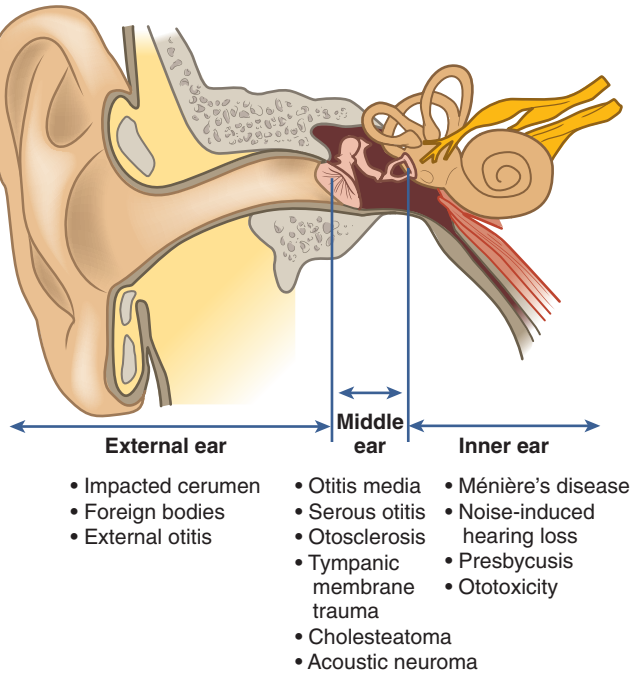

FIG. 22-10 Causes of hearing loss.

perforation of the TM, otosclerosis, and narrowing of the external auditory canal.[28]

The audiogram demonstrates better hearing through bone than through air (air-bone gap).The patient often speaks softly because hearing his or her own voice (which is conducted by bone) seems loud. This patient hears better in a noisy environment. The first step is to identify and treat the cause if possible. If correction of the cause is not possible, a hearing aid may help if the loss is greater than 40 to 50 dB.

Sensorineural Hearing Loss. *Sensorineural hearing loss* is caused by impairment of function of the inner ear or the vestibulocochlear nerve (CN VIII). Congenital and hereditary factors, noise trauma over time, aging (presbycusis), Ménière's disease, and ototoxicity can cause sensorineural hearing loss. Ototoxic drugs include aspirin, nonsteroidal antiinflammatory drugs, antibiotics (aminoglycosides, erythromycin, vancomycin), loop diuretics, and chemotherapy drugs (e.g., vincristine [Oncovin], cisplatin [Platinol]).

Systemic infections, such as Paget's disease of the bone, immune diseases, diabetes mellitus, bacterial meningitis, and trauma, are associated with this type of hearing loss. The main problems are the ability to hear sound but not to understand speech, and the lack of understanding of the problem by others. The ability to hear high-pitched sounds, including consonants, diminishes. Sounds become muffled and difficult to understand. An audiogram demonstrates a loss in decibel levels of the 4000-Hz range and eventually the 2000-Hz range. A hearing aid may help some patients, but it only makes sounds and speech louder, not clearer.

Mixed Hearing Loss. Mixed hearing loss occurs due to a combination of conductive and sensorineural causes. Careful evaluation is needed if corrective surgery for conductive loss is planned because the sensorineural component of the hearing loss will still remain.

Central and Functional Hearing Loss. Central hearing loss involves an inability to interpret sound, including speech, because of a problem in the brain (CNS). A careful history is helpful because there are usually cases of deafness in the family. Refer the patient to a qualified hearing and speech service if indicated.

Functional hearing loss may be caused by an emotional or a psychologic factor. The patient does not seem to hear or respond to pure-tone subjective hearing tests, but no physical reason for hearing loss can be identified. Psychologic counseling may help.

Classification of Hearing Loss. Hearing loss can also be classified by the decibel (dB) level or loss as recorded on the audiogram. Normal hearing is in the 0- to 15-dB range. Table 22-12 describes the levels of hearing loss.

TABLE 22-12 CLASSIFICATION OF HEARING LOSS

Decibel (dB) Loss	Meaning
0-15	Normal hearing
16-25	Slight hearing loss
26-40	Mild impairment
41-55	Moderate impairment
56-70	Moderately severe impairment
71-90	Severe impairment
>90	Profound deafness*

*Most people in this category have been deaf since birth (congenitally deaf).

Clinical Manifestations

Common early signs of hearing loss are answering questions inappropriately, not responding when not looking at the speaker, asking others to speak up, and showing irritability with others who do not speak up. Other behaviors that suggest hearing loss include straining to hear, cupping the hand around the ear, reading lips, and an increased sensitivity to slight increases in noise level. Often the patient is unaware of minimal hearing loss. Family and friends who get tired of repeating or talking loudly are often the first to notice hearing loss. Pressure exerted by significant others is a significant factor in whether the patient seeks help for hearing impairment.

Deafness is often called the "unseen handicap" because the difficulty in communication with a deaf person is not realized until you initiate a conversation with that person. You need to thoroughly validate the deaf person's understanding of health teaching. Descriptive visual aids can be helpful. If the significantly hearing-impaired individual uses sign language to communicate, the Americans with Disabilities Act[29] requires providing an interpreter when significant information is presented such as for patient consent or discharge teaching.

Interference in communication and interaction with others can be the source of many problems for the patient and caregiver. Often the patient refuses to admit or may be unaware of impaired hearing. Irritability is common because the patient must concentrate so hard to understand speech. The loss of clarity of speech in the patient with sensorineural hearing loss is most frustrating. The patient may hear what is said but not understand it. Withdrawal, suspicion, loss of self-esteem, and insecurity are commonly associated with advancing hearing loss.

Tinnitus and Hearing Loss. *Tinnitus* is the perception of *sound* in the ears where no external source is present. It is "ringing in the ears" or "head noise" (see *www.ata.org*). Tinnitus is sometimes the first symptom of hearing loss, especially in older people. It may be soft or loud, high pitched or low pitched.

Tinnitus and hearing loss are directly related. Both are caused by inner ear nerve damage. The main difference between tinnitus and hearing loss is the extent of the damage (since tinnitus can still be heard).

Although the most common cause of tinnitus is noise, it can also be a side effect of medications (see discussion on drugs causing sensorineural hearing loss on p. 407). More than 200 drugs are known to cause tinnitus.

NURSING AND COLLABORATIVE MANAGEMENT HEARING LOSS AND DEAFNESS

HEALTH PROMOTION

ENVIRONMENTAL NOISE CONTROL. Noise is the most preventable cause of hearing loss. (Fig. 22-11 lists the levels of environmental noise generated by common indoor and outdoor sounds.) Sudden severe loud noise (acoustic trauma) and chronic exposure to loud noise (noise-induced hearing loss) can damage hearing. Acoustic trauma causes hearing loss by destroying the hair cells of the organ of Corti. Sensorineural hearing loss as a result of increased and prolonged environmental noise, such as amplified sound, is occurring in young adults at an increasing rate. Amplified music (e.g., on iPods or MP3 players) should not exceed 50% of maximum volume. Ear protection should be worn when firing a gun and during other recreational pursuits with high noise levels. Health teaching regarding avoidance of continued exposure to noise levels greater than 70 dB is essential.

In work environments known to have high noise levels (more than 85 dB), ear protection should be worn. Occupational Safety and Health Administration (OSHA) standards require ear protection for workers in environments where the noise levels consistently exceed 85 dB. Periodic audiometric screening should be part of the health maintenance policies of industry. This provides baseline data on hearing to measure subsequent hearing loss.

Employees should participate in hearing conservation programs in work environments. Such programs should include noise exposure analysis, provision for control of noise exposure (hearing protectors), measurements of hearing, and employee-employer notification and education. Young adults should be encouraged to keep amplified music at a reasonable level and limit their exposure time. Hearing loss caused by noise is not reversible.

IMMUNIZATIONS. Various viruses can cause deafness as a result of fetal damage and malformations affecting the ear. Promote childhood and adult immunizations, including the measles, mumps, and rubella (MMR) vaccine. Rubella infection during the first 8 weeks of pregnancy is associated with an 85% incidence of congenital rubella syndrome, which causes senso-

HEALTHY PEOPLE

Health Impact of Wearing Ear Protection

- Ear protection should be worn during all recreational and work activities involving high noise levels.
- Ear protection can greatly reduce the damage to the ear from loud noise.
- Periodic audiometric screening is important to detect loss before it progresses.

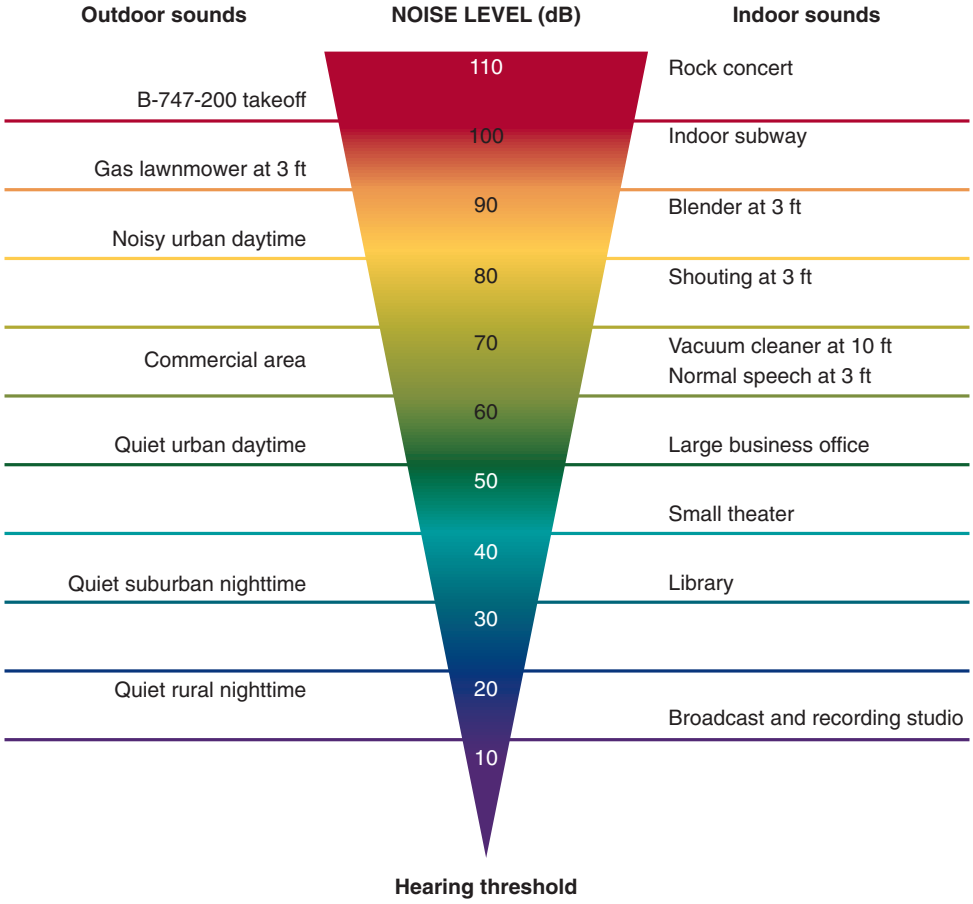

FIG. 22-11 Range of common environmental sounds.

rineural deafness. Women of childbearing age should be tested for antibodies to these viral diseases. Women should avoid pregnancy for at least 3 months after being immunized. Immunization must be delayed if the woman is pregnant. Women who are susceptible to rubella can be vaccinated safely during the postpartum period.

OTOTOXIC SUBSTANCES. Drugs commonly associated with ototoxicity include salicylates, loop diuretics, cancer chemotherapy drugs, and antibiotics.[30] Chemicals used in industry (e.g., toluene, carbon disulfide, mercury) may damage the inner ear. The patient who is receiving ototoxic drugs or is exposed to ototoxic chemicals should be monitored for signs and symptoms associated with ototoxicity, including tinnitus, diminished hearing, and changes in equilibrium. If these symptoms develop, immediate withdrawal of the drug may prevent further damage and may cause the symptoms to disappear.

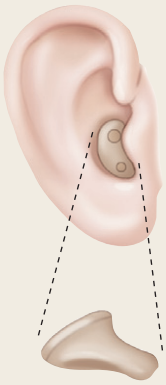
ASSISTIVE DEVICES AND TECHNIQUES

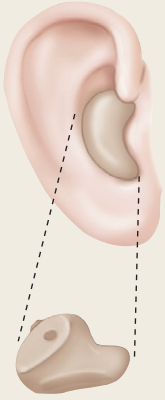
HEARING AIDS. The patient with a suspected hearing loss should have a hearing assessment by a qualified audiologist. If a hearing aid is indicated, it should be fitted by an audiologist or a speech and hearing specialist. Many types of hearing aids are available, each with advantages and disadvantages (Table 22-13). The conventional hearing aid serves as a simple amplifier. For the patient with bilateral hearing impairment, binaural hearing aids provide the best sound lateralization and speech discrimination.

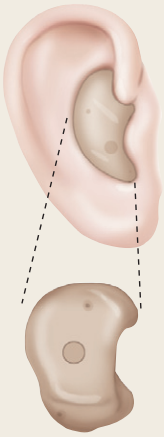
The goal of hearing aid therapy is improved hearing with consistent use. Patients who are motivated and optimistic about using a hearing aid are more successful users. Determine the patient's readiness for hearing aid therapy, including acknowledgment of a hearing problem, the patient's feelings about wearing a hearing aid, the degree to which the hearing loss affects life, and any difficulties the patient has manipulating small objects such as putting a battery in a hearing aid.

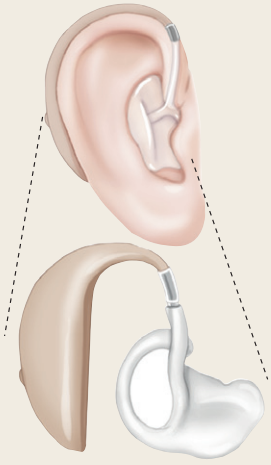
Initially, use of the hearing aid should be restricted to quiet situations in the home. The patient must first adjust to voices (including the patient's own voice) and household sounds. The patient should also experiment by increasing and decreasing the volume as situations require. As the patient adjusts to the increase in sounds and background noise, he or she can progress to situations where several people will be talking simultaneously. Next, the environment can be expanded to the outdoors and then the shopping mall or grocery store. Adjustment to

TABLE 22-13 TYPES OF HEARING AIDS









Type	Advantages	Disadvantages
Completely in the canal (mild to moderate hearing loss) 	Smallest and least visible aid. Protected from sounds such as wind noise.	Costly. No space for add-ons such as directional microphones or volume controls. Small, short-lived batteries.
In the canal (mild to severe hearing loss) 	More powerful than aids completely in the canal. Has adjustable features such as noise reduction.	Small size of aid with its additional features may be difficult to operate for patients with visual loss or arthritis.
In the ear (mild to severe hearing loss) 	Powerful amplification. Inserts and adjusts easily. Longer-lasting batteries.	Visible. May pick up wind noise readily.
Behind the ear (all types of hearing loss) 	Most powerful aid. Adjusts easily. Longest battery life.	Largest, most visible aid. Newer models may be smaller and less obvious.

TABLE 22-14 COMMUNICATION WITH HEARING-IMPAIRED PATIENT

Nonverbal Aids	Verbal Aids
• Draw attention with hand movements. • Have speaker's face in good light. • Avoid covering mouth or face with hands. • Avoid chewing, eating, smoking while talking. • Maintain eye contact. • Avoid distracting environments. • Avoid careless expression that the patient may misinterpret. • Use touch. • Move close to better ear. • Avoid light behind speaker.	• Speak normally and slowly. • Do not overexaggerate facial expressions. • Do not overenunciate. • Use simple sentences. • Rephrase sentence. Use different words. • Write name or difficult words. • Do not shout. • Speak in normal voice directly into better ear.

different environments occurs gradually, depending on the individual patient.

When the hearing aid is not being worn, it should be placed in a dry, cool area where it will not be inadvertently damaged or lost. The battery should be disconnected or removed when not in use. Battery life averages 1 week, and patients should be advised to purchase only a month's supply at a time. Ear molds should be cleaned weekly or as needed. Toothpicks or pipe cleaners may be used to clear a clogged ear tip.

An implanted hearing system (i.e., Esteem) is available to treat moderate to severe sensorineural hearing loss. The system consists of external testing and programming instruments and three implantable components: a sound processor, sensor, and driver. The device does not have external components that are visible. Criteria for placement of the device include a stable bilateral sensorineural hearing loss, a normally functioning eustachian tube, and normal middle ear anatomy.

SPEECH READING. *Speech reading,* commonly called *lip reading,* can be helpful in increasing communication. It allows for approximately 40% understanding of the spoken word. The patient is able to use visual cues associated with speech, such as gestures and facial expression, to help clarify the spoken message. In speech reading, many words look alike to the patient (e.g., rabbit, woman). Help the patient by using and teaching verbal and nonverbal communication techniques as described in Table 22-14.

SIGN LANGUAGE. *Sign language* is used as a form of communication for people with profound hearing impairment. It involves gestures and facial features such as eyebrow motion and lip-mouth movements. Sign language is not universal. American Sign Language (ASL) is used in the United States and the English-speaking parts of Canada.

COCHLEAR IMPLANT. The *cochlear implant* is used as a hearing device for people with severe to profound sensorineural hearing loss in one or both ears. The ideal candidate is one who has become deaf after acquiring speech and language. The system consists of an external microphone placed behind the ear, a speech processor and a transmitter implanted under the skin that change sounds into electrical impulses, and a group of electrodes placed within the cochlea that stimulate the auditory nerves in the ear (Fig. 22-12). Cochlear implants send information that covers the entire range of sound frequencies.[31] The cochlear implant electrodes are inserted as far as possible into the cochlea to send both high- and low-frequency information.

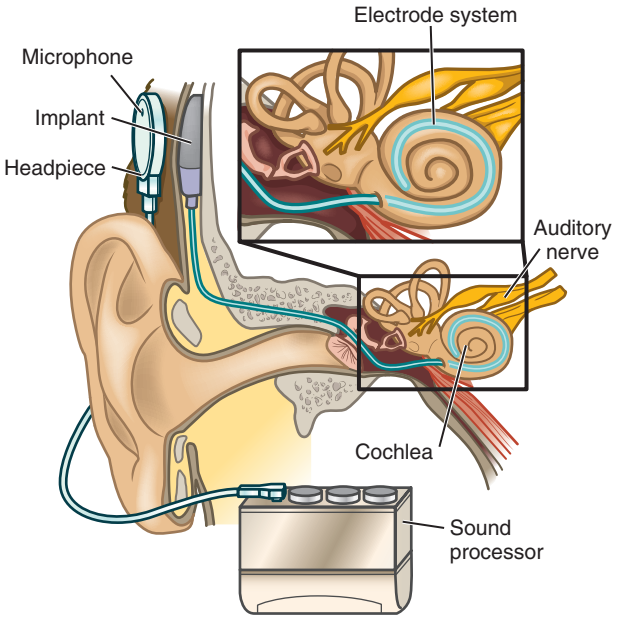


FIG. 22-12 Cochlear implant.

For patients with conductive and mixed hearing loss, the cochlear Baha system may be surgically implanted. The system works through direct bone conduction and integrates with the skull bone over time.

Extensive training and rehabilitation are essential to receive maximum benefit from these implants. The positive aspects of a cochlear implant include providing sound to the person who heard none, improving lip-reading ability, monitoring the loudness of the person's own speech, improving the sense of security, and decreasing feelings of isolation. With continued research, the cochlear implant may offer the possibility of aural rehabilitation for a wider range of hearing-impaired individuals.

The FDA has an information website on cochlear implants.[32] The website includes an animated movie to help visualize the implants and how they work.

ASSISTED LISTENING DEVICES. Numerous devices are now available to assist the hearing-impaired person. Direct amplification devices, amplified telephone receivers, alerting systems that flash when activated by sound, an infrared system for amplifying the sound of the television, and a combination FM receiver and hearing aid are all devices that you can explore based on patient needs. People with profound deafness may be assisted by text-telephone alerting systems that flash when activated by sound, closed captioning on television, and a specially trained dog. The dogs are trained to alert their owners to specific sounds within the environment, thus increasing the person's safety and independence.

GERONTOLOGIC CONSIDERATIONS

HEARING LOSS

Presbycusis, hearing loss associated with aging, includes the loss of peripheral auditory sensitivity, a decline in word recognition ability, and associated psychologic and communication issues. Because consonants (high-frequency sounds) are the letters by which spoken words are recognized, the older person with presbycusis has a diminished ability to understand the spoken word. Vowels are heard, but some consonants fall into the high-frequency range and cannot be differentiated. This

may lead to confusion and embarrassment because of the difference in what was said and what was heard.

The cause of presbycusis is related to degenerative changes in the inner ear. Noise exposure is thought to be a common factor. Table 22-15 describes the classification of specific causes and associated hearing changes of presbycusis. Often a person may have more than one type of presbycusis. The prognosis for hearing depends on the cause of the loss. Sound amplification with the appropriate device is often helpful in improving the understanding of speech. In other situations an audiologic rehabilitation program can be valuable.

The older adult is often reluctant to use a hearing aid for sound amplification.[30] Reasons cited most often include cost, appearance, insufficient knowledge about hearing aids, amplification of competing noise, and unrealistic expectations. Most hearing aids and batteries are small, and neuromuscular changes such as stiff fingers, enlarged joints, and decreased sensory perception often make the care and handling of a hearing aid difficult and frustrating for an older person. Some older adults may also tend to accept their losses as part of getting older and believe there is no need for improvement.

TABLE 22-15 CLASSIFICATION OF PRESBYCUSIS

Type	Hearing Change and Prognosis
Sensory	
Atrophy of auditory nerve. Loss of sensory hair cells	Loss of high-pitched sounds. Little effect on speech understanding. Good response to sound amplification.
Neural	
Degenerative changes in cochlea and spinal ganglion	Loss of speech discrimination. Amplification alone not sufficient.
Metabolic	
Atrophy of blood vessels in wall of cochlea with interruption of essential nutrient supply	Uniform loss for all frequencies accompanied by recruitment.* Good response to hearing aid.
Cochlear	
Stiffening of basilar membrane, which interferes with sound transmission in the cochlea	Hearing loss increases from low to high frequencies. Speech discrimination affected with higher-frequency losses. Helped by appropriate forms of amplification.

*Abnormally rapid increase in loudness as sound intensity increases.

DELEGATION DECISIONS

Corrective Lenses and Hearing Aids

Role of Registered Nurse (RN)
- Assess patient vision and hearing with and without corrective devices.
- Teach patient about the use of and care for corrective lenses and hearing aids.
- Evaluate whether corrective lenses or hearing aids are effective in maintaining or improving vision or hearing.
- Evaluate for problems that may occur with contact lenses (e.g., conjunctivitis) or with hearing aids (e.g., external ear irritation).

Role of Licensed Practical/Vocational Nurse (LPN/LVN)
- Perform Snellen and/or Jaeger testing as delegated by the RN (consider state nurse practice act and agency policy).
- Monitor for adverse effects of contact lenses (e.g., redness, complaints of irritation) and report these to the RN.

Role of Unlicensed Assistive Personnel (UAP)
- Clean corrective lenses with ordered solutions.
- Help patients with hearing aid placement.
- Clean and replace batteries in hearing aids.

CASE STUDY

Glaucoma and Diabetic Retinopathy

Kevin Peterson/ Stockbyte/Thinkstock

Patient Profile

J.K. is a 68-year-old African American woman who has been diagnosed with osteoarthritis and type 2 diabetes mellitus for the past 15 years. She now has diabetic retinopathy. She returns to the eye clinic with her daughter for continued care of primary open-angle glaucoma (POAG) and reexamination for changes in diabetic retinopathy. Her current medical regimen for POAG includes topical timolol maleate 0.5% extended (Timoptic-XE) once daily OU and latanoprost (Xalatan) 0.005% OU hs. At her last examination it was noted that she had microaneurysms and hard exudates of the retina.

Subjective Data
- She can no longer read the newspaper and reports that medication labels are difficult to read.
- States she is not always successful in getting the eyedrops instilled because her hands are gnarled and painful from osteoarthritis.

Objective Data
- Distant and near visual acuity are stable at 20/60 (OD) and 20/50 (OS). This is a reduction from 20/40 (OU) at her last visit.
- Intraocular pressures are stable at 20 mm Hg (OU). There is a new scotoma on visual field testing in the OS.
- Fluorescein angiography reveals diabetic macular edema OU.

Collaborative Care
- Brimonidine (Alphagan) 0.15% (OS) 15 min before and immediately after argon laser trabeculoplasty (ALT)
- Argon laser (OU) to seal leaking microaneurysms from macular edema
- Check intraocular pressure (IOP) 1 hr after ALT
- Continue previous glaucoma drop regimen
- Follow-up examination for glaucoma in 2 wk for possible ALT (OD)
- Follow-up examination for diabetic macular edema in 8 wk

Discussion Questions
1. Explain the etiology of the new scotoma.
2. Why might ALT be an appropriate therapy for J.K.?
3. What is the purpose of the eyedrops before and immediately after ALT?
4. ***Priority Decision:*** What are the priority topics that should be discussed in discharge teaching with J.K.?
5. What is the etiology of the vision loss from diabetic retinopathy?
6. ***Priority Decision:*** What are the priority nursing interventions for J.K.?
7. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Evidence-Based Practice:*** J.K. wants to know if her glaucoma is related to her diabetes. How would you respond to her question?

evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Presbyopia occurs in older individuals because
   - **a.** the eyeball elongates.
   - **b.** the lens becomes inflexible.
   - **c.** the corneal curvature becomes irregular.
   - **d.** light rays are focusing in front of the retina.
2. The most important intervention for the patient with epidemic keratoconjunctivitis is
   - **a.** cleansing the affected area with baby shampoo.
   - **b.** monitoring spread of infection to the opposing eye.
   - **c.** regular instillation of artificial tears to the affected eye.
   - **d.** teaching the patient and family members good hygiene techniques.
3. Inflammation and infection of the eye
   - **a.** are caused by irritants and microorganisms.
   - **b.** have a higher incidence in sexually active patients.
   - **c.** are chronic problems that result in a loss of vision.
   - **d.** are frequently treated with cold compresses and antibiotics.
4. Which patient behaviors would the nurse promote for healthy eyes and ears *(select all that apply)*?
   - **a.** Wearing protective sunglasses when bicycling
   - **b.** Supplemental intake of B vitamins and magnesium
   - **c.** Playing amplified music at 75% of maximum volume
   - **d.** Patient notifying the health care provider of tinnitus while on antibiotics
   - **e.** A woman avoiding pregnancy for 4 weeks after receiving measles, mumps, rubella (MMR) immunization
5. What should be included in the postoperative teaching of the patient who has undergone cataract surgery *(select all that apply)*?
   - **a.** Eye discomfort is often relieved with mild analgesics.
   - **b.** A decline in visual acuity is common for the first week.
   - **c.** Stay on bed rest and limit activity for the first few days.
   - **d.** Notify surgeon if an increase in redness or drainage occurs.
   - **e.** Nighttime eye shielding and activity restrictions are essential to prevent eyestrain.
6. What should be included in the nursing plan for a patient who needs to administer antibiotic eardrops?
   - **a.** Cool the drops so that they decrease swelling in the canal.
   - **b.** Avoid placing a cotton wick to assist in administering the drops.
   - **c.** Be careful to avoid touching the tip of the dropper bottle to the ear.
   - **d.** Keep the head tilted 5 to 7 minutes after administration of the drops.
7. What is important for the nurse to include in the postoperative care of the patient following tympanoplasty?
   - **a.** Check the gag reflex.
   - **b.** Encourage independence.
   - **c.** Avoid changing the cotton padding.
   - **d.** Instruct patient to refrain from forceful nose blowing.
8. The patient who has a conductive hearing loss
   - **a.** hears better in a noisy environment.
   - **b.** hears sound but does not understand speech.
   - **c.** often speaks loudly because his or her own voice seems low.
   - **d.** experiences clearer sound with a hearing aid if the loss is less than 30 dB.
9. Instruct the patient who is newly fitted with bilateral hearing aids to *(select all that apply)*
   - **a.** replace the batteries monthly.
   - **b.** clean the ear molds weekly or as needed.
   - **c.** clean ears with cotton-tipped applicators daily.
   - **d.** disconnect or remove the batteries when not in use.
   - **e.** initially restrict usage to quiet listening in the home.
10. Which strategies would best assist the nurse in communicating with a patient who has a hearing loss *(select all that apply)*?
    - **a.** Overenunciate speech.
    - **b.** Speak normally and slowly.
    - **c.** Exaggerate facial expressions.
    - **d.** Raise the voice to a higher pitch.
    - **e.** Write out names or difficult words.
11. Patients with permanent visual impairment
    - **a.** feel most comfortable with other visually impaired people.
    - **b.** may feel threatened when others make eye contact during a conversation.
    - **c.** usually need others to speak louder so they can communicate appropriately.
    - **d.** may experience the same grieving process that is associated with other losses.

1. b, 2. d, 3. a, 4. a, d, 5. a, d, 6. c, 7. d, 8. a, 9. b, d, e, 10. b, e, 11. d

LEARNING OUTCOMES

1. Describe the structures and functions of the integumentary system.
2. Link the age-related changes in the integumentary system to differences in assessment findings.
3. Select the significant subjective and objective data related to the integumentary system that should be obtained from a patient.
4. Describe specific assessments to be made during the physical examination of the skin and the appendages.
5. Compare and contrast the critical components for describing primary and secondary lesions.
6. Select appropriate techniques to use in the physical assessment of the integumentary system.
7. Specify the structural and assessment differences in light- and dark-skinned individuals.
8. Differentiate normal from common abnormal findings of a physical assessment of the integumentary system.
9. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the integumentary system.

pruritus, p. 419
sebaceous glands, p. 416

The integumentary system is the largest body organ and is composed of the skin, hair, nails, and glands. The skin is further divided into two layers: the epidermis and the dermis. The subcutaneous tissue is immediately under the dermis (Fig. 23-1).

STRUCTURES AND FUNCTIONS OF SKIN AND APPENDAGES

Structures

The epidermis is the outermost layer of the skin. The dermis, the second skin layer, contains collagen bundles and supports the nerve and vascular network. The subcutaneous layer is composed primarily of fat and loose connective tissue.

Epidermis. The **epidermis,** the thin avascular superficial layer of the skin, is made up of an outer dead cornified portion that serves as a protective barrier and a deeper, living portion that folds into the dermis. Together these layers measure 0.05 to 0.1 mm in thickness. The epidermis is nourished by blood vessels in the dermis. The epidermis regenerates with new cells every 28 days. The two major types of epidermal cells are melanocytes (5%) and keratinocytes (90%).

Melanocytes are contained in the deep, basal layer (stratum germinativum) of the epidermis. They contain melanin, a pigment that gives color to the skin and hair and protects the body from damaging ultraviolet (UV) sunlight. Sunlight and hormones stimulate the melanosome (within the melanocyte) to increase the production of melanin.[1] The wide range of skin

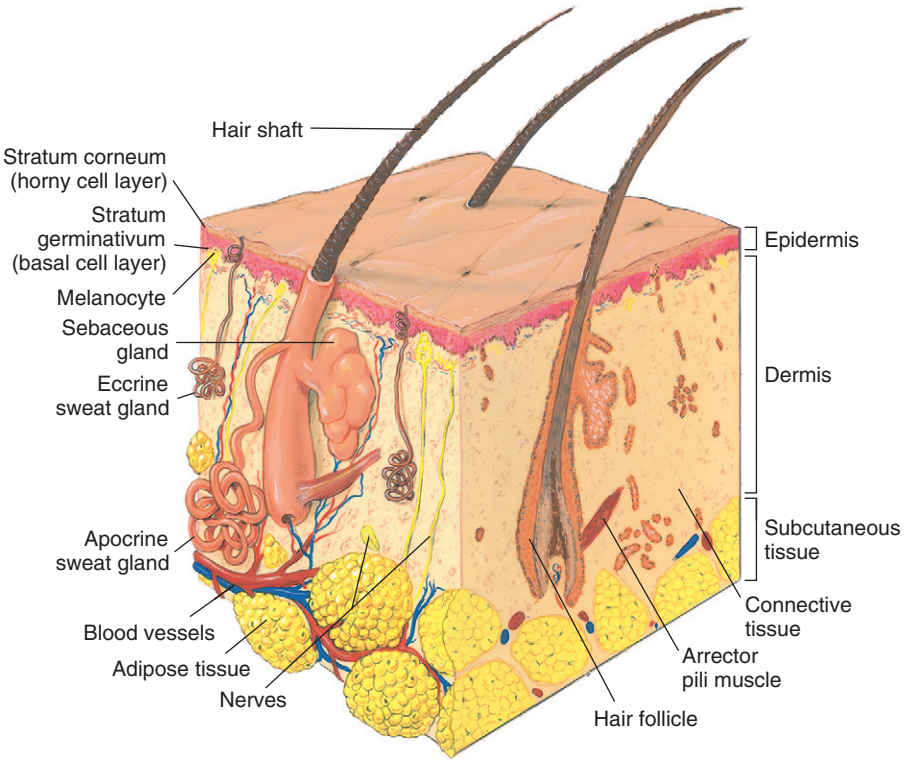

FIG. 23-1 Microscopic view of the skin in longitudinal section. From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.

color is caused by the amount of melanin produced; more melanin results in darker skin color.[2]

Keratinocytes are synthesized from epidermal cells in the basal layer. Initially these cells are undifferentiated. As they mature (keratinize), they move to the surface, where they flatten and die to form the outer skin layer (stratum corneum). Keratinocytes produce a fibrous protein, keratin, which is vital to the skin's protective barrier function. The upward movement of keratinocytes from the basement membrane to the stratum corneum takes approximately 4 weeks. If dead cells slough off too rapidly, the skin will appear thin and eroded. If new cells form faster than old cells are shed, the skin becomes scaly and thickened. Changes in this cell cycle are reflected in many skin problems, such as psoriasis.

Dermis. The **dermis** is the connective tissue below the epidermis. Dermal thickness varies from 1 to 4 mm. The dermis is very vascular.

The dermis is divided into two layers, an upper thin papillary layer and a deeper, thicker reticular layer. The papillary layer is folded into ridges, or papillae, which extend into the upper epidermal layer. These exposed surface ridges form congenital patterns called fingerprints and footprints. The reticular layer contains collagen and elastic and reticular fibers.

Collagen forms the greatest part of the dermis and is responsible for the skin's mechanical strength. The primary cell type in the dermis is the *fibroblast.* Fibroblasts produce collagen and elastin fibers and are important in wound healing. Nerves, lymphatic vessels, hair follicles, and sebaceous glands are also found in the dermis.

Subcutaneous Tissue. The subcutaneous tissue lies below the dermis and is not part of the skin. The subcutaneous tissue is often discussed with the skin because it attaches the skin to underlying tissues such as muscle and bone. The subcutaneous tissue contains loose connective tissue and fat cells that provide insulation. The anatomic distribution of subcutaneous tissue varies according to gender, heredity, age, and nutritional status. This layer also stores lipids, regulates temperature, and provides shock absorption.

Skin Appendages. Appendages of the skin include the hair, nails, and glands (sebaceous, apocrine, and eccrine). These structures develop from the epidermal layer and receive nutrients, electrolytes, and fluids from the dermis. Hair and nails form from specialized keratin that becomes hardened.

Hair grows on most of the body except for the lips, the palms of the hands, and the soles of the feet.[3] The color of the hair is a result of heredity and is determined by the type and amount of melanin in the hair shaft. Hair grows approximately 1 cm per month. On average 100 hairs are lost each day. The rate of growth is not affected by cutting.[2] When lost hair is not replaced, baldness results. The absence of hair may be related to disease, treatment, or heredity.

Nails grow from the matrix. The nail matrix is located at the proximal area of the nail plate. The matrix is commonly called the *lunula,* which is the white crescent-shaped area visible through the nail plate (Fig. 23-2). The nail bed that is under the nail matrix and nail plate is normally pink and contains blood vessels. The nail plate adheres to and is supported by the nail bed. The cuticle is part of the skin that extends a small distance on the nail plate before being shed (like the stratum corneum). The nail root is bordered by the cuticle and hidden by a fold of skin. Fingernails grow at a rate of 0.7 to 0.84 mm per week, with toenail growth 30% to 50% slower. Nails can be injured by direct trauma. A lost fingernail usually regenerates in 3 to 6 months, whereas a lost toenail may require 12 months or longer for

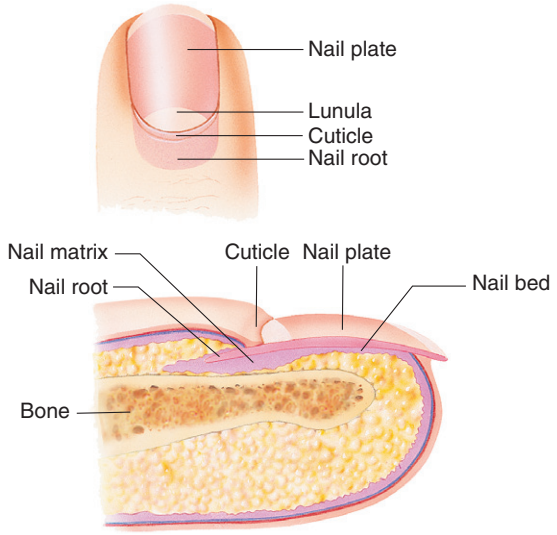

FIG. 23-2 Structure of a nail.

FIG. 23-3 Pigmented nail bed normally seen with dark skin color.

regeneration. Nail growth may vary according to the person's age and health. Nail color ranges from pink to yellow or brown depending on skin color. Pigmented longitudinal bands (melanonychia striata) may commonly occur in the nail bed in approximately 90% or more of all people with dark skin (Fig. 23-3).

Two major types of glands are associated with the skin: sebaceous and sweat (apocrine and eccrine) glands. The **sebaceous glands** secrete *sebum,* which is emptied into the hair follicles. Sebum prevents the skin and hair from becoming dry. Sebum is somewhat bacteriostatic and fungistatic and consists mainly of lipids. These glands depend on sex hormones, particularly testosterone, to regulate sebum secretion and production. Sebum secretion varies across the life span according to sex hormone levels. Sebaceous glands are present on all areas of the skin except the palms and the soles. These glands are most abundant on the face, scalp, upper chest, and back.

The *apocrine sweat glands* are located in the axillae, breast areolae, umbilical and anogenital areas, external auditory canals, and eyelids. They secrete a thick milky substance of unknown composition that becomes odoriferous when altered by skin surface bacteria. These glands enlarge and become active at puberty because of reproductive hormones.

The *eccrine sweat glands* are widely distributed over the body, except in a few areas, such as the lips. One square inch of skin contains about 3000 of these sweat glands. Sweat is a transparent watery solution composed of salts, ammonia, urea, and other wastes. The main function of these glands is to cool the body by evaporation, excrete waste products through the pores of the skin, and moisturize surface cells.

Functions of Integumentary System

The skin's primary function is to protect the underlying tissues of the body by serving as a surface barrier to the external environment. The skin also acts as a barrier against invasion by bacteria and viruses, and it prevents excessive water loss. The fat of the subcutaneous layer insulates the body and provides protection from trauma.

The skin with its nerve endings and special receptors provides sensory perception for environmental stimuli. These highly specialized nerve endings supply information to the brain related to pain, heat and cold, touch, pressure, and vibration.

The skin controls heat regulation by responding to changes in internal and external temperature with vasoconstriction or vasodilation. Heat regulation is related to the skin's function of excretion. Between 600 and 900 mL of water is lost daily through insensible perspiration. This function of the skin helps maintain homeostasis through fluid and electrolyte balance. In addition, sebum and sweat are secreted by the skin and lubricate the skin surface. Endogenous synthesis of vitamin D, which is critical to calcium and phosphorus balance, occurs in the epidermis. Vitamin D is synthesized by the action of UV light on vitamin D precursors in epidermal cells.

The esthetic functions of the skin include the expression of various emotions, such as anger or embarrassment, and the person's individual appearance. The skin is also used as a system for the delivery of drugs. An increasing number of systemic drugs are effectively delivered via patches or creams applied directly to the skin.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON INTEGUMENTARY SYSTEM

Many skin changes are associated with aging. Although many changes are not serious except for their cosmetic value, others are more serious and need careful evaluation. Age-related changes of the integumentary system and differences in assessment findings are listed in Table 23-1.

The rate of age-related skin changes is influenced by heredity, a personal history of sun exposure, hygiene practices, nutrition, and general state of health. Skin changes that are related to aging include decreased turgor, thinning, dryness, wrinkling, vascular lesions, increased skin fragility, and benign neoplasms.

The junction between the dermis and the epidermis becomes flattened and the epidermis contains fewer melanocytes, which decreases the production of melanin, resulting in gray or white hair. In addition, the dermis loses volume and has fewer blood vessels. Scalp, pubic, and axillary hair becomes depigmented and thinner. The nail plate thins, and nails become brittle and more prone to splitting and yellowing. Nails, especially the toenails, may also thicken with age.

Chronic UV exposure is the major contributor to the photoaging and wrinkling of skin.[4] Sun damage to the skin is cumulative (Fig. 23-4). The wrinkling of sun-exposed areas such as the face and hands is more marked than that of a sun-shielded area such as the buttocks. Poor nutrition, with decreased intake

TABLE 23-1 GERONTOLOGIC ASSESSMENT DIFFERENCES

Integumentary System

Changes	Differences in Assessment Findings
Skin	
Decreased subcutaneous fat, muscle laxity, degeneration of elastic fibers, collagen stiffening	Increased wrinkling, sagging breasts and abdomen, redundant flesh around eyes, slowness of skin to flatten when pinched (tenting).
Decreased extracellular water, surface lipids, and sebaceous gland activity	Dry, flaking skin with possible signs of excoriation caused by scratching.
Decreased activity of apocrine and sebaceous glands	Dry skin with minimal to no perspiration, skin color uneven.
Increased capillary fragility and permeability	Bruising.
Increased focal melanocytes in basal layer with pigment accumulation	Solar lentigines on face and back of hands.
Diminished blood supply	Decrease in rosy appearance of skin and mucous membranes. Skin cool to touch. Diminished awareness of pain, touch, temperature, peripheral vibration.
Decreased proliferative capacity	Diminished rate of wound healing.
Decreased immunocompetence	Increase in neoplasms.
Hair	
Decreased melanin and melanocytes	Gray or white hair.
Decreased oil	Dry, coarse hair. Scaly scalp.
Decreased density of hair	Thinning and loss of hair. Loss of hair in outer half or outer third of eyebrow and back of legs.
Cumulative androgen effect; decreasing estrogen levels	Facial hirsutism, baldness.
Nails	
Decreased peripheral blood supply	Thick, brittle nails with diminished growth.
Increased keratin	Longitudinal ridging.
Decreased circulation	Prolonged return of blood to nails on blanching.

of protein, calories, and vitamins, also contributes to aging of the skin. With aging, collagen fibers stiffen, elastic fibers degenerate, and the amount of subcutaneous tissue decreases. These changes, with the added effects of gravity, lead to wrinkling.

Benign neoplasms related to the aging process can occur on the skin. These growths include seborrheic keratoses, vascular lesions such as cherry angiomas, and skin tags. *Actinic keratoses* appear on areas of chronic sun exposure, especially in the person who has a fair complexion and light eyes (blue, green, or hazel). These premalignant cutaneous lesions place an individual at increased risk for squamous cell and basal cell carcinomas. The photoaged person is more susceptible to skin cancers because UV exposure decreases the capacity to repair cellular damage (especially deoxyribonucleic acid [DNA]). Chronic UV exposure from tanning beds causes the same damage as UV from the sun.

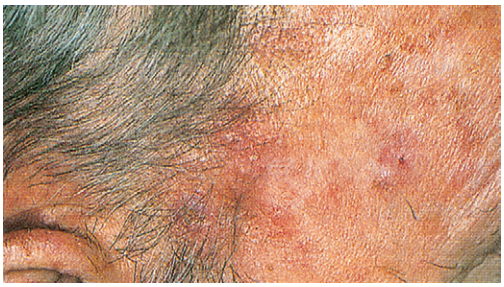

FIG. 23-4 Photoaging. Irregular pigmentation and keratoses occur on sun-damaged skin on forehead.

TABLE 23-2 NORMAL PHYSICAL ASSESSMENT OF INTEGUMENTARY SYSTEM

Skin	• Evenly pigmented; no petechiae, purpura, lesions, or excoriations. • Warm, good turgor.
Nails	• Pink, oval, adhere to nail bed with 160-degree angle.
Hair	• Shiny and full; amount and distribution appropriate for age and gender. • No flaking of scalp, forehead, or pinna.

In older adults decreased subcutaneous fat leads to an increased risk of traumatic injury, hypothermia, and skin shearing, which may lead to pressure ulcers. With aging, the apocrine and eccrine sweat glands atrophy, causing dry skin and decreased body odor. The growth rate of the hair and nails decreases as a result of atrophy of the involved structures. Hormonal and vitamin deficiencies can cause dry, thin hair and alopecia (partial or complete lack of hair).

The visible effects of aging on the skin and hair may have a profound psychologic effect. A youthful look may be tied to a person's self-image. Although fine wrinkling of the skin, thinning hair, and brittle nails are normal changes with aging, they may result in an altered self-image.[5]

ASSESSMENT OF INTEGUMENTARY SYSTEM

A general assessment of the skin begins at the initial contact with the patient and continues throughout the examination. Specific areas of the skin are assessed during the examination of other body systems unless the chief complaint is a dermatologic problem. Record a general statement about the skin's physical condition (Table 23-2). In addition, ask the health history questions presented in Table 23-3 when a skin problem is noted.

Subjective Data

Individuals with skin problems may have complaints that are not readily observed. A thorough health history yields information about possible causes and the effect of the problem on the individual's life.

Important Health Information

Past Health History. Past health history indicates previous trauma, surgery, or disease that involves the skin. Determine if the patient has noticed any dermatologic manifestations of systemic problems such as jaundice (liver disease), delayed wound

CASE STUDY

Patient Introduction

iStockphoto/Thinkstock

D.A. is a 74-year-old woman who comes to the medical clinic with concerns related to various "spots" on her face. She says they have been there for a while and she thought they were just "age spots" but got concerned after her friend was diagnosed with a malignant melanoma.

Critical Thinking

As you read through this assessment chapter, think about D.A. with the following questions in mind:

1. What are the possible causes of D.A.'s facial lesions?
2. What questions would you ask D.A. to determine the possible causes?
3. What should be included in the physical assessment? What specific characteristics of the skin lesions would you be looking for?
4. What diagnostic studies might you expect to be ordered?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

healing (diabetes mellitus), cyanosis (respiratory disorder), or pallor (anemia). eTable 24-1 lists diseases with dermatologic manifestations. Obtain specific information related to food sensitivities, pet or drug allergies, and skin reactions to insect bites and stings. Note any history of chronic or unprotected exposure to UV light, including tanning bed use and radiation treatments.

Medications. Ask the patient about skin-related problems that occurred as a result of taking prescription or over-the-counter (OTC) medications. A thorough medication history is important, especially in relation to vitamins, hormones, antibiotics, corticosteroids, and antimetabolites because these may cause side effects that are manifested in the skin.

Document the use of prescription or OTC medications used specifically to treat a primary skin problem such as acne or a secondary skin problem such as itching. If a medication is used, record the name, length of use, method of application, and effectiveness.

Surgery or Other Treatments. Determine if any surgical procedures, including cosmetic surgery, were performed on the skin. If a biopsy was done, record the result. Note any treatments specific for a skin problem (e.g., phototherapy) or for a health problem (e.g., radiation therapy). In addition, document any treatments undergone primarily for cosmetic purposes, such as tanning booth use, laser resurfacing, or cosmetic "peels."

Functional Health Patterns

Health Perception–Health Management Pattern. Question the patient about health practices related to the integumentary system, such as self-care habits related to daily hygiene. Document the frequency of use and sun protection factor (SPF) of sunscreen products. Assess the use of personal care products (e.g., shampoos, moisturizing agents, cosmetics), including brand name, quantity, and frequency. Record a description of any current skin problem, including onset, symptoms, course, and treatment. Note any medications used for treating hair loss.

GENETIC RISK ALERT

- The primary risk factor leading to skin cancer and melanoma is environmental exposure to UV radiation. UV radiation damages DNA, causing an error in the genetic code and resulting in abnormal skin cells.
- Inherited genetic factors can also increase the risk for skin cancer. A person has an increased risk for developing melanoma if he or she has a first-degree relative (e.g., parent, full sibling) who had a melanoma.
- The risk for skin cancer is increased for people who have a fair complexion (light-colored skin that easily freckles, red or blond hair, and blue or light-colored eyes).

Obtain information about the family history of any skin diseases, including congenital and familial diseases (e.g., alopecia, psoriasis) and systemic diseases with dermatologic

TABLE 23-3 HEALTH HISTORY

Integumentary System

Health Perception–Health Management
- Describe your daily hygiene practices.
- What skin products are you currently using?
- Describe any current skin condition, including onset, course, and treatment (if any).

Nutritional-Metabolic
- Describe any changes in the condition of your skin, hair, nails, and mucous membranes.
- Have you noticed any recent changes in the way sores or wounds heal?*
- Have you had any weight loss or dietary changes, including supplemental vitamins and minerals?*

Elimination
- Have you noticed recent changes in your skin related to excessive sweating, dryness, or swelling?*

Activity-Exercise
- Do your leisure or work activities involve the use of any chemicals that are irritating to your skin?*
- Do you do anything to protect yourself from the sun?*

Sleep-Rest
- Does your skin condition keep you awake or awaken you after you have fallen asleep?*

Cognitive-Perceptual
- Do you have any unusual sensations of heat, cold, or touch?*
- Do you have any pain associated with your skin condition?*
- Do you have any joint pain?*

Self-Perception–Self-Concept
- How does your skin condition make you feel about yourself?

Role-Relationship
- Has your skin condition changed your relationships with others?*
- Have you changed your lifestyle because of your skin condition?*

Sexuality-Reproductive
- Has your skin condition changed your intimate relationships with others?*
- Has your birth control method (if used) caused a skin problem?*

Coping–Stress Tolerance
- Are you aware of any situation or stressor that changes your skin condition?*
- Do you think that stress plays a role in your skin condition?*
- How do you handle stress?

Value-Belief
- Are there any cultural beliefs that influence your thinking or feelings about your skin condition?*
- Are there any treatment options that you would be opposed to using?

*If yes, describe.

manifestations (e.g., diabetes, thyroid disease, cardiovascular diseases, immune disorders). In addition, note any family and personal history of skin cancer, particularly melanoma.

Nutritional-Metabolic Pattern. Question the patient about any changes in the condition of skin, hair, nails, and mucous membranes and whether they are related to dietary changes. A diet history reveals the adequacy of nutrients essential to healthy skin such as vitamins A, D, E, and C; dietary fat; and protein. Note any food allergies that cause a skin reaction. Ask obese patients if they have areas of chafing or a rash in **intertriginous** areas, where skin surfaces overlap and rub on each other (e.g., below the breasts, axillae, and groin). Note any excessive or absent sweating. Question the patient about poor or delayed wound healing.

Elimination Pattern. Ask the patient about conditions of the skin such as dehydration, edema, and **pruritus** (itching), which can indicate alterations in fluid balance. If urinary or fecal incontinence is a problem, determine the condition of the skin in the anal and perineal areas.

Activity-Exercise Pattern. Obtain information about environmental hazards in relation to hobbies and recreational activities, including exposure to known carcinogens, chemical irritants, and allergens. Ask the patient if any changes occur in the skin during exercise or other activities.

Sleep-Rest Pattern. Question the patient about disturbances in sleep patterns caused by a skin condition. For example, pruritus can be distressing and cause major alterations in normal sleep patterns. Also, poor sleep and resulting tiredness are often reflected in a patient's face by dark circles under the eyes and a decreased firmness in the facial skin.

Cognitive-Perceptual Pattern. Determine the patient's perception of the sensations of heat, cold, pain, and touch. Note any discomfort associated with a skin condition, especially when observed in intact skin. Assess and record any joint pain. Assess the mobility of the joints, since the patient's skin condition may cause alterations in mobility.

Self-Perception–Self-Concept Pattern. Assess any feelings related to the patient's skin condition such as sadness, anxiety, despair, or altered body image. These feelings can occur with visible skin problems such as acne, rosacea, and psoriasis, which alter a person's physical appearance.

Role-Relationship Pattern. Determine how the patient's skin condition affects relationships with family members, peers, and work associates. In addition, question the patient regarding the effect of environmental factors on the skin such as occupational exposure to irritants, sun, and unusually cold or unhygienic conditions. Contact dermatitis caused by allergies and irritants is a common skin problem associated with occupation.

Sexuality-Reproductive Pattern. Tactfully question and assess the effect of the patient's skin condition on sexual activity. In particular, note the reproductive status of the female patient relative to possible therapeutic interventions. For example, isotretinoin (Accutane), used to treat acne, and topical fluorouracil (Efudex, Fluoroplex), used to treat actinic keratoses, are teratogenic drugs that may cause abnormal fetal development. These medications should not be used by pregnant women or women who could become pregnant.

Coping–Stress Tolerance Pattern. Assess and question the patient about the role that stress may play in creating or exacerbating the skin condition. Ask the patient what coping strategies are used to manage the skin condition.

CASE STUDY—cont'd

Subjective Data

iStockphoto/Thinkstock

A focused subjective assessment of D.A. reveals the following:

- ***PMH:*** Negative except for an appendectomy at age 16.
- ***Medications:*** None at present. NKA.
- ***Health Perception–Health Management:*** Currently washes her face with a skin cleanser in the morning and nighttime. After cleansing, she applies a moisturizer with SPF 15. She has used these facial products for the past 3 years since she first started noticing small age spots appearing. Before that she just used soap and water.
- ***Nutritional:*** D.A. reports that her skin seems to be drier as she ages but otherwise no changes besides the "age spots" or "whatever they are." Denies any changes in the way cuts or sores heal. No weight loss. Does not take any supplemental vitamins or minerals.
- ***Elimination:*** Although skin is a little dry, D.A. does not perceive it to be excessively dry. Denies excessive sweating or any swelling.
- ***Activity-Exercise:*** Loves to garden and go for walks outdoors. Reports a history of frequent, sometimes severe, sunburns as a child. No use of sunscreen growing up but does remember her mother making her wear T-shirts over her bathing suits to help prevent sunburn. Has used sunscreen for the past 20 years when outdoors. Reapplies as needed.
- ***Cognitive-Perceptual:*** Denies any pain or discomfort associated with skin lesions.
- ***Coping–Stress Tolerance:*** Fearful that she might have skin cancer.

Value-Belief Pattern. Ask about cultural or religious beliefs that could influence the patient's self-image as related to the skin condition. Also, assess values and beliefs that might influence or limit the choice of treatment options.

Objective Data

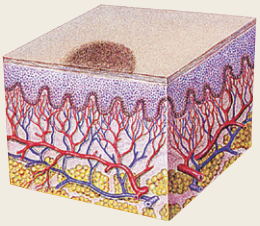
Physical Examination. Primary skin lesions develop on previously unaltered skin. The common characteristics of primary skin lesions are shown in Table 23-4. Secondary skin lesions are lesions that change with time or occur because of factors such as scratching or infection. Secondary skin lesions are shown in Table 23-5. General principles when assessing the skin are as follows:

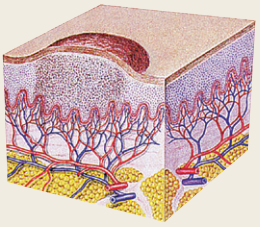
- Have a private examination room of moderate temperature with good lighting; a room with exposure to daylight is preferred.
- Ensure that the patient is comfortable and in a dressing gown that allows easy access to all skin areas.
- Be systematic and proceed from head to toe.
- Compare symmetric parts.
- Perform a general inspection and then a lesion-specific examination.
- Use the metric system when taking measurements.
- Use appropriate terminology and nomenclature when reporting or documenting.

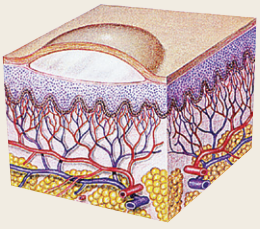
Photographs are useful when accurate findings are needed. Follow clinical agency protocol regarding obtaining a patient's consent to photograph skin lesions for inclusion in the medical record.

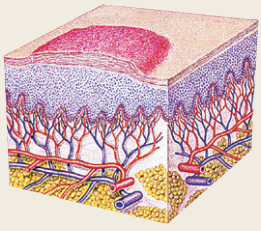
Inspection. Inspect the skin for general color and pigmentation, vascularity, bruising, and lesions or discolorations. The critical factor in assessment of skin color is change. A skin color

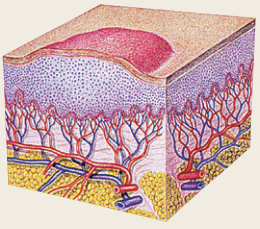
TABLE 23-4 PRIMARY SKIN LESIONS

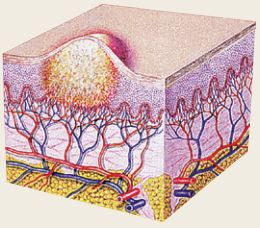


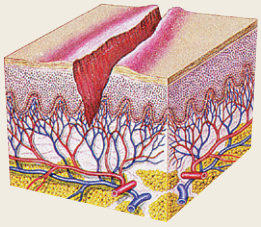


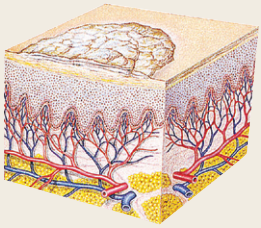


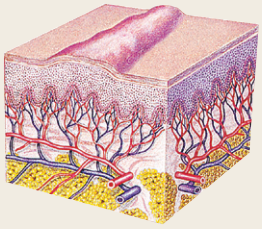


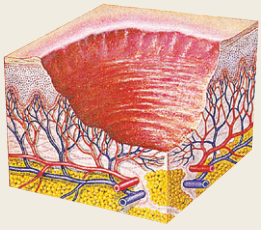


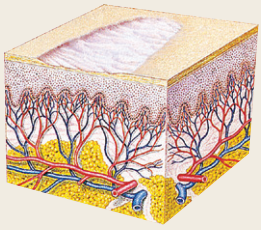


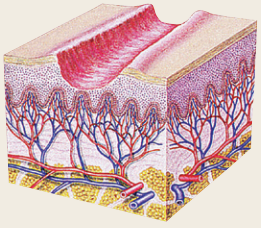












Lesion	Description
Macule 	Circumscribed, flat area with a change in skin color; <0.5 cm in diameter; if lesion >0.5 cm, it is a *patch* *Examples:* freckles, petechiae, measles, flat mole (nevus), café-au-lait spots, vitiligo (complete depigmentation)
Papule 	Elevated, solid lesion; <0.5 cm in diameter; if lesion is >0.5 cm in diameter, it is a *nodule* *Examples:* wart (verruca), elevated moles, lipoma, basal cell carcinoma
Vesicle 	Circumscribed, superficial collection of serous fluid; <0.5 cm in diameter *Examples:* varicella (chickenpox), herpes zoster (shingles), second-degree burn
Plaque 	Circumscribed, elevated, superficial, solid lesion; >0.5 cm in diameter *Examples:* psoriasis, seborrheic and actinic keratoses
Wheal 	Firm, edematous, irregularly shaped area; diameter variable *Examples:* insect bite, urticaria
Pustule 	Elevated, superficial lesion filled with purulent fluid *Examples:* acne, impetigo

TABLE 23-5 SECONDARY SKIN LESIONS

Lesion	Description
Fissure 	Linear crack or break from the epidermis to the dermis; dry or moist *Examples:* athlete's foot, cracks at corner of the mouth
Scale 	Excess, dead epidermal cells produced by abnormal keratinization and shedding *Examples:* flaking of skin after a drug reaction or sunburn
Scar 	Abnormal formation of connective tissue that replaces normal skin *Examples:* surgical incision, healed wound
Ulcer 	Loss of the epidermis, extending into the dermis; crater-like, irregular shape *Examples:* pressure ulcer, chancre
Atrophy 	Depression in skin resulting from thinning of the epidermis or dermis *Examples:* aged skin, striae
Excoriation 	Area in which epidermis is missing, exposing the dermis *Examples:* abrasion, scratch

that is normal for a particular patient can be a sign of a pathologic condition in another patient. The skin color depends on the amount of melanin (brown), carotene (yellow), oxyhemoglobin (red), and reduced hemoglobin (bluish red) present at a particular time. The most reliable areas to assess erythema, cyanosis, pallor, and jaundice are the areas of least pigmentation, such as the sclerae, conjunctivae, nail beds, lips, and buccal mucosa. The true skin color is best observed in photo-protected areas such as the buttocks. Activity, sun (UV) exposure, emotions, cigarette smoking, and edema, as well as respiratory, renal, cardiovascular, and hepatic disorders, can all directly affect skin color. Table 23-6 describes assessment variations in light- and dark-skinned individuals.

TABLE 23-6 NURSING ASSESSMENT

Assessment Variations in Light- and Dark-Skinned Individuals

Light Skin	Dark Skin
Cyanosis	
Grayish blue tone, especially in nail beds, earlobes, lips, mucous membranes, palms, and soles	Ashen or gray color most easily seen in the conjunctiva of the eye, mucous membranes, and nail beds
Ecchymosis	
Dark red, purple, yellow, or green color, depending on age of bruise	Purple to brownish black. Difficult to see unless occurring in an area of light pigmentation
Erythema	
Reddish tone, possibly accompanied by increased skin temperature secondary to localized inflammation	Deeper brown or purple skin tone with evidence of increased skin temperature secondary to inflammation
Jaundice	
Yellowish color of skin, sclera, fingernails, palms, and oral mucosa	Yellowish green color most obviously seen in sclera of eye (do not confuse with yellow eye pigmentation, which may be evident in dark-skinned patients), palms, and soles
Pallor	
Pale skin color that may appear white or ashen; also evident on lips, nail beds, and mucous membranes	Lack of underlying red tone in brown or black skin. In light-skinned African Americans, yellowish brown skin. In dark-skinned African Americans, ashen or gray skin
Petechiae	
Lesions appearing as small, reddish purple pinpoints, best observed on abdomen and buttocks	Difficult to see. May be evident in the buccal mucosa of the mouth or conjunctiva of the eye
Rash	
May be visualized and felt with light palpation	Not easily visualized, but may be felt with light palpation
Scar	
Generally heals, showing narrow scar line	Higher incidence of keloid development, resulting in a thickened, raised scar (see Table 23-5)

In your general inspection, note the presence of body art such as piercings and tattoos. The nose, ears, eyebrows, lips, navel, and nipples are common sites of piercing. Tattoo pigments deposited in the skin may cause itching, pain, and sensitivity for several weeks after the tattoo is placed.

Examine the skin for possible problems related to vascularity, including bruising and vascular and purpuric lesions such as *angioma* (benign tumor of blood or lymph vessels), *petechiae* (tiny purple spots on skin), or *purpura* (bleeding disorder caused by ecchymosis or petechiae). Note the reaction to direct pressure. If a lesion blanches on direct pressure and then refills, the redness is due to dilated blood vessels. If the discoloration remains, it is the result of subcutaneous or intradermal bleeding or a nonvascular lesion. Note any pattern of bruising such as discoloration in the shape of the hand or fingers or bruises at different stages of resolution. These may indicate other health problems or abuse and should be further investigated.

If lesions are found on the skin, record their color, size, distribution, location, and shape. Skin lesions are usually described in terms related to the lesions' configuration (solitary or pattern in relation to other lesions) and distribution (arrangement of lesions over an area of skin) (Table 23-7).

During systematic inspection, note any unusual odors. Skin sites with lesions, such as rashes, may be colonized with yeast or bacteria, which can be associated with distinctive odors in intertriginous areas (Fig. 23-5). Examine tattoos and needle-track marks and note the location and characteristics of the surrounding skin area.

TABLE 23-7 LESION DISTRIBUTION TERMINOLOGY

Term	Description
Asymmetric	Unilateral distribution
Confluent	Merging together
Diffuse	Wide distribution
Discrete	Separate from other lesions
Generalized	Diffuse distribution
Grouped	Cluster of lesions
Localized	Limited areas of involvement that are clearly defined
Solitary	A single lesion
Symmetric	Bilateral distribution
Zosteriform	Bandlike distribution along a dermatome area

FIG. 23-5 Intertrigo. Rash in body folds with *Candida* infection.

TABLE 23-8 ASSESSMENT ABNORMALITIES

Integumentary System

Finding	Description	Possible Etiology and Significance
Alopecia	Loss of hair (localized or general)	Heredity, friction, rubbing, traction, trauma, stress, infection, inflammation, chemotherapy, pregnancy, emotional shock, tinea capitis, immunologic factors
Angioma	Tumor consisting of blood or lymph vessels	Normal increase in incidence with aging, liver disease, pregnancy, varicose veins
Carotenemia (carotenosis)	Yellow discoloration of skin, no yellowing of sclerae, most noticeable on palms and soles	Vegetables containing carotene (e.g., carrots, squash), hypothyroidism
Comedo (acne lesion)	Enlarged hair follicle plugged with sebum, bacteria, and skin cells; can be open (blackhead) or closed (whitehead)	Heredity, certain drugs, hormonal changes with puberty and pregnancy
Cyanosis	Slightly bluish gray or dark purple discoloration of the skin and mucous membranes caused by excessive amounts of reduced hemoglobin in capillaries	Cardiorespiratory problems, vasoconstriction, asphyxiation, anemia, leukemia, and malignancies
Cyst	Sac containing fluid or semisolid material	Obstruction of a duct or gland, parasitic infection
Ecchymosis	Large, bruise-like lesion caused by collection of extravascular blood in dermis and subcutaneous tissue	Trauma, bleeding disorders
Erythema	Redness occurring in patches of variable size and shape	Heat, certain drugs, alcohol, ultraviolet rays, any problem that causes dilation of blood vessels to the skin
Hematoma	Extravasation of blood of sufficient size to cause visible swelling	Trauma, bleeding disorders
Hirsutism	Male distribution of hair in women	Abnormality of ovaries or adrenal glands, decrease in estrogen level, familial trait
Hypopigmentation	Loss of pigmentation resulting in lighter patches than the normal skin	Chemical agents, nutritional factors, burns, inflammation, infection
Intertrigo	Dermatitis of overlying surfaces of the skin	Moisture, irritation, obesity; may be complicated by *Candida* infection (see Fig. 23-5)
Jaundice	Yellow (in white patients) or yellowish brown (in African Americans) discoloration of the skin, best observed in the sclera, secondary to increased bilirubin in the blood	Liver disease, red blood cell hemolysis, pancreatic cancer, common bile duct obstruction
Keloid	Hypertrophied scar beyond wound margins (see Fig. 23-6)	Predisposition more common in African Americans
Lichenification	Thickening of the skin with accentuated normal skin markings	Repeated scratching, rubbing, and irritation usually as a result of pruritus or neurosis
Mole (nevus)	Benign overgrowth of melanocytes	Defects of development; excessive numbers and large, irregular moles; often familial
Petechiae	Pinpoint, discrete deposits of blood <1-2 mm in the extravascular tissues and visible through the skin or mucous membrane	Inflammation, marked vasodilation, blood vessel trauma, blood dyscrasia that results in bleeding tendencies (e.g., thrombocytopenia)
Telangiectasia	Visibly dilated, superficial, cutaneous small blood vessels, commonly found on face and thighs	Aging, acne, sun exposure, alcohol, liver failure, corticosteroids, radiation, certain systemic diseases, skin tumors
Tenting	Failure of skin to return immediately to normal position after gentle pinching	Aging, dehydration, cachexia
Varicosity	Increased prominence of superficial veins	Interruption of venous return (e.g., from tumor, incompetent valves, inflammation), commonly found on lower legs with aging
Vitiligo	Complete absence of melanin (pigment) resulting in chalky white patch (see Fig. 23-7)	Autoimmune, familial, thyroid disease

Inspection of the hair should include an examination of all body hair. Note the distribution, texture, and quantity of hair. Changes in the normal distribution of body hair and growth may indicate an endocrine or vascular disorder. Carefully inspect the nails, including nail shape, thickness, curvature, and surface. Note any grooves, pitting, ridges, or detachment from nail bed. Changes in nail smoothness or thickness can occur with anemia, psoriasis, thyroid problems, decreased vascular circulation, and some infections.

Palpation. Palpate the skin to obtain information about temperature, turgor, moisture, and texture. Temperature of the patient's skin is best assessed using the back of your hand. The skin should be warm without being hot. The temperature of the skin increases when blood flow to the dermis is increased. A localized temperature increase occurs with burns and local inflammation. A generalized increase in skin temperature occurs when a person has a fever. A decreased body temperature may occur when shock or other circulatory problems, chilling, or infection is present.

Turgor refers to the elasticity of the skin. Assess turgor by gently pinching an area of skin under the clavicle or on the back of the hand. Skin with good turgor should move easily when lifted and should immediately return to its original position when released. In patients with dehydration and aging, a loss of turgor occurs and can cause tenting of the skin (Table 23-8).

Moisture of the skin (the dampness or dryness of the skin) increases in intertriginous areas and with high humidity. Skin moisture varies with environmental temperature, muscular activity, body weight, and body temperature. The skin should be intact with no flaking, scaling, or cracking. Skin generally becomes drier with increasing age.

FOCUSED ASSESSMENT

Integumentary System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Hair loss (unusual or rapid)	Y	N
Changes in skin (e.g., lesions, bruising)	Y	N
Nail discoloration	Y	N

Objective: Diagnostic

Check the following for results and critical values.

Biopsy results	✓
Albumin	✓

Objective: Physical Examination

Inspect

Skin for color, integrity, scars, lesions, signs of breakdown	✓
Facial and body hair for distribution, color, quantity, hygiene	✓
Nails for shape, contour, color, thickness, cleanliness	✓
Dressings if present	✓

Palpate

Skin for temperature, texture, moisture, thickness, turgor, mobility	✓

Texture refers to the fineness or coarseness of the skin. The skin should feel smooth and firm with the surface evenly thin in most areas. Thickened callus areas are normal on the soles and palms and relate to weight bearing. Increased thickness is often work related and the result of excessive pressure.

A *focused assessment* is used to evaluate the status of previously identified integumentary problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the integumentary system is presented in the box on this page. Assessment abnormalities of the skin are described in Table 23-8.

Assessment of Dark Skin

A normal range of differences occurs in the physical examination of skin, hair, and nails. Genetic factors determine a person's skin color, which can vary from white to dark brown with overtones of yellow, olive, and red. The darker skin tones result from the reflection of light as it strikes the underlying skin pigment. An increased amount of melanin pigment produced by the melanocytes causes the darker skin color. This increased melanin forms a natural sun shield for dark skin and results in a decreased incidence of skin cancer in these individuals.

The structures of dark skin are no different from those of lighter skin, but they are often more difficult to assess (see Table 23-6). Color is more easily assessed in areas where the epidermis is thin and pigmentation is not influenced by sun exposure such as the lips, mucous membranes, nail beds, and protected areas (e.g., buttocks). Palmar and plantar surfaces are lighter than other skin areas in darker-skinned individuals. Rashes are often more difficult to observe and may need to be palpated.[6] Wrinkling is more apparent in light-skinned individuals than in dark-skinned individuals.

Individuals with dark skin are predisposed to certain skin and hair conditions. **Keloid** is an overgrowth of collagenous tissue at the site of a skin injury (e.g., ear piercing) (Fig. 23-6).

FIG. 23-6 Keloid. Hypertrophic scarring after skin injury, which is more common in dark-skinned individuals.

FIG. 23-7 Vitiligo. Total loss of pigment in the affected area.

Vitiligo is total loss of pigment in the affected area (Fig. 23-7). In *dermatosis papulosa nigra,* small, pigmented wartlike papules are commonly found on the face. *Nevus of Ota* is a slate-gray or blue-gray birthmark located on the forehead and face around the eye area; it may also involve the sclera (Fig. 23-8). *Traction alopecia* may be noted due to trauma from hair rollers or from tight braiding of the hair (Fig. 23-9). The hair loss may be temporary or permanent. *Pseudofolliculitis* is an inflammatory response to ingrown hairs that occurs after shaving too closely in the beard area. It is characterized by pustules and papules.

Because of the darkness of the skin of some individuals, color often cannot be used as an indicator of systemic conditions (e.g., flushed skin with fever). Cyanosis may be difficult to determine because a normal bluish hue occurs in dark-skinned people.

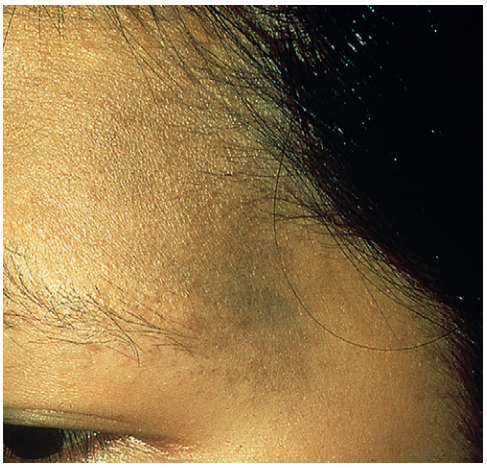


FIG. 23-8 Nevus of Ota. Flat gray to blue pigmentation in the upper trigeminal area, which is more common in dark-skinned individuals.

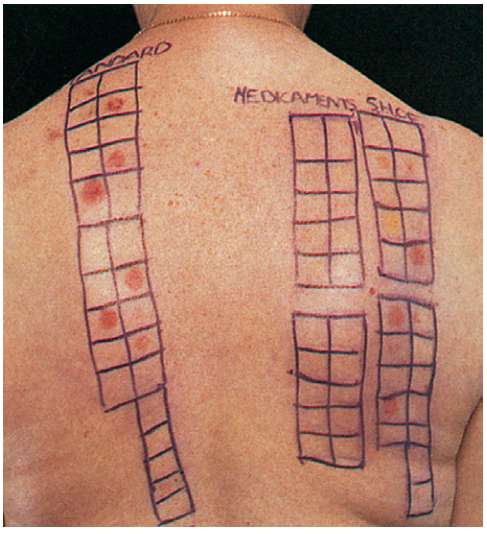
FIG. 23-9 Traction alopecia. Hair loss in scalp because of prolonged tension from hair rollers, braiding, or straightening combs.



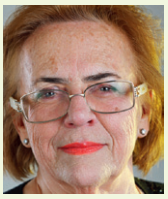


FIG. 23-10 Patch test. Results from an application of possible allergens to the skin shows positive reactions in the sites labeled "standard" and "shoe."

CASE STUDY—cont'd

Objective Data

iStockphoto/Thinkstock

Physical Examination

Physical examination findings of D.A.'s skin are as follows:

- Complexion fair. Wrinkles around eyes, above upper lip, and on sides of cheeks bilaterally. Normal skin temperature and turgor.
- Lesion on upper right forehead measuring 2 × 3 mm; on left forehead near hairline measuring 1 × 2 mm; and on left lower cheek measuring 2 × 2.5 mm.
- All lesions are slightly erythematous but do not blanch when direct pressure is applied. Borders distinct. Minimal elevation noted on palpation.
- No other skin lesions noted on rest of body.

As you continue to read this chapter, consider diagnostic studies you would anticipate being performed for D.A. Also identify patient problems and appropriate nursing interventions for D.A. while she is a patient in the clinic.

Diagnostic Studies

The health care provider examines the lesion via dermatoscopy and also uses a Wood's lamp to rule out a fungal infection. The provider suspects basal cell carcinoma, which is confirmed by a shave biopsy.

DIAGNOSTIC STUDIES OF INTEGUMENTARY SYSTEM

Diagnostic studies provide important information in monitoring the patient's condition and planning interventions. These studies are considered to be objective data. Table 23-9 contains diagnostic studies commonly used for the integumentary system.

The main diagnostic techniques related to skin problems are inspection of an individual lesion and a careful history related to the problem. If a definitive diagnosis cannot be made by these techniques, additional tests may be indicated, such as *dermatoscopy* (examination of the skin through a lighted instrument with optical magnification).[6]

Biopsy is one of the most common diagnostic tests used to evaluate a skin lesion. A biopsy is indicated in all conditions in which a malignancy is suspected or a specific diagnosis is questionable. Techniques include punch, incisional, excisional, and shave biopsies. The method used is related to factors such as the site of the biopsy, the cosmetic result desired, and the type of tissue to be obtained.

Other diagnostic procedures include stains and cultures for fungal, bacterial, and viral infections. Direct immunofluorescence is a special diagnostic technique used on biopsy specimens and may be indicated in certain conditions such as bullous diseases and systemic lupus erythematosus. Indirect immunofluorescence is performed on a sample of blood. Patch testing (Fig. 23-10) and photopatch testing may be used to evaluate allergic dermatitis and photoallergic reactions.[2]

TABLE 23-9 DIAGNOSTIC STUDIES

Integumentary System

Study	Description and Purpose	Nursing Responsibility
Biopsy		
Punch	Special punch biopsy instrument of appropriate size used. Instrument rotated to appropriate level to include dermis and some fat. Suturing may or may not be done. Provides full-thickness skin for diagnostic purposes.	Verify that consent form is signed (if needed). Assist with preparation of site, anesthesia, procedure, and hemostasis. Apply dressing, give postprocedure instructions to patient. Properly identify specimen.
Excisional	Used when good cosmetic results and/or entire lesion removal desired. Skin closed with subcutaneous and skin sutures.	Same as above.
Incisional	Wedge-shaped incision made in lesion too large for excisional biopsy. Useful when larger specimen than shave or punch biopsy is needed.	Same as above.
Shave	Single-edged razor blade used to shave off superficial lesions or small sample of a large lesion. Provides thin specimen for diagnostic purposes.	Same as above.
Microscopic Tests		
Potassium hydroxide (KOH)	Hair, scales, or nails examined for superficial fungal infection. Specimen put on glass slide and 10%-20% concentration of KOH added.	Instruct patient regarding purpose of test. Prepare slide.
Tzanck test (Wright's and Giemsa's stain)	Fluid and cells from vesicles examined. Used to diagnose herpes infections. Specimen put on slide, stained, and examined microscopically.	Inform patient of purpose of test. Use sterile technique for collection of fluid.
Culture	Test identifies fungal, bacterial, and viral organisms. For *fungi,* scraping or swab of skin performed. For *bacteria,* material obtained from intact pustules, bullae, or abscesses. For *viruses,* vesicle or bulla and exudate taken from base of lesion.	Instruct patient regarding purpose and procedure. Properly identify specimen. Follow instructions for storage of specimen if not immediately sent to laboratory.
Mineral oil slides	To check for infestations, scrapings are placed on slide with mineral oil and viewed microscopically.	Instruct patient about purpose of test. Prepare slide.
Immunofluorescent studies	Some skin diseases have specific, abnormal antibody proteins that can be identified by fluorescent studies. Both skin tissue and serum can be examined.	Inform patient about purpose of test. Assist in obtaining specimen. For punch biopsy of tissue, place specimen in special fixative (e.g., Michel's) and not formalin.
Miscellaneous		
Wood's lamp (black light)	Examination of skin with long-wave ultraviolet light causes specific substances to fluoresce (e.g., *Pseudomonas* organisms, fungal infections, vitiligo).	Explain purpose of examination. Inform patient it is not painful. Room is darkened for examination.
Patch test	Used to determine whether patient is allergic to specific testing material. Small amount of potentially allergenic material applied, usually to skin on back.	Explain purpose and procedure to patient. Instruct patient to return in 48-72 hr for removal of allergens and at 96 hr for preliminary evaluation (see Fig. 23-10).

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The primary function of the skin is
   - **a.** insulation.
   - **b.** protection.
   - **c.** sensation.
   - **d.** absorption.
2. Age-related changes in the hair and nails include *(select all that apply)*
   - **a.** oily scalp.
   - **b.** scaly scalp.
   - **c.** thinner nails.
   - **d.** thicker, brittle nails.
   - **e.** longitudinal nail ridging.
3. When assessing the nutritional-metabolic pattern in relation to the skin, the nurse questions the patient regarding
   - **a.** joint pain.
   - **b.** the use of moisturizing shampoo.
   - **c.** recent changes in wound healing.
   - **d.** self-care habits related to daily hygiene.
4. During the physical examination of a patient's skin, the nurse would
   - **a.** use a flashlight in a poorly lit room.
   - **b.** note cool, moist skin as a normal finding.
   - **c.** pinch up a fold of skin to assess for turgor.
   - **d.** perform a lesion-specific examination first and then a general inspection.
5. The nurse assessed the patient's skin lesions as firm, edematous, irregularly shaped with a variable diameter. They would be called
   - **a.** wheals.
   - **b.** papules.
   - **c.** pustules.
   - **d.** plaques.
6. To assess the skin for temperature and moisture, the most appropriate technique for the nurse to use is
   - **a.** palpation.
   - **b.** inspection.
   - **c.** percussion.
   - **d.** auscultation.

7. Individuals with dark skin are more likely to develop
   a. keloids.
   b. wrinkles.
   c. skin rashes.
   d. skin cancer.
8. On inspection of a patient's dark skin, the nurse notes a blue-gray birthmark on the forehead and eye area. This assessment finding is called
   a. vitiligo.
   b. intertrigo.
   c. telangiectasia.
   d. Nevus of Ota.
9. Diagnostic testing is recommended for skin lesions when
   a. a health history cannot be obtained.
   b. a more definitive diagnosis is needed.
   c. percussion reveals an abnormal finding.
   d. treatment with prescribed medication has failed.

1. b, 2. b, d, e, 3. c, 4. c, 5. a, 6. a, 7. a, 8. d, 9. b

LEARNING OUTCOMES

1. Specify health promotion practices related to the integumentary system.
2. Explain the etiology, clinical manifestations, and nursing and collaborative management of common acute dermatologic problems.
3. Summarize the psychologic and physiologic effects of chronic dermatologic conditions.
4. Explain the etiology, clinical manifestations, and nursing and collaborative management of malignant dermatologic disorders.
5. Explain the etiology, clinical manifestations, and nursing and collaborative management of bacterial, viral, and fungal infections of the integument.
6. Describe the etiology, clinical manifestations, and nursing and collaborative management of infestations and insect bites.
7. Explain the etiology, clinical manifestations, and nursing and collaborative management of allergic dermatologic disorders.
8. Explain the etiology, clinical manifestations, and nursing and collaborative management related to benign dermatologic disorders.
9. Distinguish the dermatologic manifestations of common systemic diseases.
10. Explain the indications and nursing management related to common cosmetic procedures and skin grafts.

In this chapter health promotion of the skin, common dermatologic conditions, and malignant skin neoplasms are discussed. Nursing management of patients with dermatologic conditions is emphasized.

HEALTH PROMOTION

Health promotion practices related to the skin often parallel practices for general good health. The skin reflects both physical and psychologic well-being. Specific health promotion activities appropriate to good skin health include avoidance of environmental hazards, adequate hygiene and nutrition, and skin self-examination.

Environmental Hazards

Sun Exposure. Years of exposure to the sun are cumulative and damaging. The ultraviolet (UV) rays of the sun cause degenerative changes in the dermis, resulting in premature

Reviewed by Lakshi M. Aldredge, RN, MSN, ANP-BC, Nurse Practitioner, Dermatology Service, Portland VA Medical Center, Portland, Oregon; and Brenda C. Morris, RN, EdD, CNE, Senior Director, Baccalaureate Nursing and Clinical Associate Professor, College of Nursing and Health Innovation, Arizona State University, Phoenix, Arizona.

aging (e.g., loss of elasticity, thinning, wrinkling, drying of the skin). Prolonged and repeated sun exposure is a major factor in precancerous and cancerous lesions. Actinic keratosis, basal cell carcinoma, squamous cell carcinoma, and malignant melanoma are dermatologic problems that are associated with direct or indirect sun exposure.

Safe sun practices are important for you to emphasize to the patient. Specific wavelengths of the sun (Table 24-1) have different effects on the skin. Sunlight is composed of visible light and UV light. There are two types of UV light: UVA and UVB. UVA light is responsible for tanning and UVB for sunburn. Both types can damage the skin and increase the risk of skin cancer. Both UVA and UVB can cause collagen damage and accelerate the aging of skin. Tanning is the skin's response to injury and is caused by the increased production of melanin. When sun exposure is excessive, the turnover time of the skin becomes shortened, which can result in peeling. Fair-skinned persons should be especially cautious about excessive sun exposure because they have less melanin and thus less natural protection.

TABLE 24-1 WAVELENGTHS OF SUN AND EFFECTS ON SKIN

Wavelength	Effect
Long (ultraviolet A [UVA])	Can produce elastic tissue damage and actinic skin damage. Contributes to formation of skin cancer.
Middle (ultraviolet B [UVB])	Causes sunburn and cumulative effect of sun damage. Major factor in development of skin cancer.
Short (ultraviolet C [UVC])	Does not reach earth, since it is blocked by atmosphere.

EVIDENCE-BASED PRACTICE

Applying the Evidence

You are a nurse helping in a skin cancer screening clinic. W.S., a 24-year-old woman with a fair skin type (blond hair and blue eyes), is completing her health history before her screening examination. She indicates that she visits an indoor tanning salon every other week. She tells you that being tan makes her feel "more attractive." You spend time explaining the increased risk of skin cancer associated with the use of tanning booths.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
American Academy of Dermatology reports a strong link between exposure to indoor tanning devices and development of skin cancer and melanoma.	You note that W.S. has the following skin cancer risk factors: fair skin, blond hair, blue eyes, frequent use of tanning booths.	After listening, the patient tells you that she will consider reducing the frequency of her visits—going only when she has an important event to attend.

Your Decision and Action

As her nurse, you accept her decision, tell her that this is a step in the right direction, and encourage her to consider completely stopping her usage of the tanning booth.

Reference for Evidence

American Academy of Dermatology: The dangers of indoor tanning. Retrieved from *www.aad.org/skin-care-and-safety/skin-cancer-prevention/indoor-tanning*.

Patients should recognize that sun safety guidelines include sun avoidance (especially during the midday hours), protective clothing, and sunscreen. Advise the patient on ways to avoid the damaging effects of the sun, such as wearing a large-brimmed hat, sunglasses, and a long-sleeved shirt of a lightly woven fabric or carrying an umbrella. Patients need to know that the rays of the sun are most dangerous between 10:00 AM and 2:00 PM standard time or 11:00 AM and 3:00 PM daylight saving time, regardless of the latitude. Even on overcast days, serious sunburn can occur because up to 80% of the sun's UV rays can penetrate the clouds.

Other factors that increase the possibility of sunburn include being at high altitude, being in snow (reflects 80% of the sun's rays), or being in or near water. Warn people of the dangers of tanning booths and sun lamps, which are UVA. Tanning booths increase the risk of sunburn and contribute to the development of skin cancer.[1]

Sunscreens can filter both UVA and UVB wavelengths. The two types of topical sunscreens are chemical and physical. Chemical sunscreens are light creams or lotions designed to absorb or filter UV light, resulting in diminished UV light penetration. Physical sunscreens are thick, opaque, heavy creams that reflect UV radiation.

The U.S. Food and Drug Administration (FDA) rates sunscreen products on their **sun protection factor (SPF).** The SPF

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Is Sun-Protective Counseling Effective?

Clinical Question

In adults (P) does sun-protective counseling (I) improve safe sun behaviors (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Five RCTs (n = 6949) of middle-aged white men and women and three RCTS (n = 897) of young adults examined the effect of counseling on sun-protective behaviors. Trials ranged from one to several sessions of in-person counseling, phone counseling, or tailored risk written feedback.
- Counseling with tailored feedback influenced sun-protective behaviors in older adults.
- Appearance-focused counseling reduced indoor tanning use among young adult women.

Conclusion

- Relevant counseling by primary health care providers can increase sun-protective behaviors and decrease indoor tanning.

Implications for Nursing Practice

- Promote safe sun behaviors for patients to decrease ultraviolet exposure, including sunscreen use, sun avoidance hours, and protective clothing.
- Emphasize the dangers of tanning booth use among college students.
- Tailor sun safety interventions to the target population.

Reference for Evidence

Lin J, Eder M, Weinmann S: Behavioral counseling to prevent skin cancer: a systematic review for the U.S. Preventive Services Task Force, *Ann Intern Med* 154:190, 2011.

P, Patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see p. 12).

measures the effectiveness of a sunscreen in filtering and absorbing UV radiation. All sunscreen labels in the United States must state which rays they protect against. Products labeled with "broad protection" block both UVA and UVB.[2] Sunscreen broad protection labeling is allowed only if the product has an SPF of at least 15. Sunscreen should no longer be labeled as "waterproof" and "sweat proof." The product should only state if it is "water resistant."

Consumers need to select the sunscreen most appropriate for their needs. Para-aminobenzoic acid (PABA) and PABA esters, cinnamates, salicylates, and methyl anthranilate block UVB rays. PABA has been removed from many sunscreen products because it stains clothing and can cause allergic reactions, including contact dermatitis. Avobenzone (Parsol) blocks UVA rays and has been added to some sunscreens. The benzophenones block both UVA and UVB rays.

The general recommendation is that everyone should use a sunscreen with a minimum SPF of 15 daily. Teach patients to look for the term *broad spectrum* on sunscreen packaging. Sunscreens with an SPF of 15 or more filter 92% of the UVB rays that are responsible for erythema, and make sunburn unlikely when applied appropriately. Patients who have a history of skin cancer or problems with sun sensitivity should use a product with an SPF of at least 30. Sunscreens should be applied 20 to 30 minutes before going outdoors, even in cloudy weather. The SPF value of all sunscreens decreases with time after application, and therefore sunscreen should be reapplied every 2 hours in a sufficient amount. One ounce per total body application is recommended. The ears, toes, and lips also need sunscreen. Sunscreens are not "waterproof" and should be reapplied immediately after swimming. Regular sunscreen use decreases the rate of developing melanoma.[3]

Certain topical and systemic medications potentiate the effect of the sun, even with brief exposure. Categories of drug therapy that may contain common photosensitizing medications are listed in Table 24-2. Be aware that many drugs are included in these categories. Examine the photosensitivity of each individual drug. The chemicals in these medications absorb light when exposed to natural sunlight and release energy that harms cells and tissues. The clinical manifestations of drug-induced photosensitivity (Fig. 24-1) are similar to those of exaggerated sunburn. These include swelling; erythema; vesicles; and papular, plaquelike lesions. Skin that is at risk for photosensitivity reactions can be protected by the use of sunscreen products. Teach patients who are taking these drugs about their photosensitizing effect.

CULTURAL & ETHNIC HEALTH DISPARITIES

Integumentary Problems

- African Americans and Native Americans have a lower incidence of skin cancer than whites.
- Melanoma can occur in dark-skinned individuals, but often goes unrecognized until the advanced stages.
- Skin assessment may be difficult in individuals with darker skin. The oral mucous membranes and conjunctiva are areas where pallor, cyanosis, and jaundice are more readily detected. The palms of the hands and soles of the feet can also be used for assessment of the skin of darker individuals.
- When darker skin heals after injury or inflammation, it tends to be hypopigmented or hyperpigmented.

Irritants and Allergens. Patients can seek treatment for irritant or allergic dermatitis, which are two types of contact dermatitis. *Irritant contact dermatitis* is produced by direct chemical injury to the skin. *Allergic contact dermatitis* is an antigen-specific, type IV delayed hypersensitivity response. This response requires sensitization and occurs only in individuals who are predisposed to react to a particular antigen (see Chapter 14).

Counsel patients to avoid known irritants (e.g., ammonia, harsh detergents). Skin patch testing (application of allergens) can sometimes help determine the most likely sensitizing agent. Sometimes the health care provider is the first to detect a contact

TABLE 24-2 DRUG THERAPY

Drugs That May Cause Photosensitivity

Categories	Examples
Anticancer drugs	methotrexate, vinorelbine (Navelbine)
Antidepressants	amitriptyline (Elavil), clomipramine (Anafranil), doxepin (Sinequan)
Antidysrhythmics	quinidine, amiodarone (Cordarone)
Antihistamines	diphenhydramine (Benadryl), chlorpheniramine, clemastine (Tavist)
Antimicrobials	tetracycline, sulfamethoxazole, azithromycin (Zithromax), ciprofloxacin (Cipro)
Antifungals	griseofulvin, ketoconazole (Nizoral)
Antipsychotics	chlorpromazine (Thorazine), haloperidol (Haldol)
Diuretics	furosemide (Lasix), hydrochlorothiazide (HydroDIURIL)
Hypoglycemics	tolbutamide (Orinase), glipizide (Glucotrol), chlorpropamide (Diabinese)
Nonsteroidal antiinflammatory drugs	diclofenac (Voltaren), piroxicam (Feldene), sulindac (Clinoril)

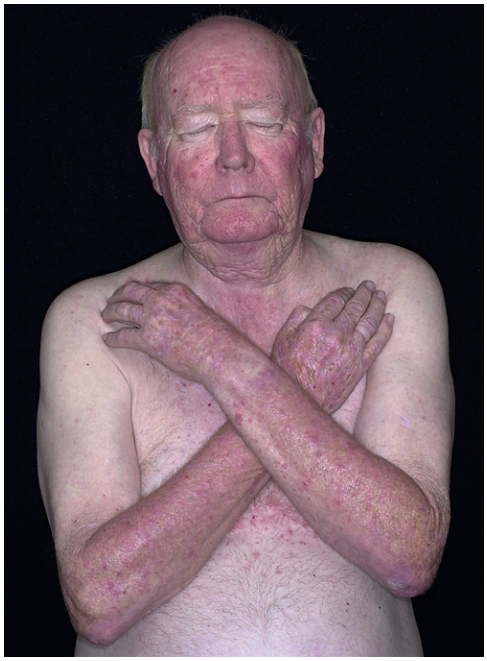

FIG. 24-1 Intense eruption in areas exposed to sunlight after patient started on hydrochlorothiazide.

allergy to various metals, gloves (latex), and adhesives. Prescribed and over-the-counter (OTC) topical and systemic medications used to treat a variety of conditions may contain fragrances and preservatives that can cause dermatologic reactions.

Radiation. Although most radiology departments are extremely cautious in protecting both themselves and their patients from the effects of excessive radiation, it is important for you to help the patient make decisions about radiologic procedures. X-rays are valuable in both diagnosis and therapy but can cause serious side effects to the skin, including erythema, dry and moist desquamation, edema, and hypopigmentation or hyperpigmentation. In the past (30 years ago), acne and hirsutism were treated with radiation. This information is important for you to obtain because of an increased incidence of carcinoma for these patients.

Rest and Sleep

Sleep is restorative to the skin, as well as to the rest of the body. Pruritic skin diseases often interfere with sleep. Therefore helping patients obtain high-quality sleep is an important health-promotion consideration. Adequate rest increases the patient's ability to tolerate itching, thereby decreasing skin damage from the resultant scratching.

Exercise

Exercise increases circulation and dilates the blood vessels. In addition to the healthy glow produced by exercise, the psychologic effects can also improve one's appearance and mental outlook. However, caution must be used to prevent overexposure to heat, cold, and sun during outdoor exercise.

Hygiene

Hygienic practices are influenced by the patient's skin type, lifestyle, culture, age, and gender. The normal acidity of the skin and perspiration protect against bacterial overgrowth. Most soaps are alkaline and neutralize the skin surface, leading to a loss of protection. The use of mild, moisturizing soaps (e.g., Ivory) and lipid-free cleansers, plus avoidance of hot water and vigorous scrubbing, can noticeably decrease local skin irritation and inflammation. Skin piercings where jewelry has been inserted can be cared for with antibacterial soaps that do not contain sulfites.

In general, the skin and hair should be washed often enough to remove excess oil and excretions and to prevent odor. Older persons should avoid harsh soaps and shampoos and frequent bathing because of the dryness of their skin and scalp. Moisturizers should be used immediately after a bath or shower while the skin is still damp to seal in this moisture.

Nutrition

A well-balanced diet adequate in all food groups can produce healthy skin, hair, and nails. Important elements of skin nutrition include the following:

- *Vitamin A:* Essential for maintenance of normal cell structure, specifically epithelial cells. It is necessary for normal wound healing. The absence of vitamin A causes dryness of the conjunctiva and poor wound healing.
- *Vitamin B complex:* Essential for complex metabolic functions. Deficiencies of niacin and pyridoxine (B_6) manifest as dermatologic symptoms such as erythema, bullae, and seborrhea-like lesions.
- *Vitamin C (ascorbic acid):* Essential for connective tissue formation and normal wound healing. Absence of vitamin C causes symptoms of scurvy, including petechiae, bleeding gums, and purpura.
- *Vitamin D_3 (cholecalciferol):* Essential for bone health. It is produced naturally by cutaneous photosynthesis after UVB exposure. A deficiency manifests as bone and muscle weakness and pain.
- *Vitamin K:* Essential for synthesizing blood clotting factors. A deficiency interferes with normal prothrombin synthesis in the liver and can lead to bruising.
- *Protein:* Necessary in amounts adequate for cell growth and maintenance. It is also necessary for normal wound healing.
- *Unsaturated fatty acids:* Necessary to maintain the function and integrity of cellular and subcellular membranes in tissue metabolism. Linoleic and arachidonic acids are particularly important.

A deficiency of biotin, a water-soluble B-complex vitamin, may result in rashes and alopecia. The effectiveness of biotin supplements has not been proven. Foods high in biotin include liver, cauliflower, salmon, carrots, bananas, soy flour, cereals, and yeast.

Obesity has adverse effects on the skin. The increase in subcutaneous fat can lead to stretching and overheating (see Chapter 41). Overheating secondary to the greater insulation provided by fat causes increased sweating, which inflames and dries the skin. Obesity is also a risk factor for poor wound healing. Obesity can be associated with the development of type 2 diabetes mellitus, which may cause skin symptoms such as velvety dark skin of neck and body folds *(acanthosis nigricans),* rash in intertriginous sites *(intertrigo),* skin tags *(acrochordons),* and impaired arterial and venous flow (see Chapter 49).

Self-Treatment

Determine if the patient is aware of the dangers of self-diagnosis and treatment. The increasing variety of OTC skin preparations can be confusing.

In your general instructions to the patient, stress the duration of the treatment and the need to closely follow package directions. Skin problems may be slow to produce symptoms and slow to resolve. If the package insert of an OTC drug says its use should not exceed 7 days, patients should heed this warning. Tell the patient to always follow package directions for use of OTC drugs. If any systemic signs of inflammation or extensions of the skin problem (e.g., an increased number of lesions or increased erythema or swelling) develop, the patient should stop self-care and seek the help of a health care provider.

MALIGNANT SKIN NEOPLASMS

Skin cancer is the most commonly diagnosed cancer.[4] Skin cancers are either nonmelanoma or melanoma. A persistent skin lesion that does not heal is highly suspicious for malignancy and should be examined by a health care provider. Early detection and treatment can often lead to a highly favorable prognosis. The fact that skin lesions are so visible increases the likelihood of early detection and diagnosis.

Teach patients to self-examine their skin at least on a monthly basis. The cornerstone of skin self-examination is the ABCDE rule,[5] which is easy to teach and remember. Examine skin lesions for ***A**symmetry, **B**order* irregularity, ***C**olor* change and

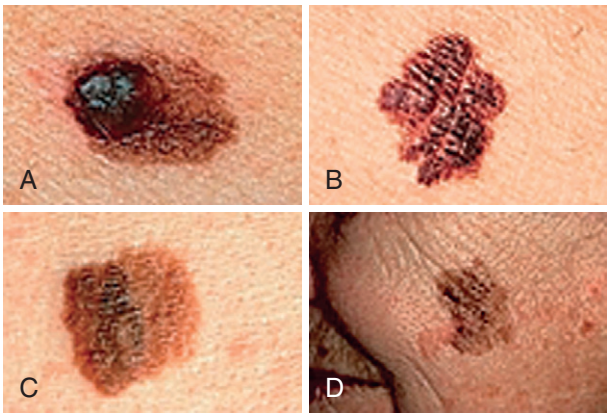

FIG. 24-2 The ABCDEs of melanoma. **A,** Asymmetry: one half unlike the other half. **B,** Border irregularity: edges are ragged, notched, or blurred. **C,** Color: varied pigmentation; shades of tan, brown, and black. **D,** Diameter: greater than 6 mm (diameter of a pencil eraser). **E,** (not pictured) Evolving; changing appearance (change in shape, size, color, or other characteristic is noted over time).

variation, ***D****iameter* of 6 mm or more, and ***E****volving* in appearance (Fig. 24-2). Emphasize that lesions once flat and now raised, or once small and recently growing or changing in appearance, are warning signs and should be examined by a health care provider.

Risk Factors

Risk factors for skin malignancies include having a fair skin type (blond or red hair and blue or green eyes), history of chronic sun exposure, family history of skin cancer, and exposure to tar and systemic arsenicals.[6] Environmental factors that increase the risk of skin malignancies include living near the equator, outdoor occupations, and frequent outdoor recreational activities. Behavioral factors such as using indoor tanning booths and outdoor sunbathing are controllable risk factors for skin malignancies. Patients treated with oral methoxsalen (psoralen) and psoralen plus ultraviolet A radiation (PUVA) may be at greater risk for melanoma.

Dark-skinned persons are less susceptible to skin cancer because of the naturally occurring increased melanin, which is a sunscreen. However, although dark skin lowers the risk of melanoma, people with dark skin can develop melanoma, most often on the palms, soles, and mucous membranes.

The Fitzpatrick classification of skin type can assist you in determining how a patient will respond or react to facial treatments, and how likely they are to get skin cancer. This system classifies skin into six different skin types, skin color, and reaction to sun exposure.

- Type I (very white or freckled): Always burn
- Type II (white): Usually burn
- Type III (white to olive): Sometimes burn
- Type IV (brown): Rarely burn
- Type V (dark brown): Very rarely burn
- Type VI (black): Never burn

NONMELANOMA SKIN CANCERS

Nonmelanoma skin cancers, either basal cell or squamous cell carcinoma, are the most common forms of skin cancer.[7] More than 2.2 million new cases are diagnosed every year. Nonmelanoma skin cancers develop in the epidermis. They do not develop from melanocytes, the skin cells that make melanin, as melanoma skin cancers do. The most common sites for the development of nonmelanoma skin cancer are in sun-exposed areas, such as the face, head, neck, back of the hands, and arms.

Although relatively few deaths are attributable to nonmelanoma skin cancer, the tumors have an inherent potential for severe local destruction, permanent disfigurement, and disability. The most common etiologic factor is sun exposure. Avoidance of exposure to the midday sun and the use of protective clothing and sunscreens beginning early in life can prevent the formation of skin malignancies later in life.

Actinic Keratosis

Actinic keratosis, also known as solar keratosis, consists of hyperkeratotic papules and plaques on sun-exposed areas. Actinic keratoses are premalignant skin lesions that affect nearly all of the older white population. These are the most common of all precancerous skin lesions. The clinical appearance of actinic keratoses can be highly varied. The typical lesion is an irregularly shaped, flat, slightly erythematous papule with indistinct borders and an overlying hard keratotic scale or horn (Table 24-3).

Many forms of treatment are used, including cryosurgery, fluorouracil (5-FU), surgical removal, tretinoin (Retin-A), imiquimod (Aldara), diclofenac (Solaraze), chemical peeling agents, dermabrasion, laser resurfacing, and photodynamic therapy (PDT, with 5-aminolevulinic acid [5-ALA] or methyl aminolevulinate [MAL] followed by light irradiation). (These treatments are discussed later in this chapter.) Any lesion that persists should be evaluated for a possible biopsy.

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is a locally invasive malignancy arising from epidermal basal cells. It is the most common type of skin cancer and also the least deadly. BCC usually occurs in middle-aged to older adults. Clinical manifestations are described in Table 24-3. The cancerous cells of BCC almost never spread beyond the skin (Fig. 24-4). However, if BCC is left untreated, massive tissue destruction may result. Some BCCs are pigmented with curled borders and an opaque appearance and may be misinterpreted as a melanoma. A tissue biopsy is needed to confirm the diagnosis.[8]

Multiple treatment modalities are used depending on the tumor location and histologic type, history of recurrence, and patient characteristics. Treatment modalities include surgical excision, electrodesiccation and curettage, cryosurgery, radiation therapy, topical or systemic chemotherapy, and photodynamic therapy. (These treatments are discussed later in this chapter.) Electrodesiccation and curettage, cryosurgery, and surgical excision all have a cure rate of greater than 90% when used correctly on primary lesions. Location and size are important factors in determining the best treatment.

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a malignant neoplasm of keratinizing epidermal cells (see eFig. 24-1 available on the website for this chapter). It frequently occurs on sun-exposed skin at the base of an actinic keratosis or another lesion. SCC is less common than BCC. SCC can be highly aggressive, has the potential to metastasize, and may lead to death if not treated early and correctly. Pipe, cigar, and cigarette smoking contribute

TABLE 24-3 PREMALIGNANT AND MALIGNANT CONDITIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Actinic Keratosis		
Actinic (sun) damage. Premalignant skin lesions. Common in older whites.	Flat or elevated, dry, hyperkeratotic scaly papule. Possibly flat, rough, or verrucous (wartlike). Adherent scale, which returns when removed. Often multiple. Rough scale on red base. Often on erythematous sun-exposed area. Increase in number with age.	Cryosurgery, chemical peels, laser resurfacing, topical application of 5-FU over entire area for 14-28 days or topical application of imiquimod (Aldara) for 16 wk, photodynamic therapy followed by light irradiation. Recurrence possible even with adequate treatment.
Atypical or Dysplastic Nevi		
Morphologically between common acquired nevi and melanoma. May be precursor of malignant melanoma.	Often >5 mm. Irregular border, possibly notched. Variegated color of tan, brown, black, red, or pink within single mole. Presence of at least one flat portion, often at edge of mole. Frequently multiple. Most common site on back, but possible in uncommon mole sites such as scalp or buttocks (Fig. 24-3).	Increased risk for melanoma. Careful monitoring of persons suspected of familial tendency to melanoma or dysplastic nevi. Excisional biopsy for suspicious lesions.
Basal Cell Carcinoma		
Change in basal cells. No maturation or normal keratinization. Continuing division of basal cells and formation of enlarging mass. Related to excessive sun exposure, genetic skin type, x-ray radiation, scars, and some types of nevi.	*Nodular and ulcerative:* Small, slowly enlarging papule. Borders semitranslucent or "pearly," with overlying telangiectasia. Erosion, ulceration, and depression of center. Normal skin markings lost (see Fig. 24-2). *Superficial:* Erythematous, pearly, sharply defined, barely elevated plaques.	Surgical excision, chemosurgery, electrosurgery, chemotherapy, cryosurgery. 90% cure rate. Slow-growing tumor that invades local tissue. Metastasis rare. 5-FU and imiquimod for superficial lesions, photodynamic therapy for small lesions, vismodegib (Erivedge) for metastatic or recurrent locally invasive lesions.
Squamous Cell Carcinoma		
Frequent occurrence on previously damaged skin (e.g., from sun, radiation, scar). Malignant tumor of squamous cell of epidermis. Invasion of dermis, surrounding skin.	*Superficial:* Thin, scaly erythematous plaque without invasion into the dermis. *Early:* Firm nodules with indistinct borders, scaling and ulceration (see eFig. 24-1). *Late:* Covering of lesion with scale or horn from keratinization, ulceration. Most common on sun-exposed areas such as face and hands.	Surgical excision, cryosurgery, radiation therapy, chemotherapy, electrodesiccation and curettage. Untreated lesion may metastasize to regional lymph nodes and distant organs. High cure rate with early detection and treatment.
Malignant Melanoma		
Neoplastic growth of melanocytes anywhere on skin, eyes, or mucous membranes. Classification according to major histologic mode of spread. Potential invasion and widespread metastases.	Irregular color, surface, and border. Variegated color, including red, white, blue, black, gray, brown. Flat or elevated. Eroded or ulcerated. Often <1 cm in size. Most common sites in males are back, then chest. In females are legs, then back (see Fig. 24-2).	Surgical excision and possible sentinel lymph node evaluation depending on the depth. Correlation of survival rate with depth of invasion. Poor prognosis unless diagnosed and treated early. Spreading by local extension, regional lymphatic vessels, and bloodstream. Possible use of adjuvant therapy after surgery if lesion >1.5 mm in depth.
Cutaneous T-Cell Lymphoma		
Origination in skin. Localized chronic, slowly progressing disease. Possibly related to environmental toxins and chemical exposure. Mycosis fungoides (MF) is most common form. Sézary syndrome is an advanced form of MF. Prevalence twice as high in men as in women in United States.	Classic presentation involves three stages—patch (early), plaque, and tumor (advanced). History of persistent macular eruption followed by gradual appearance of indurated erythematous plaques on the trunk that appear similar to psoriasis. Pruritus, lymphadenopathy.	Treatment usually controls symptoms, not curative. UVB, PUVA, corticosteroids, topical nitrogen mustard, radiation therapy in patch and plaque stage disease. Interferon, systemic chemotherapy, extracorporeal photopheresis, romidepsin (Istodax) for progressive disease. Bexarotene (Targretin), denileukin diftitox (Ontak), and vorinostat (Zolinza) for advanced disease. Disease course is unpredictable, 10% will have progressive disease.

5-FU, Fluorouracil; *PUVA,* psoralen ultraviolet A; *UVB,* ultraviolet B.

to the formation of SCC on the mouth and lips. The clinical manifestations of SCC are described in Table 24-3. A biopsy should always be performed when a lesion is suspected to be SCC.

MALIGNANT MELANOMA

Malignant melanoma is a tumor arising in melanocytes, which are the cells producing melanin. Melanoma causes the majority of skin cancer deaths. More than 132,000 new cases are diagnosed every year worldwide. Melanoma has the ability to metastasize to any organ, including the brain and the heart. The death rate of melanoma is 10 times higher in white persons than in African Americans.[4]

Although the exact cause of melanoma is unknown, a combination of environmental and genetic factors is involved. The use of immunosuppressive drugs and a history of dysplastic nevi also increase a person's risk. UV radiation from the sun is

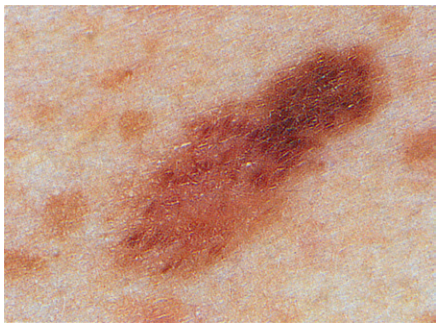

FIG. 24-3 Dysplastic nevus. Irregular border and color.

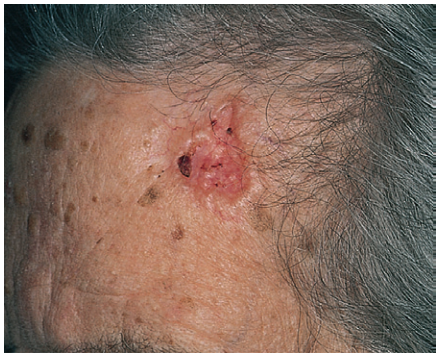

FIG. 24-4 Basal cell carcinoma. Rolled, well-defined border and central erosion.

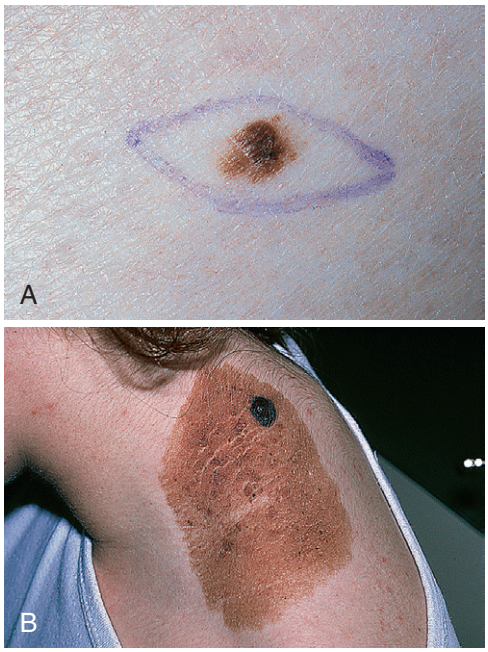

FIG. 24-5 Breslow measurement of tumor thickness. **A,** Thin (0.08 mm) superficial spreading melanoma, good prognosis. **B,** Thick nodular melanoma with lymph node involvement, poor prognosis.

the main cause of melanomas and other skin cancer, but artificial sources of UV radiation, such as sunlamps and tanning booths, also play a role. UV radiation damages the deoxyribonucleic acid (DNA) in skin cells, creating "misspellings" in their genetic code. As a result, these cells are altered.

Although anyone can develop melanoma, the risk is greatest for people who have red or blond hair, blue or light-colored eyes, and light-colored skin that freckles easily. These people have less melanin and thus less protection from UV radiation.

A person may have a genetic predisposition toward getting melanoma. Between 5% and 10% of people who develop melanoma have a first-degree relative (e.g., parent, full sibling) who developed melanoma. This risk increases significantly if multiple relatives have a history of melanoma. Mutated genes have been identified in some families who have a high familial incidence of melanoma.

Clinical Manifestations

About one fourth of melanomas occur in existing nevi or moles; about 20% occur in dysplastic nevi (see Table 24-3). Melanoma frequently occurs on the lower legs and backs in women and on the trunk, head, and neck in men. Because most melanoma cells continue to produce melanin, melanoma tumors are often dark brown or black. Individuals should consult their health care provider immediately if their moles or lesions show any of the clinical signs (ABCDEs) of melanoma (see Fig. 24-2). Any sudden or progressive change or increase in the size, color, or shape of a mole should be evaluated.

When melanoma begins in the skin, it is called *cutaneous melanoma*. Melanoma can also occur in the eye (see Fig. 22-8), meninges, lymph nodes, digestive tract, and anywhere else in the body where melanocytes are found.

Collaborative Care

Pigmented lesions suspicious for melanoma should not be shave-biopsied, shave-excised, or electrocauterized. Handheld screening devices (e.g., MelaFind) can assist the health care provider in determining if a lesion without the obvious ABCDE signs should be biopsied. All suspicious lesions should be biopsied using an excisional biopsy technique.

The most important prognostic factor is tumor thickness at the time of diagnosis. Two methods to determine thickness are currently being used. The *Breslow measurement* indicates the depth of the tumor in millimeters (Fig. 24-5), and the *Clark level* indicates the depth of invasion of the tumor; the higher the number, the deeper the melanoma.

Treatment depends on the site of the original tumor, the stage of the cancer, and the patient's age and general health. The staging of melanoma (stages 0 to IV) is based on tumor size (thickness), nodal involvement, and metastasis. In stage 0 the melanoma is confined to one place (in situ) in the epidermis. Melanoma is nearly 100% curable by excision if diagnosed at stage 0. The 5-year survival rate depends on sentinel node biopsy results, which indicate if metastasis has occurred. If metastasis to other organs is found (stage IV), treatment then becomes palliative.

Initial treatment of malignant melanoma is surgical excision, which may require a skin graft to close (discussed later in the chapter). Melanoma that has spread to the lymph nodes or nearby sites usually requires additional (adjuvant) therapy such as chemotherapy, biologic therapy (e.g., α-interferon, interleukin-2), and/or radiation therapy. Examples of chemotherapy agents used are dacarbazine (DTIC), temozolomide (Temodar), procarbazine (Matulane), carmustine (BCNU), and lomustine (CCNU).

Newer treatment options for patients with metastatic melanoma are ipilimumab (Yervoy), vemurafenib (Zelboraf), dab-

rafenib (Tafinlar), and trametinib (Mekinist). Ipilimumab, a type of immunotherapy, is a monoclonal antibody that locks onto CTLA-4, a protein that normally helps keep T cells in check. By blocking the action of CTLA-4, ipilimumab boosts the immune response against melanoma cells.[9] Vemurafenib, dabrafenib, and trametinib are used for patients whose melanoma tumors express a gene mutation called *BRAF V600*.

Atypical or Dysplastic Nevus

An abnormal nevus pattern called *dysplastic nevus syndrome* identifies an individual at increased risk of melanoma. Approximately 2% to 8% of the white population has moles classified as atypical or dysplastic nevi. **Dysplastic nevi (DN),** or atypical moles, are nevi that are larger than usual (greater than 5 mm across) with irregular borders and various shades of color (see

TABLE 24-4 COMMON BACTERIAL INFECTIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Impetigo		
Group A β-hemolytic streptococci, staphylococci, or combination of both. Associated with poor hygiene. Primary or secondary infection. Contagious.	Vesiculopustular lesions that develop thick, honey-colored crust surrounded by erythema. Pruritic. Most common on face as primary infection.	*Systemic antibiotics:* Oral penicillin, benzathine penicillin, erythromycin. *Local treatment:* Warm saline or aluminum acetate soaks followed by soap-and-water removal of crusts. Topical antibiotic cream or ointment (mupirocin [Bactroban], retapamulin [Altabax]). With no treatment, glomerulonephritis possible when streptococcal strain nephritogenic. Meticulous hygiene essential.
Folliculitis		
Usually staphylococci. Present in areas subjected to friction, moisture, rubbing, or oil. Increased incidence in patients with diabetes mellitus.	Small pustule at hair follicle opening with minimal erythema. Development of crusting. Most common on scalp, beard, extremities in men. Tender to touch.	Antistaphylococcal soap (e.g., Hibiclens, Lever 2000, Dial) and water cleansing. Topical antibiotics (e.g., mupirocin). Warm compresses of water or aluminum acetate solution. Healing usually without scarring. If lesions extensive and deep, possible scarring, loss of involved hair follicles, and treatment with systemic antibiotics.
Furuncle		
Deep infection with staphylococci around hair follicle, often associated with severe acne or seborrheic dermatitis.	Tender erythematous area around hair follicle. Draining pus and core of necrotic debris on rupture. Most common on face, back of neck, axillae, breasts, buttocks, perineum, thighs. Painful.	Incision and drainage, possibly with packing, antibiotics, meticulous care of involved skin, frequent application of warm, moist compresses.
Furunculosis		
Increased incidence in patients who are obese, diabetic, chronically ill, or regularly exposed to moisture, pressure.	Lesions as above. Malaise, regional adenopathy, elevated body temperature.	Incision and drainage of painful nodules. Warm, moist compresses to erythematous plaques. Systemic antibiotic after culture and sensitivity study of drainage (usually semisynthetic, penicillinase-resistant, oral penicillin such as cloxacillin and oxacillin). Measures to reduce surface staphylococci include antimicrobial cream to nares, armpits, and groin and antiseptic to entire skin. Often recurrent with scarring. Prevention or correction of predisposing factors. Meticulous personal hygiene.
Carbuncle		
Multiple, interconnecting furuncles.	Many pustules appearing in erythematous area, most common at nape of neck.	Treatment same as for furuncles. Often recurrent despite production of antibodies. Healing slow with scar formation.
Cellulitis		
Inflammation of subcutaneous tissues. Possibly secondary complication or primary infection. Often following break in skin. *Staphylococcus aureus* and streptococci usual causative agents. Deep inflammation of subcutaneous tissue from enzymes produced by bacteria.	Hot, tender, erythematous, and edematous area with diffuse borders. Chills, malaise, and fever (Fig. 24-6).	Moist heat, immobilization and elevation, systemic antibiotic therapy, hospitalization if severe. Progression to gangrene possible if untreated.
Erysipelas		
Superficial cellulitis primarily involving the dermis. Group A β-hemolytic streptococci.	Red, hot, sharply demarcated plaque that is indurated and painful. Bacteremia possible. Most common on face and extremities. Toxic signs, such as fever, ↑ white blood cell count, headache, malaise.	Systemic antibiotics, usually penicillin. Hospitalization often required.

Fig. 24-3). These nevi may have the same ABCDE characteristics as melanoma, but they are less pronounced. The earliest clinically detectable abnormality associated with DN is an increase in the number of morphologically normal-looking nevi that occur in children between 2 and 6 years of age. Another proliferation occurs around adolescence, and new nevi continue to appear throughout the person's life. The average number of normal nevi in adults is about 40. Individuals with DN may have more than 100 normal-appearing nevi. Obtain a detailed family history related to melanoma and DN. The risk of developing melanoma doubles with the presence of one DN, and having multiple DN increases the risk up to 12-fold.

SKIN INFECTIONS AND INFESTATIONS

Bacterial Infections

The skin provides an ideal environment for bacterial growth with an abundant supply of nutrients, water, and warm temperature. Bacterial infection occurs when the balance between the host and the microorganisms is altered. This can occur as a primary infection after a break in the skin. It can also occur as a secondary infection to already damaged skin or as a sign of a systemic disease (Table 24-4). *Staphylococcus aureus* and group A β-hemolytic streptococci are the major types of bacteria responsible for primary and secondary skin infections.

Healthy persons can develop bacterial skin infections. Predisposing factors such as moisture, obesity, atopic dermatitis, systemic corticosteroids and antibiotics, and chronic disease such as diabetes mellitus all increase the likelihood of infection. Good hygiene practices and general good health inhibit bacterial infections. If an infection is present, the resulting drainage is infectious. Good skin hygiene and infection control practices are necessary to prevent the spread of the infection.

Viral Infections

Viral infections of the skin are as difficult to treat as viral infections anywhere in the body. When a virus infects a cell, a skin lesion may develop. Lesions can also result from an inflammatory response to viral infections. Herpes simplex, herpes zoster (Fig. 24-7), and warts (Fig. 24-8) are the most common viral infections affecting the skin (Table 24-5).

FIG. 24-6 Cellulitis with characteristic erythema, tenderness, and edema.

FIG. 24-7 Herpes zoster (shingles) on the anterior chest, classic dermatomal distribution.

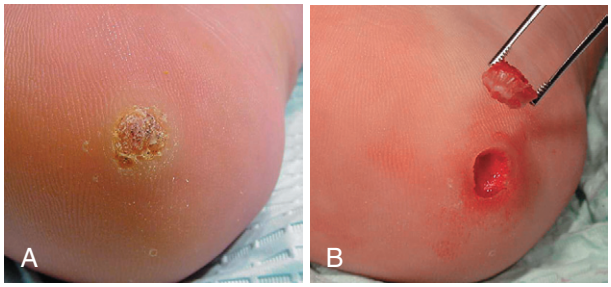

FIG. 24-8 Plantar wart. **A,** Keratotic lesion. **B,** After excision.

Fungal Infections

Because of the large number of fungi that are present everywhere, exposure to some pathologic varieties may occur. Skin, hair, and nails may all become infected with fungi, including candidiasis (see eFig. 24-2 available on the website for this chapter) and tinea unguium (Fig. 24-9). Common fungal infections of the skin are presented in Table 24-6. Most infections are relatively harmless in healthy adults, but they can be embarrassing and distressing to the patient.[10]

The microscopic examination of the scraping of suspicious scaly skin lesions in 10% to 20% potassium hydroxide (KOH) is an inexpensive diagnostic measure to determine the presence of a fungus. The appearance of microscopic hyphae (threadlike structures) is indicative of a fungal infection.

FIG. 24-9 Tinea unguium (onychomycosis). Fungal infection of toenails. Crumbly, discolored, and thickened nails.

TABLE 24-5 COMMON VIRAL INFECTIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Herpes Simplex Virus (HSV) Types 1 and 2 Oral or genital HSV infections can be serotyped as either HSV-1 or HSV-2. Both are recurrent lifelong viral infections. Exacerbated by sunlight, trauma, menses, stress, and systemic infection. Contagious to those not previously infected. Transmission by respiratory droplets or virus-containing fluid (e.g., saliva, cervical secretions). Infection in one area is readily transmitted to another site by contact.	*First episode:* Symptoms occurring 3-7 days or more after contact, Painful local reaction. Single or grouped vesicles on erythematous base. Systemic symptoms (e.g., fever, malaise) possible or no symptoms possible. *Recurrent:* Small. Recurrence in similar spot. Characteristic grouped vesicles on erythematous base.	Symptomatic medication. Soothing, moist compresses. White petrolatum to lesions. Scarring not usual result. Antiviral agents such as acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex). Vaccine not currently available for HSV-1 or HSV-2.
Herpes Zoster (Shingles) Activation of the varicella-zoster virus. Incidence increases with age. Potentially contagious to anyone who has not had varicella or who is immunosuppressed. >1 million cases annually in the United States.	Linear distribution along a dermatome of grouped vesicles and pustules on erythematous base resembling chickenpox. Usually unilateral on trunk, face, and lumbosacral areas. Burning, pain, and neuralgia preceding outbreak. Mild to severe pain during outbreak (see Fig. 24-7).	Symptomatic. Antiviral agents such as acyclovir, famciclovir, and valacyclovir within 72 hr to prevent postherpetic neuralgia. Wet compresses, silver sulfadiazine (Silvadene) to ruptured vesicles. Analgesia. Mild sedation at bedtime. Gabapentin (Neurontin) to treat postherpetic neuralgia. Usually heals without complications, but scarring and postherpetic neuralgia possible. Vaccine (Zostavax) to prevent shingles is available for adults ≥50 yr.
Verruca Vulgaris Caused by human papillomavirus (HPV). Spontaneous disappearance in 1-2 yr possible. Mildly contagious by autoinoculation. Specific response dependent on body part affected. Prevalence greater in youth and immunosuppressed.	Circumscribed, hypertrophic, flesh-colored papule limited to epidermis. Painful on lateral compression.	Multiple treatments, including surgery using blunt dissection with scissors or curette. Liquid nitrogen therapy. Blistering agent (cantharidin). Keratolytic agent (salicylic acid). CO_2 laser destruction.
Plantar Warts Caused by HPV.	Wart on bottom surface of foot, growing inward because of pressure of walking or standing. Painful when pressure applied. Interrupted skin markings. Cone shaped with black dots (thrombosed vessels) when wart removed (see Fig. 24-8).	Topical immunotherapy (imiquimod), cryosurgery, salicylic acid, duct tape.

TABLE 24-6 COMMON FUNGAL INFECTIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Candidiasis Caused by *Candida albicans*. Also known as moniliasis. 50% of adults symptom-free carriers. Appears in warm, moist areas such as groin area, oral mucosa, and submammary folds. HIV infection, chemotherapy, radiation, and organ transplantation related to depression of cell-mediated immunity that allows yeast to become pathogenic.	*Mouth:* White, cheesy plaque, resembles milk curds. *Vagina:* Vaginitis with red, edematous, painful vaginal wall, white patches. Vaginal discharge. Pruritus. Pain on urination and intercourse. *Skin:* Diffuse papular erythematous rash with pinpoint satellite lesions around edges of affected area (see eFig. 24-2).	Microscopic examination and culture. Azole antifungals (e.g., fluconazole, ketoconazole) or other specific medication such as vaginal suppository or oral lozenge. Sexual abstinence or use of condom. Skin hygiene to keep area clean and dry. Powder is effective on nonmucosal surfaces of skin to prevent recurrence.
Tinea Corporis Various dermatophytes, commonly referred to as ringworm.	Typical annular (ringlike) scaly appearance, well-defined margins. Erythematous.	Cool compresses. Topical antifungals for isolated patches. Creams or solutions of miconazole, ketoconazole, clotrimazole, butenafine.
Tinea Cruris Various dermatophytes, commonly referred to as jock itch.	Well-defined scaly plaque in groin area. Does not affect mucous membranes.	Topical antifungal cream or solution.
Tinea Pedis Various dermatophytes, commonly referred to as athlete's foot.	Interdigital scaling and maceration. Scaly plantar surfaces sometimes with erythema and blistering. May be pruritic. Possibly painful.	Topical antifungal cream, gel, solution, spray, or powder.
Tinea Unguium (Onychomycosis) Various dermatophytes. Incidence increases with age.	Only few nails on one hand may be affected. Toenails more commonly affected. Scaliness under distal nail plate. Brittle, thickened, broken, or crumbling nails with yellowish discoloration (see Fig. 24-9).	Oral antifungal (terbinafine [Lamisil], itraconazole [Sporanox]). Topical antifungal cream or solution (minimal effectiveness) if unable to tolerate systemic treatment. Thinning of toenails if needed. Nail avulsion (removal) is an option.

TABLE 24-7 COMMON INFESTATIONS AND INSECT BITES

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Bees and Wasps *Hymenoptera* species.	Intense, burning, local pain. Swelling and itching. Severe hypersensitivity possibly leading to anaphylaxis.	Cool compresses. Local application of antipruritic lotion. Antihistamines if indicated. Usually uneventful recovery.
Bedbugs *Cimicidae* species. Feeding periodic, usually at night. Present in furniture, walls during day.	Wheal surrounded by vivid flare. Firm urticaria transforming into persistent lesion. Severe pruritus. Often grouped in threes appearing on uncovered parts of body.	Bedbug controlled by chlorocyclohexane. Lesions usually requiring no treatment. Severe itching possibly requiring use of antihistamines or topical corticosteroids.
Pediculosis (Head Lice, Body Lice, Pubic Lice) *Pediculus humanus* var. *capitis, Pediculus humanus* var. *corporis, Phthirus pubis.* Obligate parasites that suck blood, leave excrement and eggs on skin and hair, live in seams of clothing (if body lice) and in hair as nits. Transmission of pubic lice often by sexual contact.	Minute, red, noninflammatory. Points flush with skin. Progression to papular wheal-like lesions. Pruritus. Secondary excoriation, especially parallel linear excoriations in intrascapular region. Firmly attached to hair shaft in head and body lice.	γ-Benzene hexachloride or pyrethrins to treat various parts of body. Application as directed. Spinosad (Natroba) topical suspension 0.9% to treat scalp and hair. Close contacts (e.g., bed partners and playmates) should be screened and treated. Do not share head gear.
Scabies *Sarcoptes scabiei.* Mite penetrates stratum corneum, deposits eggs. Allergic reaction to eggs, feces, mite parts. Transmission by direct physical contact, only occasionally by shared personal items. Rarely seen in dark-skinned people.	Severe itching, especially at night, usually not on face. Presence of burrows, especially in interdigital webs, flexor surface of wrists, genitalia, and anterior axillary folds. Erythematous papules (may be crusted), possible vesiculation, interdigital web crusting (see eFig. 24-3).	5% permethrin topical lotion, one overnight application with second application 1 wk later, may yield 95% eradication. Treat all family members, treat environment with plastic covering for 5 days, launder all clothes and linen with bleach. Treat sexual partner. Antibiotics if secondary infections present. Possible residual pruritus up to 4 wk after treatment. Recurrence possible if inadequately treated.
Ticks *Borrelia burgdorferi* (spirochete transmitted by ticks in certain areas) causes Lyme disease. Endemic areas include Northeast, Mid-Atlantic states, parts of Midwest and West (see Chapter 65).	Spreading, ringlike rash 3-4 wk after bite (see Fig. 65-7). Rash commonly in groin, buttocks, axillae, trunk, and upper arms and legs. Warm, itchy, or painful rash. Flu-like symptoms. Cardiac, arthritic, and neurologic manifestations possible. Unreliable laboratory test. No acquired immunity.	Oral antibiotics, such as doxycycline, tetracycline. IV antibiotics for arthritic, neurologic, and cardiac symptoms. Rest and healthy diet. Most patients recover.

Infestations and Insect Bites

The possibilities for exposure to *infestations* (harboring insects or worms) and insect bites are numerous. In many instances an allergy to the venom plays a major role in the reaction. In other cases the clinical manifestations are a reaction to the eggs, feces, or body parts of the invading organism. Some individuals react with a severe hypersensitivity (anaphylaxis), which can be life threatening. (Anaphylaxis is discussed in Chapter 14.)

Prevention of insect bites by avoidance or by the use of repellents is somewhat effective. Meticulous hygiene related to personal articles, clothing, bedding, and examination and care of pets, as well as careful selection of sexual partners, can reduce the incidence of infestations. Routine skin inspection is necessary in geographic areas where there is a risk of tick bites (Table 24-7). (Lyme disease, which is caused by a tick, is discussed in Chapter 65.)

ALLERGIC DERMATOLOGIC PROBLEMS

Dermatologic problems associated with allergies and hypersensitivity reactions may present a challenge to the clinician (Table 24-8). The pathophysiology related to allergic and contact dermatitis is discussed in Chapter 14. A careful family history and discussion of exposure to possible offending agents can provide valuable data. Patch testing involves the application of allergens to the patient's skin (usually on the back) for 48 hours with reevaluation at 96 hours. Test sites are examined for erythema, papules, vesicles, or all of these. Patch testing is used to aid in determining possible causative agents (see Fig. 23-10). The best treatment of allergic dermatitis is avoidance of the causative agent. The extreme pruritus of contact dermatitis and its potential for chronicity make it a frustrating problem for you and the patient, especially if the offending agent cannot be identified.

BENIGN DERMATOLOGIC PROBLEMS

Although the list of benign dermatoses is extensive, some of the most commonly seen and distressing problems include acne vulgaris (Fig. 24-10), psoriasis (Fig. 24-11), and seborrheic keratoses (see eFig. 24-4 available on the website for this chapter). Benign problems are summarized in Table 24-9.

Psoriasis is a common benign disorder that currently affects 125 million people worldwide.[11] The disease usually develops in individuals between 15 and 35 years old. One third of people

TABLE 24-8 COMMON ALLERGIC CONDITIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Allergic Contact Dermatitis		
Manifestation of delayed hypersensitivity, absorbed agent acting as antigen, sensitization after one or more exposures, appearance of lesions 2-7 days after contact with allergen.	Red papules and plaques. Sharply circumscribed with occasional vesicles. Usually pruritic. Area of dermatitis frequently takes shape of causative agent (e.g., metal allergy and bandlike dermatitis on ring finger) (see Fig. 14-9).	Topical or oral corticosteroids, antihistamines. Skin lubrication. Elimination of contact allergen. Avoidance of irritating affected area. Systemic corticosteroids if sensitivity severe.
Urticaria		
Usually allergic phenomenon. Erythema and edema in upper dermis resulting from a local increase in permeability of capillaries (usually from histamine release).	Spontaneously occurring, raised or irregularly shaped wheals, varying size, usually multiple. A single lesion usually resolves in 24 hr. Can occur anywhere on the body.	Removal of triggering agent, if known. Oral antihistamine therapy. Possibly systemic corticosteroids.
Drug Reaction		
May be caused by any drug that acts as antigen and causes hypersensitivity reaction. Certain drugs (e.g., penicillin) more likely to cause reactions. Not all reactions are allergic, some are intolerance (e.g., gastric upset).	Rash of any morphology. Often red, macular and papular, semiconfluent, generalized rash with abrupt onset. Appearance as late as 14 days after cessation of drug. Possibly pruritic. Some reactions may be life threatening requiring immediate and intensive care.	Withdrawal of drug if possible. Antihistamines, topical or systemic corticosteroids may be necessary depending on severity of symptoms.
Atopic Dermatitis		
Genetically influenced, chronic, relapsing disease associated with immunologic irregularity involving inflammatory mediators, exaggerated by a cutaneous response to environmental allergens. Associated with allergic rhinitis and asthma.	Multiple presentations, including acute, subacute, and chronic stages. All are pruritic. *Acute stage* with bright erythema, oozing vesicles, with extreme pruritus. *Subacute stage* with scaly, light red to red-brown plaques. *Chronic stage* with thickened skin with accentuation of skin markings (lichenification), possible hypopigmentation or hyperpigmentation. Dry skin. Common in antecubital and popliteal space.	Lubrication of dry (xerotic) skin, restoration of skin barrier function. Topical immunomodulators (pimecrolimus [Elidel], tacrolimus [Protopic]). Corticosteroids, phototherapy for severe inflammation and pruritus. Reduction of stress reduces flares. Antibiotics for secondary infection as needed.

with psoriasis have at least one relative with the disease. Diagnosis is often based on the appearance of the skin (see Fig. 24-11). Most people have mild disease that affects at least 3% of the body. Severe disease is when psoriasis affects more than 10% of the body. Patients with severe disease often have a weakened immune system and are at risk for cardiovascular disease. Monitor the laboratory values (e.g., cholesterol, triglycerides) of patients with severe psoriasis to assist in early detection and intervention strategies for cardiovascular disease.

The chronicity of psoriasis can be severe and disabling as people withdraw from social contacts because of visible lesions. Quality of life is also negatively affected. Psoriatic arthritis affects 10% to 30% of all persons with psoriasis. (Psoriatic arthritis is discussed in Chapter 65.)

DRUG ALERT: Isotretinoin (Accutane)

- Can cause serious damage to fetus
- Blood donation prohibited for those taking the drug and for 1 month after treatment ends
- Contraindicated in women who are pregnant or who are intending to become pregnant while on the drug
- Linked to liver function test abnormalities

DISEASES WITH DERMATOLOGIC MANIFESTATIONS

Dermatologic manifestations of various diseases are listed in eTable 24-1 (available on the website for this chapter). Always consider the possibility that a particular skin manifestation is a clue to an internal, less obvious disease or disorder.

FIG. 24-10 Acne vulgaris. Papules and pustules.

FIG. 24-11 Psoriasis. Characteristic inflammation and scaling.

TABLE 24-9 COMMON BENIGN CONDITIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Acne Vulgaris		
Inflammatory disorder of sebaceous glands. More common in teenagers but possible development and persistence in adulthood. Flare can occur with use of corticosteroids and androgen-dominant birth control pills and before menses.	Noninflammatory lesions, including open comedones (blackheads) and closed comedones (whiteheads). Inflammatory lesions, including papules and pustules. Most common on face, neck, and upper back (see Fig. 24-10).	Mechanical removal of multiple lesions with comedo extractor. Topical benzoyl peroxide or other antimicrobials. Veltin gel (clindamycin and tretinoin). Topical retinoids, systemic antibiotics. Aim of treatment to suppress new lesions and minimize scarring. Spontaneous remission possible. Often improvement with exposure to sun. May last many years. Use of isotretinoin (Accutane) for severe nodulocystic acne to possibly provide lasting remission (see Drug Alert on p. 438 for contraindications). Pregnancy tests, monitoring of liver function, cholesterol, triglycerides, and for depression essential.
Nevi (Moles)		
Grouping of normal cells derived from melanocyte-like precursor cells.	Hyperpigmented areas that vary in form and color. Flat, slightly elevated, verrucoid, polypoid, dome-shaped, sessile, or papillomatous. Preservation of normal skin markings. Hair growth possible.	No treatment necessary except for cosmetic reasons. Skin biopsy for suspicious nevi.
Psoriasis		
Autoimmune chronic dermatitis that involves excessively rapid turnover of epidermal cells. Family predisposition. Usually develops before age 40.	Sharply demarcated silvery scaling plaques on reddish colored skin commonly on the scalp, elbows, knees, palms, soles, and fingernails. Itching, burning, pain. Localized or general, intermittent or continuous. Symptoms vary in intensity from mild to severe (see Fig. 24-11).	Goal to reduce inflammation and suppress rapid turnover of epidermal cells. No cure, but control is possible. *Topical treatments:* corticosteroids, tar, calcipotriene, anthralin. Intralesional injection of corticosteroids for chronic plaques. *Systemic treatments:* natural or artificial UVB. PUVA (UVA with topical or systemic photosensitizer (psoralen). Antimetabolite (methotrexate), retinoid (acitretin), immunosuppressant (cyclosporine), biologic therapy (adalimumab [Humira], alefacept [Amevive], etanercept [Enbrel], infliximab [Remicade], ustekinumab [Stelara]) for moderate to severe plaque disease.
Seborrheic Keratoses		
Benign, familial, exact etiology unknown. Usually occur after age 40, increase in number with age.	Irregularly round or oval, often verrucous papules or plaques. Well-defined shape, appearance of being stuck on. Increase in pigmentation with time. Usually multiple and possibly itchy (see eFig. 24-4).	Removal by curettage or cryosurgery for cosmetic reasons or to eliminate source of irritation. Biopsy if unable to distinguish from melanoma.
Acrochordons (Skin Tags)		
Common after midlife. Appearance on neck, axillae, and upper trunk secondary to mechanical friction or redundant skin (associated with obesity).	Small, skin-colored, soft, pedunculated papules. May become irritated.	No treatment medically necessary. Surgical removal when needed. Usually just snipping without anesthesia.
Lipoma		
Benign tumor of adipose tissue, often encapsulated, most common in 40- to 60-yr-old age-group.	Rubbery, compressible, round mass of adipose tissue. Single or multiple. Variable in size, possibly extremely large. Most common on trunk, back of neck, and forearms.	Usually no treatment, biopsy to differentiate from liposarcoma, excision usual treatment (when indicated).
Lentigo		
Increased number of normal melanocytes in basal layer of epidermis related to sun exposure and aging. Also called "liver spots" or "age spots."	Hyperpigmented, brown to black macule or patch (flat lesion) on sun-exposed areas.	Evaluate carefully for progression. Treatment only for cosmetic purposes: liquid nitrogen, laser resurfacing. May recur. Biopsy when suspicious of melanoma.

PUVA, Psoralen ultraviolet A; *UBA,* ultraviolet A; *UVB,* ultraviolet B.

COLLABORATIVE CARE DERMATOLOGIC PROBLEMS

Diagnostic Studies

A careful history is of prime importance in the diagnosis of skin problems. The clinician must be skilled at detecting any evidence that could lead to the cause of many different skin diseases and conditions. After a careful history and physical examination, inspect individual lesions. Based on the history, physical examination, and appropriate diagnostic tests, either medical, surgical, or combination therapy is planned.

Collaborative Therapy

Many different treatment methods are used in dermatology. Advances in this field have brought relief to many previously chronic, untreatable conditions. Many of the specific therapeutic treatments require specialized equipment and are usually reserved for use by the dermatologist. Many clinicians prescribe drug therapy. The effectiveness of topical therapy can often be related to the base (or vehicle) in which the medication is prepared. Table 24-10 summarizes the common agents used as bases for topical preparations and their therapeutic considerations.

Phototherapy. Ultraviolet light (UVL) of different wavelengths may be used to treat many dermatologic conditions, including psoriasis, cutaneous T-cell lymphoma, atopic dermatitis, vitiligo, and pruritus. Light sources available to treat skin problems include broadband UVB, narrowband UVB, and long-wave UV (UVA1). One form of phototherapy involves the use of psoralen plus UVA light (PUVA). The photosensitizing drug psoralen is given to patients for a prescribed amount of time before exposure to UVA (see eFig. 24-5 available on the website for this chapter).

Treatments are generally given two to four times a week. Side effects of oral psoralen include nausea and vomiting, sunburn, and persistent pruritus. Perform frequent skin assessments on all patients receiving phototherapy, since erythema is a side effect of treatment. Topical corticosteroids may be given for painful erythema. Psoralen should be used with extreme caution in patients with liver or renal disease because slower metabolism and excretion can lead to prolonged photosensitivity.

Caution patients about the potential hazards of using photosensitizing chemicals and further exposure to UV rays from sunlight or artificial UVL during the course of phototherapy. Protective eyewear that blocks 100% of UVL is prescribed for patients receiving PUVA because psoralen is absorbed by the lens of the eye. The eyewear is used to prevent cataract formation. Instruct patients to use the eyewear for 24 hours after taking the medication when outdoors or near a bright window because UVA penetrates glass. Ongoing monitoring of these patients is essential because of the immunosuppressive effects of PUVA, including an increased risk of squamous and basal cell carcinomas and melanoma.

Photodynamic therapy is a special type of phototherapy that may be used in the treatment of actinic keratosis and malignant skin tumors.[12] This therapy uses a photosensitizing agent in a different way than some phototherapy treatments to selectively cause tumor necrosis.

Radiation Therapy. The use of radiation for the treatment of basal and squamous cell carcinomas and malignant melanoma varies greatly according to local practice and availability.[13] Even if radiation therapy is planned, a biopsy must first be performed to obtain a pathologic diagnosis.

Radiation to malignant cutaneous lesions may be given to reduce tumor size or in palliative treatment. One advantage of this therapy is minimal damage to surrounding tissue, which is of prime consideration in locations such as the nose, eyelids, and canthal areas. Careful shielding is necessary to prevent ocular lens damage if the irradiated area is around the eyes. Radiation therapy is particularly effective for the older adult or debilitated patient who cannot tolerate even a minor surgical procedure.

Radiation therapy usually requires multiple visits to a radiology department. It can produce permanent hair loss *(alopecia)* of the irradiated areas. Other adverse effects, depending on anatomic location and dose of radiation delivered, include telangiectasia, atrophy, hyperpigmentation, depigmentation, ulceration, hearing loss, ocular damage, atrophy, and mucositis. (Radiation therapy is discussed in Chapter 16.)

Total-body skin irradiation (body is bombarded with high-energy electrons) is one treatment for cutaneous T-cell lymphoma. Treatment follows a lengthy course and causes premature aging of the skin. Patients experience varying degrees of permanent alopecia and radiation dermatitis with a transient loss of sweat gland function.

Laser Technology. Laser treatment is expanding rapidly as an efficient surgical tool for many types of dermatologic problems (Table 24-11). Lasers are able to produce measurable, repeatable, consistent zones of tissue damage. They can cut, coagulate, and vaporize tissue to some degree. The wavelength determines the type of delivery system used and the intensity of the energy delivered.

The surgical use of laser energy requires a focusing device to produce a small, high-density spot of energy. Written policies and procedures should cover laser safety and be reviewed by all personnel working with laser equipment. Laser light does not

TABLE 24-10 DRUG THERAPY

Common Bases for Topical Medications

Agent	Therapeutic Considerations
Powder	Promotion of dryness. Lubricates skinfold areas to prevent irritation. Base for antifungal preparations. Protect patient from inhaling
Lotion	Oil and water emulsions. Cooling and drying. Some leave residual powder film after evaporation of water. Useful in subacute pruritic eruptions
Cream	Emulsions of oil and water. Most common base for topical medications. Lubrication and protection
Ointment	Oil with differing amounts of water added in suspension. Lubrication and prevention of dehydration. Petrolatum most common
Paste	Mixture of powder and ointment, used when drying effect necessary because moisture is absorbed
Gel	Nongreasy combination of propylene glycol and water. May contain alcohol

accumulate in body cells and cannot cause cumulative cellular changes or damage.

Several types of lasers are available in most offices and hospitals. The CO_2 laser, the most common, has numerous applications as a vaporizing and cutting tool for most tissues. The argon laser emits light that is primarily absorbed by hemoglobin and helps in the treatment of vascular and other pigmented lesions. Other, less common lasers include the use of copper and gold vapors and neodymium:yttrium-aluminum-garnet (Nd:YAG).

Drug Therapy

Antibiotics. Antibiotics are used both topically and systemically to treat dermatologic problems, and are often used in combination. When using topical antibiotics, apply a thin film lightly to clean skin. Common OTC topical antibiotics include bacitracin-neomycin-polymyxin (Neosporin), bacitracin, and polymyxin B. Many health care providers do not recommend Neosporin because it often causes allergic contact dermatitis. Prescription topical antibiotics include mupirocin (for superficial *Staphylococcus* infections such as impetigo), gentamicin (used for *Staphylococcus* and most gram-negative organisms), and erythromycin (used for gram-positive cocci [staphylococci and streptococci] and gram-negative cocci and bacilli). Topical erythromycin and clindamycin (Cleocin solutions or gels) are used in the treatment of acne vulgaris. Topical metronidazole is used to treat rosacea and bacterial vaginosis. Many of the more popular systemic antibiotics are not used topically because of the danger of allergic contact dermatitis.

If there are manifestations of systemic infection, a systemic antibiotic should be used. Systemic antibiotics are useful in the treatment of bacterial infections and acne vulgaris. The most frequently used are synthetic sulfur, penicillin, minocycline, erythromycin, and tetracycline (or doxycycline). These drugs are particularly useful for erysipelas, cellulitis, carbuncles, and severe infected eczema. Culture and sensitivity of the lesion can guide the choice of antibiotic. Patients require drug-specific instructions on the proper technique of taking or applying antibiotics. For instance, oral tetracycline must be taken on an empty stomach. It should never be taken within 1 hour before consuming a dairy product or 2 hours after, since this would interfere with its absorption.

Corticosteroids. Corticosteroids are particularly effective in treating a wide variety of dermatologic conditions and can be used topically, intralesionally, or systemically. Topical corticosteroids are used for their local antiinflammatory and antipruritic effects. Attempts to diagnose a skin problem should be made *before* a corticosteroid preparation is applied, since corticosteroids may alter the clinical manifestations. Once a sufficient amount of medication is dispensed, limits should be set on the duration and frequency of application.

The potency of a particular preparation is related to the concentration of active drug. With prolonged use, more potent corticosteroid formulations can cause adrenal suppression, especially if a large surface area is covered and occlusive dressings are used. Over time, high-potency corticosteroids may produce side effects, including atrophy of the skin resulting from impaired cell mitosis, capillary fragility, and susceptibility to bruising. In general, dermal and epidermal atrophy does not occur until a corticosteroid has been used for 2 to 3 weeks. If drug use is discontinued at the first sign of atrophy, recovery usually occurs in several weeks. Rosacea eruptions and severe exacerbations of acne vulgaris may also occur. Rebound dermatitis is not uncommon when therapy is stopped. This can be reduced by tapering the use of high-potency topical corticosteroids when improvement is noted.

Low-potency corticosteroids such as hydrocortisone act more slowly but can be used for a longer time without producing serious side effects. Low-potency corticosteroids are safe to use on the face and intertriginous areas, such as the axillae and groin.

The most potent delivery system for a topical corticosteroid is an ointment form. Creams and ointments should be applied in thin layers and slowly massaged into the site one to three times a day as prescribed. Accurate and adequate topical therapy is often the key to a successful outcome.

Intralesional corticosteroids are injected directly into or just beneath the lesion. This method provides a reservoir of medication with an effect lasting several weeks to months. Intralesional injection is commonly used in the treatment of psoriasis, alopecia areata (patchy hair loss), cystic acne, hypertrophic scars, and keloids. Triamcinolone acetonide (Kenalog) is the most common drug used for intralesional injection.

Systemic corticosteroids can have remarkable results in the treatment of dermatologic conditions. However, they often have undesirable systemic effects (see Chapter 50). Corticosteroids can be administered as short-term therapy for acute conditions such as contact dermatitis caused by poison ivy. Long-term corticosteroid therapy for dermatologic conditions is reserved for severe disease such as bullous (blistering) disorders.

Antihistamines. Oral antihistamines are used to treat conditions that exhibit urticaria, angioedema, and pruritus.[14] Dermatologic problems such as atopic dermatitis, allergic dermatitis, and other allergic cutaneous reactions can be reduced with the use of histamine blockers. Antihistamines compete with histamine for the receptor site, thus preventing its effect. Antihistamines may have anticholinergic and/or sedative effects. Several different antihistamines may have to be tried before the satisfactory therapeutic effect is achieved. Sedating antihistamines, such as hydroxyzine (Atarax) and diphenhydramine (Benadryl), are often preferred for pruritic conditions because the tranquilizing and sedative effects offer symptomatic relief. Warn the patient about sedative effects, a particular problem when driving or operating heavy machinery. Antihistamines such as loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec) bind to peripheral histamine receptors, providing antihistamine action without sedation. These nonsedating antihistamines are not effective for controlling pruritus. Antihistamines should be used with particular caution in older adults because of their long half-life and their anticholinergic effects.

Topical Fluorouracil. Fluorouracil (5-FU) is a topical cytotoxic agent with selective toxicity for sun-damaged cells. 5-FU is available in four strengths (0.5%, 1%, 2%, and 5%) and is used for the treatment of premalignant (especially actinic keratosis) and some malignant skin diseases. Because systemic absorption of the drug is minimal, systemic side effects are virtually nonexistent. Patient compliance is a consideration in the use of 5-FU. The medication produces erythema and pruritus within 3 to 5 days and painful, eroded areas over the damaged skin within 1 to 3 weeks, depending on skin thickness at the site. Low-potency topical corticosteroids are often prescribed to be applied 20 minutes after 5-FU to reduce erythema and pruritus and increase patient adherence with therapy. Treatment must continue with applications one (only in the 0.5% strength) or two times a day for 2 to 6 weeks. Healing may take up to 4 weeks after medication is stopped.

Because 5-FU is a photosensitizing drug, instruct the patient to avoid sunlight during treatment. Teach patients about the effect of the medication and that they will look worse before they look better. Adherence depends on thoroughness of your instruction, which should include a written handout. After effective treatment, treated skin is smooth and free of actinic keratosis. Actinic keratosis may recur in treated areas, and multiple courses of chemotherapy may be necessary over the years for individuals with severely sun-damaged skin.

Immunomodulators. Topical immunomodulators, such as pimecrolimus (Elidel) and tacrolimus (Protopic), are used to treat atopic dermatitis. They work by suppressing an overreactive immune system. The side effects are minimal and may include a transient burning or feeling of heat at the application site. An increased risk of skin cancer and precancerous lesions may be associated with these drugs.

Another topical immunomodulator, imiquimod, acts to stimulate the production of α-interferon and other cytokines to enhance cell-mediated immunity. It boosts the immune response only where applied and is safe for transplant patients. This medication is used for external genital warts, actinic keratoses, and superficial BCC. Most patients using this cream experience skin reactions, including redness, swelling, blistering, excoriations, peeling, itching, and burning.

Diagnostic and Surgical Therapy

Skin Scraping. Scraping is done with a scalpel blade to obtain a sample of surface cells (stratum corneum) for microscopic inspection and diagnosis. The most common tests of skin scrapings are potassium hydroxide (KOH) for fungus and mineral oil examination for scabies.

Electrodesiccation and Electrocoagulation. Electrical energy can be converted to heat with the tip of an electrode. This results in tissue being destroyed by burning. The major uses of this type of therapy are coagulation of bleeding vessels to obtain hemostasis and destruction of small *telangiectasias* (dilation of groups of superficial capillaries and venules). *Electrodesiccation* usually involves more superficial destruction, and a monopolar electrode is used. *Electrocoagulation* has a deeper effect, with better hemostasis and an increased possibility of scarring. A dipolar electrode is used for electrocoagulation.

Curettage. Curettage is the removal and scooping away of tissue using an instrument with a circular cutting edge attached to a handle (see eFig. 24-6 available on the website). Although the curette is not usually strong enough to cut normal skin, it is useful for removing many types of small, soft skin tumors and superficial lesions, such as warts, actinic keratoses, and small basal and squamous cell carcinomas. The area to be curetted is anesthetized before the procedure. Hemostasis is obtained by one of several methods: electrodesiccation, ferric subsulfate (Monsel solution), gelatin foam, aluminum chloride (Drysol), or a gauze pressure dressing. A small scar and hypopigmentation can result. The curetted tissue should be sent for biopsy.

Punch Biopsy. Punch biopsy is a common dermatologic procedure used to obtain a tissue sample for histologic study or to remove small lesions (Fig. 24-12). It is generally reserved for lesions smaller than 0.5 cm.[15] Before local anesthesia is used, the biopsy area is outlined so that landmarks will not be obscured by the anesthetizing agent. The punch biopsy instrument is twirled between the fingers, and its sharp edge cores out a small cylinder of skin. The core of skin is snipped from the subcutaneous fat and appropriately preserved for examination in a fixative solution. Hemostasis is achieved by using methods similar to those used with curettage, but sites of 4 mm or larger are usually closed with sutures. Other types of biopsies are discussed in Table 23-9 and Chapter 23.

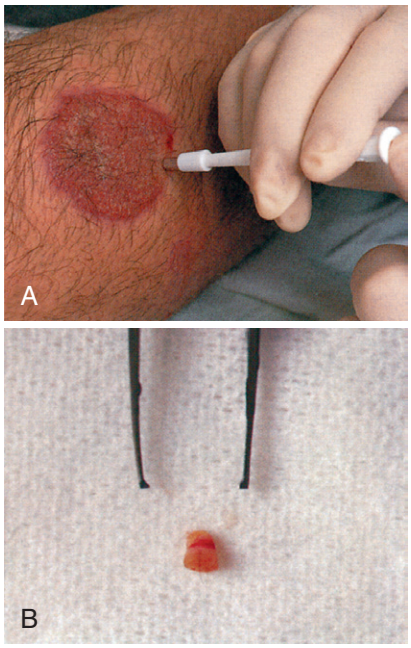

FIG. 24-12 Punch biopsy. **A,** Removal of skin for diagnostic purposes. **B,** Specimen obtained.

Cryosurgery. Cryosurgery is the use of subfreezing temperatures to destroy epidermal lesions. Cryosurgery is a useful treatment for common benign, precancerous conditions, including common and genital warts, cutaneous tags, thin seborrheic keratoses, lentigines, actinic keratoses, and nonmelanoma skin cancers. Topical liquid nitrogen (–196° F) is the agent most commonly used for cryosurgery.[15] The mechanism of injury involves direct cellular freezing and vascular stasis (stoppage or slowdown in the flow of blood), which develops after thawing. Intracellular ice formation causes the cell to rupture during thaw, leading to cell death and necrosis of the treated tissue.

Liquid nitrogen can be applied topically (directly onto the lesion) with a direct spray or a cotton-tipped applicator. Patients are informed that they will feel a stinging cold sensation. The lesion first becomes swollen and red, and it may blister. A scab forms and falls off in 1 to 3 weeks. The skin lesion is sloughed along with the scab. Growth of new skin follows.

Because of the temperature of the liquid nitrogen, melanocytes can easily be destroyed, leaving an area of hypopigmentation resembling a scar. The size of an affected area to be treated may limit the use of cryotherapy. The disadvantages of this treatment are (1) the lack of a tissue specimen for histologic confirmation of cell type before destruction and (2) the potential for destruction of adjacent healthy tissue.

Excision. Excision should be considered if the lesion to be removed involves the dermis. Complete closure of the excised area usually results in a good cosmetic result.

A specific type of excision is *Mohs' surgery,* which is a microscopically controlled removal of a cutaneous malignancy. This procedure sections the surgical specimen horizontally, so that

FIG. 24-13 **A,** Removal of melanoma by Mohs' surgery. **B,** After plastic surgery using a skin flap to repair defect.

100% of the surgical margin can be examined. Tissue is removed in thin layers, and all margins of the specimen are mapped to determine whether any malignant cells remain (Fig. 24-13). Any residual tumor not removed by the first surgical excision can be removed in serial excisions performed the same day. The benefits of this treatment are preserving normal tissue, producing the smallest possible wound, and completely removing the cancer before surgical closure. Although this can become a lengthy procedure, it is performed in an outpatient setting with the patient under local anesthesia.

NURSING MANAGEMENT DERMATOLOGIC PROBLEMS

AMBULATORY AND HOME CARE

Dermatologic conditions are not usually the primary reason for hospitalization. Nevertheless, many hospitalized patients exhibit concurrent skin problems that warrant nursing intervention and patient education.

If the patient is in an acute care setting, you both administer and teach the appropriate treatments. In an outpatient setting the focus is on patient teaching, with opportunities provided for demonstration and repeated demonstration. Subsequent visits allow you to evaluate patient understanding and treatment effectiveness.

Nursing interventions related to dermatologic conditions fall into broad categories. They are applicable to many skin problems in both inpatient and outpatient settings. (A nursing care plan for the patient with chronic skin lesions [eNursing Care Plan 24-1] is available on the website for this chapter.)

WET DRESSINGS. Wet dressings are commonly used when there is oozing from the skin. Oozing usually indicates an infection and/or inflammation. Salt water or a prescribed solution (e.g., Domeboro powder) is used on the skin by soaking (a foot or hand) or applying compresses to a larger area. Wet dressings are also used to relieve itching, suppress inflammation, and debride a wound. In addition, wet dressings increase penetration of topical medications; promote sleep by relieving discomfort; and enhance removal of scales, crusts, and exudate. Materials such as thin sheeting, gauze sponges, thermal underwear, or tube socks can be used for dressings. Ingenuity is sometimes required when odd-shaped body parts must be covered.

Place the prescribed dressing material into fresh solution, and squeeze until it is no longer dripping. Then apply it to the affected area, avoiding normal skin tissue. If the desired effect is drying, soaks or compresses are left in place for 20 minutes, three times daily for 2 or 3 days. Take care to avoid overdrying, since new problems such as fissuring may result. Wet dressings for uses other than drying should be left in place 10 to 30 minutes, two to four times a day as ordered. If the skin appears *macerated* (softens and turns white), discontinue the dressings for 2 to 3 hours. Protect the patient from discomfort and chilling by using linens and bedclothes with pads or plastic.

Wet dressings do not need to be sterile. Tap water at room temperature is the most common solution where water quality is adequate. Filtered or sterile water may be indicated in some locations. Wet dressings should be cool when an antiinflammatory effect is desired and tepid when the purpose is to debride an infected, crusted lesion. These treatments are excellent ways to remove the scabs left by the collection of debris at a wound site.

BATHS. Baths are appropriate when large body areas need to be treated. They also have sedative and antipruritic effects. Some agents, such as oilated oatmeal (Aveeno) and sodium bicarbonate, can be added directly to bath water. Fill the tub to cover the affected areas. Both the bath water and the prescribed solution should be at a lukewarm (tepid) temperature. Have the patient soak for 15 to 20 minutes three or four times a day, depending on the severity of the dermatitis and the patient's discomfort. Stress to the patient that the skin must not be rubbed dry with a towel but gently patted to prevent increased irritation and inflammation. The addition of oils makes the bathtub extremely slippery and should be avoided. If oils are used in the tub, use caution in transferring patients to prevent accidents. To sustain the hydrating effect, apply cream or ointment emollients (moisturizers) or other prescribed topical agents after the bath. This helps retain the moisture in the hydrated cells and increases the absorption of a prescribed topical medication.

TOPICAL MEDICATIONS. A thin layer of ointment, cream, lotion or solution, or gel should be applied to clean skin and spread evenly in a downward motion. Thickly applied topical medications waste medication and leave the skin greasy. An alternative method is for you to apply the medication directly onto a dressing. Pastes are designed to protect the affected area. Apply pastes thickly with a tongue blade or a gloved hand. Draining lesions and lesions with oily medication can be covered with a light dressing to avoid soiling clothes. Provide specific directions to patients on the proper application technique of prescribed topical medications.

CONTROL OF PRURITUS. *Pruritus* (itching) can be caused by dry skin, almost any physical or chemical stimulus to the skin (such as drugs or insects), and any scaling skin disorder. The itch sensation is carried by the same nonmyelinated nerve fibers as pain. If the epidermis is damaged or absent, the sensation will be felt as pain rather than an itch.

The itch/scratch cycle must be broken to prevent excoriation and lichenification. Control of pruritus is also important

because it is difficult to diagnose a lesion that is excoriated and inflamed. Certain circumstances make itching worse. Anything that causes vasodilation, such as heat or rubbing, should be avoided. Dryness of the skin lowers the itch threshold and increases the itch sensation.

Inform the patient of the various methods that may be helpful in breaking the itch/scratch cycle. A cool environment may cause vasoconstriction and decrease itching. Topically applied menthol, camphor, or phenol can be used to numb the itch receptors.[16] Systemic antihistamines may provide relief while the underlying cause of the patient's pruritus is diagnosed and treated. The principal side effect of most antihistamines is sedation. This may be desirable because pruritus is often worse at night and can interfere with sleep.

Wet dressings may also relieve pruritus. Thin cotton sheets or thermal underwear should be placed in warm water, wrung out, and placed over the pruritic area. After 10 to 15 minutes remove the dressing, pat the skin dry, and then apply a lubricant or medication. This procedure can be repeated as necessary for comfort.

Lichenification is a thickening of skin as a result of the proliferation of keratinocytes with accentuation of the normal markings of the skin. Lichenification is caused by chronic scratching or rubbing of the skin and is often associated with atopic dermatoses and pruritic conditions. Although any area of the body may be affected, the hands, forearms, shins, and nape of the neck are common sites. Excoriations may be evident in the lichenified skin as a result of persistent pruritus and scratching. Treatment of the cause of the itching is the key to prevention of lichenification.

PREVENTION OF SPREAD. Although most skin problems are not contagious, infection control precautions indicate the need for gloves with open or bleeding wounds or any lesion with purulent drainage. Explain procedures to the patient to avoid provoking undue anxiety. Careful hand washing and the safe disposal of soiled dressings are the best means of preventing the spread of skin problems. The most common contagious lesions include impetigo, staphylococcal infections, pyoderma, fungal infections, primary chancre, scabies, and pediculosis.

PREVENTION OF SECONDARY INFECTIONS. Open lesions on the skin are susceptible to invasion by other viral, bacterial, or fungal organisms. Meticulous hygiene, hand washing, and dressing changes are important to minimize the potential for secondary infections. Warn the patient about scratching the lesions, which can cause excoriations and create a portal of entry for pathogens. Trim the patient's nails short to minimize trauma from scratching.

SPECIFIC SKIN CARE. You are often in a position to advise patients regarding care of the skin after simple dermatologic surgical procedures, such as skin biopsy, excision, and cryosurgery. Patient follow-up should be individualized. In general, your instructions should include dressing changes, use of topical antibiotics, and the signs and symptoms of infection. After a dermatologic procedure, any oozing wound should be cleansed with a saline solution twice daily or as ordered by the provider. A wound that is not oozing may be washed with soap and plain water. An antibiotic ointment or plain petrolatum ointment may then be applied with a dressing that is both absorbent and nonadherent.

Wounds that are kept moist and covered heal more rapidly and with less scarring. The initial crust that forms should be left undisturbed as a protective coating for the damaged skin beneath it. Healing crusts that have been moisturized and protected will separate naturally from healed epidermis.

A wound that required sutures can be covered with a variety of different dressings. Sutures are generally removed in 4 to 14 days, depending on the placement site. Sometimes alternating sutures are removed after the third day. Incision lines may require daily cleansing, usually with plain tap water. If necessary, a topical antibiotic is applied and the wound is either covered with a dry sterile dressing or left open to air. The patient may experience some swelling and discomfort in the first 24 hours, during the first phase of wound healing. Ice packs may be applied over the surgical dressing to reduce edema. Mild analgesics such as acetaminophen or a nonsteroidal antiinflammatory medication should control the discomfort. Teach the patient the manifestations of inflammation, such as redness, fever, or increased pain or swelling, and signs of infection, such as purulent drainage. If these manifestations occur, they should be reported to the health care provider.

PSYCHOLOGIC EFFECTS OF CHRONIC DERMATOLOGIC PROBLEMS. Emotional stress can occur for persons who suffer from chronic skin problems such as psoriasis, atopic dermatitis, or acne. The sequelae of chronic skin problems could result in social and employment problems with subsequent financial implications, a poor self-image, problems with sexuality, and increasing and progressive frustration. The usual lack of systemic overt illness coupled with the visibility of the skin lesions often presents a real problem to the patient.

Help the patient comply with the prescribed regimen. The patient must be allowed to verbalize the "Why me?" question, even though there is no ready answer. Dermatology patient support groups are listed on the American Academy of Dermatology website *(www.aad.org)*. These groups are extremely helpful for patient support and accurate education materials.

Many lesions can be camouflaged with the skillful use of cosmetics. Individual sensitivity to product ingredients must always be considered in the selection of a cosmetic product. Oil-free, hypoallergenic cosmetics are available and may be beneficial to the allergic patient. Rehabilitative cosmetics are available to help camouflage and deemphasize such lesions as *vitiligo* (loss of pigmentation), *melasma* (tan to brown patches on the face), or healed postoperative wound sites. These commercially available products are opaque, smudge resistant, and water resistant.

In addition to specific skin conditions that tend to be chronic, other factors affecting the outcome of long-term dermatologic problems include skin type, history of previous exacerbations, family history, complications, intolerance to therapy, environmental factors, lack of adherence to the prescribed regimen, endocrine factors, and psychologic factors.

PHYSIOLOGIC EFFECTS OF CHRONIC DERMATOLOGIC PROBLEMS. Scarring and lichenification are the results of chronic dermatologic problems. Scars occur when ulceration takes place. Scars are pink and vascular at first. With time, they become avascular and white (scars on individuals with darker skin may be hyperpigmented) with increasing strength. Different regions of the body scar differently. For example, the face and neck heal fairly rapidly because they are well vascularized. Regions of the lower body with less vascularization tend to scar more easily and heal more slowly. Scar formation is described in Chapter 12.

The location of the scar is the determining factor with respect to its cosmetic implications. Facial scars are the most damaging

TABLE 24-12 COMMON COSMETIC TOPICAL PROCEDURES

	Tretinoin (Retin-A, Renova)	Chemical Peels	Microdermabrasion	α-Hydroxy Acids (e.g., Glycolic Acid, Lactic Acid)
Indications	Improves appearance of photodamaged skin, especially fine wrinkling. Reduces actinic keratoses.	Improves appearance of photodamaged skin, acne scarring, actinic and seborrheic keratoses.	Smoothes appearance of photodamaged and wrinkled skin, acne scarring.	Similar indications as microdermabrasion. Also called a "light chemical peel."
Description	Applied initially qod, nightly applications as tolerated, since preparation is inactivated by light. Treatment stopped if severe inflammation occurs. Maximum response in 8-12 mo.	Solution applied (e.g., trichloroacetic acid, phenol) in varying amounts to the skin, causing a controlled burn with a loss of melanin.	Epidermis and top dermal layer removed by applying aluminum oxide or baking soda crystals. Re-epithelialization of abraded surface then occurs.	Low concentrations (<10%) in many skin care products consumers can apply to the skin. Higher concentrations (50%-70%) given only by a health care provider.
Side Effects	Erythema, swelling, flaking, pigmentation changes. Teratogenic. Increases phototoxicity if also taking other photosensitive drugs (see Table 24-2).	Moderate swelling and crusting for 1 wk. Redness for 6-8 wk. Pink tone possible for several mo. Photosensitivity.	Light pink tone that resolves within 24 hr. Photosensitivity.	Photosensitivity, slight irritation at lower concentrations, severe redness, oozing, and flaking skin possible with higher concentrations.
Patient Teaching	Apply emollients, use sunscreen (SPF 15 or higher), use sun avoidance measures, avoid use of abrasive or drying facial cleansers for severe sensitivity (e.g., excess irritation).	Use sunscreen, avoid sun for 6 mo to prevent hyperpigmentation.	Generous application of emollients and sunscreen.	Use sunscreen.

qod, Every other day; *SPF,* sun protection factor.

psychologically, because they are so visible. Creative use of cosmetics can do much to mask the scarring of chronic skin conditions. The best treatment is the prevention of scarring by controlling the problem in the acute phase.

COSMETIC PROCEDURES

A vast array of cosmetic procedures is available, including chemical peels, toxin injections, fillers, laser surgery, breast enlargement and reduction (see Chapter 52), face-lift, eyelid-lift, and liposuction. Common cosmetic topical procedures are presented in Table 24-12. Other types of cosmetic procedures include the injection of botulinum toxin (Botox), calcium hydroxylapatite (Radiesse), collagen (Zyplast), and hyaluronic acid fillers (Restylane, Perlane). Transitory side effects may occur such as mild redness, pain, swelling, and bruising. Uncommon side effects from cosmetic procedures include allergic reaction, infection, or lumps at the injection sites; undercorrection or overcorrection of wrinkles; and reactivation of human papillomavirus (HPV). Instruct the patient that he or she will need to repeat the procedure at prescribed intervals to maintain the appearance desired.

The reasons for undergoing these procedures are as varied as the techniques. The most common reason that people suffer the discomfort and financial expense (most are not covered by health insurance) of a cosmetic procedure is to improve their body image. If they feel better about themselves after having cosmetic procedures, they often act more confident and self-assured. Often social position and economic considerations are part of the decision. Increased longevity provides a larger population to whom cosmetic procedures are especially appealing.

Regardless of the patient's reasons for seeking cosmetic procedures, maintain a supportive, nonjudgmental attitude about these procedures. If the patient wishes to change or enhance a body feature perceived as unattractive and has realistic expectations about the outcome, you should support this decision.

Elective Surgery

Laser Surgery. When a laser beam enters the skin, the light can affect skin structures by scattering, absorbing, or passing through different layers. The spectrum of clinical application for each laser depends on the depth of the wavelength emitted and the operator technique. Alterations in technique, such as pulse duration and the number of passes over the skin, vary the result. New handpiece technology with multiple spot size and cooling device additions has also generated new flexibility in laser surgery.

Lasers can reduce scarring and fine wrinkles around the lips or eyes and remove facial lesions[17] (see Table 24-11). Swelling, redness, and bruising are common after treatment. The treated areas usually are kept moist with ointment or occlusive dressings (surgical bandages) for the first few days. The treated skin must be protected from the sun.

Face-Lift. A face-lift *(rhytidectomy)* is the lifting and repositioning of the lower two thirds of the face and neck to improve appearance (Fig. 24-14). Indications for this procedure include the following:

- Redundant soft tissue or scarring resulting from disease (e.g., acne scarring)
- Asymmetric redundancy of soft tissues (e.g., facial palsy)
- Redundant soft tissue resulting from trauma
- Preauricular lesions

FIG. 24-14 Face-lift. **A,** Preoperative. **B,** Postoperative.

- Redundant soft tissues resulting from *solar elastosis* (sagging of the skin as a result of sun damage), changes in body weight, and the effects of gravity
- Restoration of body image

The surgical approach and lines of incisions vary according to the desired correction and the position of the hairline. Eyelid-lifts *(blepharoplasty)* with similar indications are performed to remove redundant tissue and possibly improve the field of vision. Prevention of hematoma formation is the most important postoperative consideration. Ice packs are usually applied for the first 24 to 48 hours to reduce swelling and decrease the possibility of hematoma formation. Complications can occur if the person smokes or is involved in vigorous exercise. Usually the pain is minimal. Antibiotics are used at the surgeon's discretion.

Liposuction. Liposuction is a technique for removing subcutaneous fat to improve facial and body contours. Although not a substitute for diet and exercise, it can be successful in removing areas of fat from virtually any body area that is resistant to other techniques.

Liposuction is relatively free of complications, but possible contraindications include use of anticoagulants, uncontrolled hypertension, diabetes mellitus, and poor cardiovascular status. Persons under 40 years of age with good skin elasticity are the best candidates. However, patients ranging in age from 16 to 70 years can be treated successfully.

The procedure is usually performed on an outpatient basis with the aid of local anesthesia. One or more sessions may be necessary, depending on the size of the area to be treated. A blunt-tipped cannula is inserted through a 0.5-in incision and pushed into the fat to break it loose from the fibrous stroma. Multiple repeated thrusts disrupt the fat and create tunnels. The loosened fat is removed with a powerful suction. The incision sites are taped because firm, absorbent bandaging reduces the amount of postoperative bleeding and fluid accumulation.[18] Bandaging also helps to contour the skin. It may take several months for the final results to be evident.

NURSING MANAGEMENT
COSMETIC SURGERY

Many cosmetic surgical procedures are performed in well-equipped day-surgery units or in dermatology surgeons' or plastic surgeons' office surgery suites.

DELEGATION DECISIONS

Skin Care

Role of Registered Nurse (RN)

- Assess patient's skin for acute and chronic integumentary problems.
- Assess patient's risk factors for integumentary problems.
- Document skin condition and risk factor assessment, and develop a plan of care.
- Determine whether patient is taking drugs that increase photosensitivity.
- Teach about risks associated with sun exposure and methods for decreasing exposure to the sun.
- Teach about therapies that are used for integumentary disorders, including dressings, baths, and oral or topical medications used on an outpatient basis.
- Evaluate treatment for effectiveness and any adverse effects.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Administer prescribed therapies such as dressings and oral or topical medications.
- Monitor the skin for changes in appearance or texture that may indicate worsening of integumentary problem or adverse reactions to treatment.
- Reinforce teaching done by the RN.

Role of Unlicensed Assistive Personnel (UAP)

- Assist patient with bathing.
- Apply wet dressings to skin or add medications (such as oilated oatmeal) to patient baths (consider state nurse practice act and agency policy).
- Report changes in skin appearance or patient complaints of discomfort to the RN.

PREOPERATIVE MANAGEMENT

A major preoperative management consideration relates to informed consent and realistic expectations of what cosmetic surgery can accomplish. Although the surgeon should provide this information, reinforce it and answer questions and concerns. For instance, a face-lift has little or no effect on deep wrinkling of the forehead and temples, deep nasolabial grooves, or vertical lip wrinkles. Before-and-after treatment photographs of similar cases are often useful in helping the patient to set realistic expectations.

Your teaching plan should include patient understanding of the timeframe for healing. Because wound healing may not be complete for 1 year, immediate, complete results should not be anticipated. Explain the oozing, crusting stage of the abrasive procedure so the patient can plan time off from work if necessary. The final results of the cosmetic procedure are affected by the patient's age, general state of health, and skin type and the extent (severity) of the condition being treated. If a health problem is present, efforts should be made to correct or control the problem before the procedure is performed.

POSTOPERATIVE MANAGEMENT

Most cosmetic procedures are not extremely painful. Usually mild analgesics are sufficient to keep the patient comfortable.

Although infection is not a common problem after cosmetic surgery, assess the surgical sites for signs of infection. Inform the patient of the signs and symptoms of infection with instructions to report them immediately so that appropriate antibiotic intervention can be started.

If the surgery involved an alteration in the circulation to the skin, as in a face-lift, carefully monitor for adequate circulation.

Warm, pink skin that blanches on pressure indicates that adequate circulation is present in the surgical area. Supportive, compressive dressings and ice packs may be necessary early in the postoperative period.

SKIN GRAFTS

Uses

Skin grafts may be necessary to protect underlying structures or to reconstruct areas for cosmetic or functional purposes. Ideally, wounds heal by primary intention. However, large wounds, surgically created wounds, trauma, and chronic wounds can cause extensive tissue destruction, making primary intention healing impossible. In these cases, skin grafting may be necessary to close the defect. Improved surgical techniques make it possible to graft skin, bone, cartilage, fat, fascia, muscles, and nerves. For cosmetically pleasing results, the color, thickness, texture, and hair-growing nature of skin used for grafting must be chosen to match the recipient site. (Skin grafting is also discussed in Chapter 25.)

Types

The two types of skin grafts are free grafts and skin flaps. Free grafts are further classified according to the method of providing a blood supply to the grafted skin. One method is to transfer the graft (epidermis and part or all of the dermis) to the recipient site from the donor site. If the graft is an *autograft* (from the patient's own body) or an *isograft* (from an identical twin), it will revascularize and become fixed to the new site. Chapter 25 discusses full- and split-thickness skin grafts. Another method of free skin grafting is by *reconstructive microsurgery.* With the use of an operating microscope, circulation is immediately established in the free flap by anastomosis of the blood vessels from the skin flap to the vessels in the recipient site.

Skin flaps involve moving a section of skin and subcutaneous tissue from one part of the body to another without terminating the vascular attachment.[19] The vascular attachment is called a *pedicle.* Skin flaps are used to cover wounds with a poor vascular bed, to provide padding when needed, and to cover wounds over cartilage and bone. The patient may need intermediate flap placement if the recipient site is far removed from the donor site. For instance, a skin flap from the thigh to the head would require an intermediate graft. The flap is advanced to the recipient site when circulation is well established at the intermediate site. The type of flap and the route of transfer are determined according to the patient's needs and the defect being repaired.

Soft tissue expansion is a technique for providing skin for resurfacing of a defect, such as a burn scar; for removal of a disfiguring mark (e.g., a tattoo); or as a preliminary step in breast reconstruction. A subcutaneous tissue expander of an appropriate size and shape is placed under the skin, usually as an outpatient procedure. Weekly expansion with saline solution can be done in a health care setting or by the patient at home. This expansion procedure is repeated until the skin reaches the size needed for the repair. This may take from several weeks to 3 to 4 months. Once sufficient skin is available, the old incision is opened, the expander is removed, and the soft tissue is ready to be used as an advancement flap. The tissue expander next to a defect retains the primary tissue characteristics such as color and texture.

CASE STUDY

Malignant Melanoma and Dysplastic Nevi

Hemera/Thinkstock

Patient Profile

G.L. is a 59-year-old white fair-skinned man who is a long-distance truck driver. In his leisure time, he enjoys swimming. He comes to the clinic for evaluation of a changing lesion on his left arm.

Subjective Data

- History of a basal cell carcinoma (BCC) on his left ear in the last 4 years
- Father treated for metastatic malignant melanoma in the last 2 years
- First noted the lesion 5 months ago when it started changing size
- Anxious the lesion might have spread and require extensive, disfiguring surgery

Objective Data

Physical Examination

- Has a 4-mm lesion, dark brown, scalloped with vaguely defined borders
- Four dysplastic nevi found on back

Diagnostic Studies

- Excisional biopsy confirmed malignant melanoma.
- Sentinel node biopsy results were negative.
- Diagnostic tests indicate melanoma stage I.

Discussion Questions

1. What risk factors for malignant melanoma does he have?
2. What are the usual clinical manifestations associated with malignant melanoma?
3. What is the prognosis for a patient with this stage of malignant melanoma?
4. What treatment options are available for him?
5. How would you help G.L. deal with his anxiety over the treatment outcomes?
6. ***Priority Decision:*** What is the priority of care for G.L.?
7. What would you include in his patient teaching plan to address future sun exposure?
8. ***Delegation Decision:*** Which of the following nursing personnel should be responsible for teaching G.L.: RN, LPN/LVN, or UAP?
9. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
10. ***Evidence-Based Practice:*** G.L. wants to know whether regularly applying sunscreen will reduce his risk for developing a second melanoma. How would you reply?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which safe sun practices would the nurse include in the teaching care plan for a patient who has photosensitivity *(select all that apply)*?
   - **a.** Wear protective clothing.
   - **b.** Apply sunscreen liberally and often.
   - **c.** Emphasize the short-term use of a tanning booth.
   - **d.** Avoid exposure to the sun, especially during midday.
   - **e.** Wear any sunscreen as long as it is purchased at a drugstore.
2. In teaching a patient who is using topical corticosteroids to treat acute dermatitis, the nurse should tell the patient that *(select all that apply)*
   - **a.** the cream form is the most efficient system of delivery.
   - **b.** short-term use of topical corticosteroids usually does not cause systemic side effects.
   - **c.** creams and ointments should be applied with a glove in small amounts to prevent further infection.
   - **d.** abruptly discontinuing the use of topical corticosteroids may cause a reappearance of the dermatitis.
   - **e.** systemic side effects may be experienced from topical corticosteroids if the person is malnourished.
3. A patient with acne vulgaris tells the nurse that she has quit her job as a receptionist because she believes her facial appearance is unattractive to customers. The nursing diagnosis that best describes this patient response is
   - **a.** ineffective coping related to lack of social support.
   - **b.** impaired skin integrity related to presence of lesions.
   - **c.** anxiety related to lack of knowledge of the disease process.
   - **d.** social isolation related to decreased activities secondary to fear of rejection.
4. In teaching a patient with malignant melanoma about this disorder, the nurse recognizes that the patient's prognosis is most dependent on
   - **a.** the thickness of the lesion.
   - **b.** the degree of asymmetry in the lesion.
   - **c.** the amount of ulceration in the lesion.
   - **d.** how much the lesion has spread superficially.
5. The nurse determines that a patient with a diagnosis of which disorder is most at risk for spreading the disease?
   - **a.** Tinea pedis
   - **b.** Impetigo on the face
   - **c.** Candidiasis of the nails
   - **d.** Psoriasis on the palms and soles
6. A mother and her two children have been diagnosed with pediculosis corporis at a health care center. An appropriate measure in treating this condition is
   - **a.** applying pyrethrins to the body.
   - **b.** topical application of griseofulvin.
   - **c.** moist compresses applied frequently.
   - **d.** administration of systemic antibiotics.
7. A common site for the lesions associated with atopic dermatitis is the
   - **a.** buttocks.
   - **b.** temporal area.
   - **c.** antecubital space.
   - **d.** plantar surface of the feet.
8. During the assessment of a patient, you note an area of red, sharply defined plaques covered with silvery scales that are mildly itchy on the patient's knees and elbows. You recognize this finding as
   - **a.** lentigo.
   - **b.** psoriasis.
   - **c.** actinic keratosis.
   - **d.** seborrheic keratosis.
9. Dermatologic manifestation(s) of Addison's disease can include *(select all that apply)*
   - **a.** urticaria.
   - **b.** loss of body hair.
   - **c.** increased sweating.
   - **d.** generalized hyperpigmentation.
   - **e.** hypopigmentation in the legs and trunk.
10. Important patient teaching after a chemical peel includes
    - **a.** avoidance of sun exposure.
    - **b.** application of firm bandages.
    - **c.** limitation of vigorous exercise.
    - **d.** use of moist heat to relieve discomfort.

1. a, b, d, 2. b, d, 3. d, 4. a, 5. b, 6. a, 7. c, 8. b, 9. b, d, 10. a

LEARNING OUTCOMES

1. Relate the causes of and prevention strategies for burn injuries.
2. Differentiate between partial-thickness and full-thickness burns.
3. Apply the tools used to determine the severity of burns.
4. Compare the pathophysiology, clinical manifestations, complications, and collaborative management throughout the three burn phases.
5. Compare the fluid and electrolyte shifts during the emergent and acute burn phases.
6. Differentiate the nutritional needs of the burn patient throughout the three burn phases.
7. Compare the various burn wound care techniques and surgical options for partial-thickness versus full-thickness burn wounds.
8. Prioritize nursing interventions in the management of the burn patient's physiologic and psychosocial needs.
9. Examine the various physiologic and psychosocial aspects of burn rehabilitation.
10. Design a plan of care to prepare the burn patient and caregiver for discharge.

The focus of this chapter is the care of patients who have experienced a burn. A **burn** is an injury to the tissues of the body caused by heat, chemicals, electric current, or radiation. The resulting effects are influenced by the temperature of the burning agent, duration of contact time, and type of tissue that is injured.

An estimated 450,000 Americans seek medical care each year for burns.[1,2] Approximately 45,000 people are hospitalized, one half of whom require care in specialized burn centers. About 3500 Americans die annually as a direct result of their injuries. The highest fatality rates occur in children ages 4 years and younger and adults over age 65. Around the world, nearly 11 million people need medical attention annually for burn injuries, and about 300,000 die.[3]

Although burn incidence has decreased over the past 20 years, burn injuries still occur too frequently and mainly to people at a lower socioeconomic level. Most burn incidents should be viewed as preventable. Today, the focus of burn prevention programs has shifted from blaming individuals and changing behaviors to making legislative changes and collecting global burn data to address the unique prevention needs of developing countries.[4]

Coordinated national programs in developed countries have focused on child-resistant lighters, nonflammable children's clothing, tap water anti-scald devices, fire-safe cigarettes, stricter building codes, hardwired smoke detectors and alarms, and fire sprinklers. As a nurse, you can advocate for burn risk reduction strategies in the home and at work, and

TABLE 25-1 SOURCES OF BURN INJURY*

Home Hazards

Kitchen and Bathroom

- Microwaved food
- Steam, hot grease or liquids from cooking
- Hot water heaters set at 140° F (60° C) or higher

General Household

- Fireplaces (e.g., gas, wood)
- Open space heaters
- Radiators (e.g., home, automobile)
- Outdoor grills (e.g., propane, charcoal)
- Frayed or defective wiring
- Multiple extension cords per outlet
- Flammables (e.g., starter fluid, gasoline, kerosene)
- Carelessness with cigarettes, matches, candles

Occupational Hazards

- Tar
- Chemicals
- Hot metals
- Steam pipes
- Combustible fuels
- Fertilizers, pesticides
- Electricity from power lines
- Sparks from live electric sources

*List is not all-inclusive.

TABLE 25-2 STRATEGIES TO REDUCE BURN INJURY

Flame or Contact

- Never leave candles unattended or near open windows or curtains.
- Use "child-resistant" lighters.
- Hold regular home fire exit drills.
- Never use gasoline or other flammable liquids to start a fire.
- Never leave hot oil unattended while cooking.
- Never smoke in bed.
- Consider a flame-retardant smoking apron for older or "at-risk" people.
- Exercise caution when microwaving food and beverages.

Scald

- Lower hot water temperature to the "lowest point" or 120° F (40° C).
- Use "anti-scald" devices with showerhead or faucet fixtures.
- Supervise bathing with small children, older adults, or anyone with impaired physical movement, physical sensation, or judgment.
- After running bath water, check temperature with back of hand or bath thermometer.

Inhalation

- Install smoke and carbon monoxide detectors.

Chemical

- Store chemicals safely in approved containers and label clearly.
- Ensure safety of workers and students handling chemicals (education, protective eyewear, gloves, masks, clothing).

Electrical

- Avoid or repair frayed wiring.
- Ensure electrical power source is shut off before beginning repairs.
- Wear protective eyewear and gloves when making electrical repairs.
- Avoid outdoor activities during electrical (i.e., lightning) storms.

you can teach workers to reduce burn injuries in both settings (Tables 25-1 and 25-2).

TYPES OF BURN INJURY

Thermal Burns

Thermal burns, caused by flame, flash, scald, or contact with hot objects, are the most common type of burn injury (Fig. 25-1). The severity of the injury depends on the temperature of the burning agent and the duration of contact time. Scald injuries can occur in the bathroom or while cooking. Flash, flame, or contact burns can occur while cooking, smoking, burning leaves in the backyard, or using gasoline or hot oil.

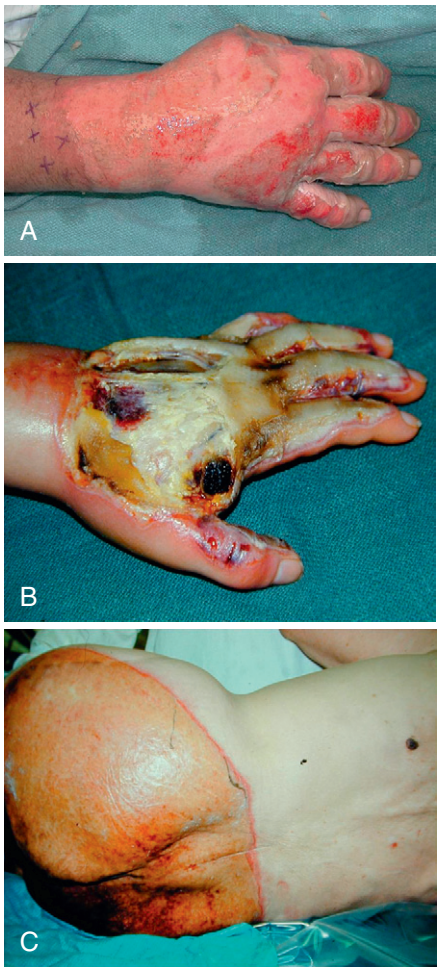

FIG. 25-1 Types of burn injury. **A,** Partial-thickness thermal hand burn. **B,** Full-thickness thermal hand burn. **C,** Full-thickness scald burn to the buttock and lower back secondary to immersion in hot water.

Chemical Burns

Chemical burns are the result of contact with acids, alkalis, and organic compounds. In addition to tissue damage, eyes can be injured if they are splashed with the chemical. Acids are found in the home and at work and include hydrochloric, oxalic, and hydrofluoric acid. Alkali burns can be more difficult to manage than acid burns, since alkalis adhere to tissue, causing protein hydrolysis and liquefaction. Alkalis are found in oven and drain cleaners, fertilizers, and heavy industrial cleansers. Organic compounds, including phenols (chemical disinfectants) and petroleum products (creosote and gasoline), produce contact burns and systemic toxicity.

Smoke and Inhalation Injury

Smoke and inhalation injuries from breathing hot air or noxious chemicals can cause damage to the respiratory tract. Three types of smoke and inhalation injuries can occur: metabolic asphyxiation, upper airway injury, and lower airway injury. Because smoke inhalation injuries are a major predictor of mortality in burn patients, rapid assessment is critical.[5]

TABLE 25-3 MANIFESTATIONS OF LUNG INJURY ASSOCIATED WITH BURNS

Upper Airway	Lower Airway
• Blisters, edema • Hoarseness • Difficulty swallowing • Copious secretions • Stridor • Substernal and intercostal retractions • Total airway obstruction	• High degree of suspicion if patient was trapped in a fire in an enclosed space or clothing caught fire • Presence of facial burns or singed nasal or facial hair • Dyspnea • Carbonaceous sputum • Wheezing • Hoarseness • Altered mental status

Metabolic Asphyxiation. The majority of deaths at a fire scene are the result of inhaling certain smoke elements, primarily carbon monoxide (CO) or hydrogen cyanide. Oxygen delivery to or consumption by tissues is impaired. The result is hypoxia and, ultimately, death when **carboxyhemoglobin** (i.e., hemoglobin combined with CO) blood levels are greater than 20%. CO and hydrogen cyanide poisoning may occur in the absence of burn injury to the skin.

Upper Airway Injury. Upper airway injury results from an inhalation injury to the mouth, oropharynx, and/or larynx. The injury may be caused by thermal burns or the inhalation of hot air, steam, or smoke. Mucosal burns of the oropharynx and the larynx are manifested by redness, blistering, and edema (Table 25-3). The swelling can be massive and the onset rapid. Flame burns to the neck and the chest may make breathing more difficult because of the burn eschar, which becomes tight and constricting from the underlying edema. Swelling from scald burns to the face and the neck can also be lethal, as can external pressure from edema pressing on the airway. Mechanical obstruction can occur quickly, presenting a true medical emergency.

Carefully assess the patient for facial burns, singed nasal hair, hoarseness, painful swallowing, darkened oral and nasal membranes, carbonaceous sputum, history of being burned in an enclosed space, and clothing burns around the chest and neck.

Lower Airway Injury. An inhalation injury to the trachea, bronchioles, and alveoli is usually caused by breathing in toxic chemicals or smoke. Tissue damage is related to the duration of exposure to toxic fumes or smoke. Clinical manifestations of lower airway lung injury are presented in Table 25-3. Pulmonary edema may not appear until 12 to 24 hours after the burn, and then it may manifest as acute respiratory distress syndrome (ARDS) (see Chapter 68).

Electrical Burns

Electrical burns result from intense heat generated from an electric current. Direct damage to nerves and vessels, causing tissue anoxia and death, can also occur. The severity of the electrical injury depends on the amount of voltage, tissue resistance, current pathways, surface area in contact with the current, and length of time that the current flow was sustained (Fig. 25-2). Tissue densities offer various amounts of resistance to electric current. For example, fat and bone offer the most resistance, whereas nerves and blood vessels offer the least resistance. Current that passes through vital organs (e.g., brain, heart, kidneys) produces more life-threatening sequelae than

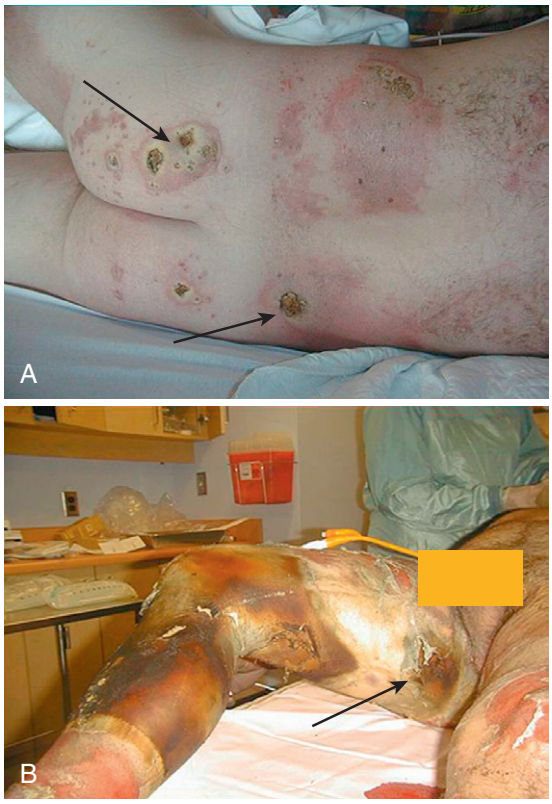

FIG. 25-2 Electrical injury produces heat coagulation of blood supply and contact area as electric current passes through the skin. **A,** Back and buttock (arrows). **B,** Leg (arrow).

that which passes through other tissues. In addition, electric sparks may ignite the patient's clothing, causing a flash injury.

As with inhalation injury, perform a rapid assessment of the patient with electrical injury. Transfer to a burn center is indicated. The severity of an electrical injury can be difficult to determine, since most of the damage is below the skin (known as the *iceberg effect*). Determination of electric current contact points and history of the injury may help determine the probable path of the current and potential areas of injury. Contact with electric current can cause muscle contractions strong enough to fracture the long bones and vertebrae. Another reason to suspect long bone or spinal fractures is a fall resulting from the electrical injury. For this reason, all patients with electrical burns should be considered at risk for a potential cervical spine injury. Cervical spine immobilization must be used during transport and subsequent diagnostic testing completed to rule out any injury.

Electrical injury puts the patient at risk for dysrhythmias or cardiac arrest, severe metabolic acidosis, and myoglobinuria. The electric shock event can cause immediate cardiac standstill or ventricular fibrillation. Delayed cardiac dysrhythmias or arrest may also occur without warning during the first 24 hours after injury. Myoglobin from injured muscle tissue and hemoglobin from damaged red blood cells (RBCs) are released into the circulation whenever massive muscle and blood vessel damage occurs. The released myoglobin pigments travel to the kidneys and can block the renal tubules, which can result in acute tubular necrosis (ATN) and acute kidney injury (see Chapter 47).

Cold Thermal Injury

Cold thermal injury, or frostbite, is discussed in Chapter 69.

TABLE 25-4 BURN CENTER REFERRAL CRITERIA

Burn injuries that should be referred to a burn center include the following:

1. Partial-thickness burns >10% of total body surface area (TBSA).
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints.
3. Third-degree burns in any age-group.
4. Electrical burns, including lightning injury.
5. Chemical burns.
6. Inhalation injury.
7. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality risk (e.g., heart or kidney disease).
8. Any patients with burns and concomitant trauma (e.g., fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn center. The health care provider will need to use his or her judgment, in consultation with the regional medical control plan and triage protocols.
9. Burn injury in children in hospitals without qualified personnel or equipment needed to care for them.
10. Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention.

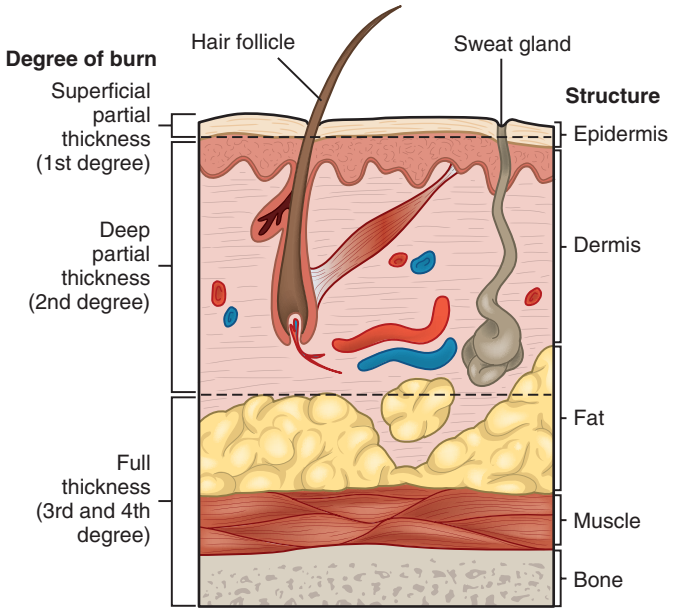

FIG. 25-3 Cross section of skin indicating the depth of burn and structures involved.

CLASSIFICATION OF BURN INJURY

The treatment of burns is related to the severity of the injury.[6] Severity is determined by (1) depth of burn, (2) extent of burn calculated in percent of total body surface area (TBSA), (3) location of burn, and (4) patient risk factors (e.g., age, past medical history). The American Burn Association (ABA) has established referral criteria to determine which burn injuries should be treated in burn centers with specialized facilities (Table 25-4). The majority of patients with minor burn injuries can be managed in community hospitals.[7]

Depth of Burn

Burn injury involves the destruction of the integumentary system. The skin is divided into three layers: epidermis, dermis, and subcutaneous tissue (Fig. 25-3). The *epidermis,* or nonvascular protective outer layer of the skin, is approximately as thick as a sheet of paper. (The structure and function of the skin are discussed in Chapter 23.)

The *dermis,* which lies below the epidermis, is approximately 30 to 45 times thicker than the epidermis. The dermis contains connective tissues with blood vessels, hair follicles, nerve endings, sweat glands, and sebaceous glands.

Under the dermis lies the *subcutaneous tissue,* which contains major vascular networks, fat, nerves, and lymphatics. The subcutaneous tissue acts as a heat insulator for underlying structures, including muscles, tendons, bones, and internal organs.

Burns continue to be defined by degrees: first, second, third, and fourth degree. The ABA recommends a more precise definition and classifies burns according to depth of skin destruction: **partial-thickness burns** and **full-thickness burns** (see Fig. 25-3). Skin-reproducing (re-epithelializing) cells are located along the shafts of the hair follicles, sweat glands, and oil glands. If significant damage occurs to the dermis (i.e., a full-thickness burn), not enough skin cells remain to regenerate new skin. A permanent, alternative source of skin needs to be found. Table 25-5 compares the various burn classifications according to the depth of injury.

Extent of Burn

Two commonly used guides for determining the TBSA affected or the extent of a burn wound are the *Lund-Browder chart* (Fig. 25-4, *A*) and the *Rule of Nines* (Fig. 25-4, *B*). (First-degree burns, equivalent to a sunburn, are not included when calculating TBSA.) The Lund-Browder chart is considered more accurate because it considers the patient's age in proportion to relative body-area size. The Rule of Nines is often used for initial assessment of a burn patient because it is easy to remember. For irregular- or odd-shaped burns, the patient's hand (including the fingers) is approximately 1% TBSA. The *Sage Burn Diagram* is a free, Internet-based tool for estimating TBSA burned (*www.sagediagram.com*).

Location of Burn

The severity of the burn injury is also determined by the location of the burn wound. Burns to the face and neck and circumferential burns to the chest or back may interfere with breathing as a result of mechanical obstruction from edema or leathery, devitalized burn tissue *(eschar).* These burns may also indicate possible inhalation injury and respiratory mucosal damage.

Burns to the hands, feet, joints, and eyes are of concern because they make self-care difficult and may jeopardize future function. Burns to the hands and feet are challenging to manage because of superficial vascular and nerve supply systems that need to be protected while the burn wounds are healing.

Burns to the ears and the nose are susceptible to infection because of poor blood supply to the cartilage. Burns to the buttocks or perineum are highly susceptible to infection from urine or feces contamination. Circumferential burns to the extremi-

TABLE 25-5 CLASSIFICATION OF BURN INJURY DEPTH

Classification	Appearance	Possible Cause	Structures Involved
Partial-Thickness Skin Destruction			
Superficial (first-degree) burn	Erythema, blanching on pressure, pain and mild swelling, no vesicles or blisters (although after 24 hr skin may blister and peel).	Superficial sunburn Quick heat flash	Superficial epidermal damage with hyperemia. Tactile and pain sensation intact.
Deep (second-degree) burn	Fluid-filled vesicles that are red, shiny, wet (if vesicles have ruptured). Severe pain caused by nerve injury. Mild to moderate edema.	Flame Flash Scald Contact burns Chemical Tar Electric current	Epidermis and dermis involved to varying depths. Skin elements, from which epithelial regeneration occurs, remain viable.
Full-Thickness Skin Destruction			
Third- and fourth-degree burns	Dry, waxy white, leathery, or hard skin; visible thrombosed vessels. Insensitivity to pain because of nerve destruction. Possible involvement of muscles, tendons, and bones.	Flame Scald Chemical Tar Electric current	All skin elements and local nerve endings destroyed. Coagulation necrosis present. Surgical intervention required for healing.

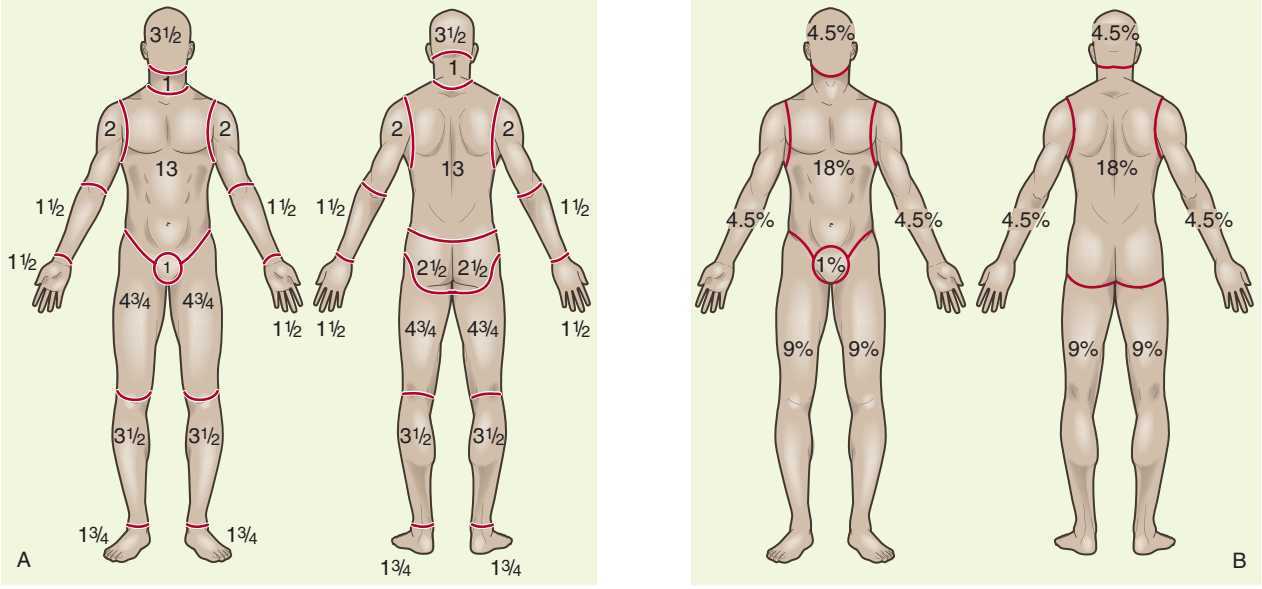

FIG. 25-4 A, Lund-Browder chart. By convention, areas of partial-thickness injury are colored in blue and areas of full-thickness injury in red. Superficial partial-thickness burns are not calculated. **B,** Rule of Nines chart.

ties can cause circulation problems distal to the burn, with possible nerve damage to the affected extremity. Patients may also develop compartment syndrome (see Chapter 63) from direct heat damage to the muscles, swelling, and/or preburn vascular problems.

Patient Risk Factors

Any patient with preexisting cardiovascular, respiratory, or renal disease has a poorer prognosis for recovery because of the tremendous demands placed on the body by a burn injury. The patient with diabetes mellitus or peripheral vascular disease is at high risk for poor healing, especially with foot and leg burns.[8] General physical debilitation from any chronic disease, including alcoholism, drug abuse, or malnutrition, makes it challenging for the patient to fully recover from a burn injury. In addition, the burn patient who has also sustained fractures, head injuries, or other trauma has a more difficult time recovering.

PHASES OF BURN MANAGEMENT

Burn management can be organized chronologically into three phases: emergent (resuscitative), acute (wound healing), and rehabilitative (restorative). Overlap in care does exist. For example, the emergent phase begins at the time of the burn injury, and care often begins in the prehospital phase, depending on the skill level of providers at the scene. Planning for rehabilitation begins on the day of the burn injury or admission to the burn center. Formal rehabilitation begins as soon as functional assessments can be performed. Wound care is the primary focus of the acute phase, but wound care also takes place in both the emergent and rehabilitation phases.

PREHOSPITAL CARE

At the scene of the injury, priority is given to removing the person from the source of the burn and stopping the burning

TABLE 25-6 EMERGENCY MANAGEMENT

Thermal Burns

Etiology	Assessment Findings	Interventions
• Hot liquids or solids • Flash flame • Open flame • Steam • Hot surface • Ultraviolet rays	***Partial-Thickness (superficial; first-degree) Burn*** • Redness • Pain • Moderate to severe tenderness • Minimal edema • Blanching with pressure ***Partial-Thickness (deep; second-degree) Burn*** • Moist blebs, blisters • Mottled white, pink to cherry-red • Hypersensitive to touch or air • Moderate to severe pain • Blanching with pressure ***Full-Thickness (third- and fourth-degree) Burns*** • Dry, leathery eschar • Waxy white, dark brown, or charred appearance • Strong burn odor • Impaired sensation when touched • Absence of pain with severe pain in surrounding tissues • Lack of blanching with pressure	**Initial** • Assess airway, breathing, and circulation. • Stabilize cervical spine. • Assess for inhalation injury. • Provide supplemental O_2 as needed. • Anticipate endotracheal intubation and mechanical ventilation with circumferential full-thickness burns to the neck and chest or large TBSA burn. • Monitor vital signs, level of consciousness, respiratory status, O_2 saturation, and heart rhythm. • Remove nonadherent clothing, shoes, watches, jewelry, glasses or contact lenses (if face was exposed). • Cover burned areas with dry dressings or clean sheet. • Establish IV access with two large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limbs above heart to decrease edema. • Administer IV analgesia and assess effectiveness frequently. • Identify and treat other associated injuries (e.g., fractures, head injury). **Ongoing Monitoring** • Monitor airway. • Monitor vital signs, heart rhythm, level of consciousness, respiratory status, and O_2 saturation. • Monitor urine output.

TBSA, Total body surface area.

process. Rescuers must also protect themselves from being injured. In the case of electrical and chemical injuries, initial management involves removal of the patient from contact with the electrical or chemical source.

Small thermal burns (10% or less of TBSA) should be covered with a clean, cool, tap water–dampened towel for the patient's comfort and protection until medical care is available.[9] Cooling of the injured area (if small) within 1 minute helps minimize the depth of the injury. If the burn is large (greater than 10% TBSA) or an electrical or inhalation burn is suspected, first focus your attention on the ABCs:

- *Airway:* Check for patency, soot around nares and on the tongue, singed nasal hair, darkened oral or nasal membranes.
- *Breathing:* Check for adequacy of ventilation.
- *Circulation:* Check for presence and regularity of pulses, and elevate the burned limb(s) above the heart to decrease pain and swelling.

To prevent hypothermia, cool large burns for no more than 10 minutes. Do not immerse the burned body part in cool water because it may cause extensive heat loss. Never cover a burn with ice, since this can cause hypothermia and vasoconstriction of blood vessels, thus further reducing blood flow to the injury. Gently remove as much burned clothing as possible to prevent further tissue damage. Leave adherent clothing in place until the patient is transferred to a hospital. Wrap the patient in a dry, clean sheet or blanket to prevent further contamination of the wound and to provide warmth.

Chemical burns are best treated by quickly removing any chemical particles or powder from the skin. Remove all clothing containing the chemical because the burning process continues while the chemical is in contact with the skin. Flush the affected area with copious amounts of water to irrigate the skin anywhere from 20 minutes to 2 hours postexposure. Tap water is acceptable for flushing eyes exposed to chemicals. Tissue destruction may continue for up to 72 hours after contact with some chemicals.

Observe patients with inhalation injuries closely for signs of respiratory distress. These patients need to be treated quickly and efficiently if they are to survive. If CO poisoning is suspected, treat the patient with 100% humidified O_2. Patients who have both body burns and an inhalation injury must be transferred to the nearest burn center.

Always remember that the burn patient may also have sustained other injuries that could take priority over the burn itself. Individuals involved in the prehospital phase of burn care must adequately communicate the circumstances of the injury to hospital providers. This is especially important when the patient's injury involves being trapped in a closed space, exposure to hazardous chemicals or electricity, or a possible traumatic injury (e.g., fall).

Prehospital care and emergency management are presented in tables that describe thermal burns (Table 25-6), inhalation injury (Table 25-7), electrical burns (Table 25-8), and chemical burns (Table 25-9).

EMERGENT PHASE

The *emergent (resuscitative) phase* is the time required to resolve the immediate, life-threatening problems resulting from the burn injury. This phase usually lasts up to 72 hours from the time the burn occurred. The primary concerns are the onset of hypovolemic shock and edema formation. The emergent phase ends when fluid mobilization and diuresis begin.

TABLE 25-7 EMERGENCY MANAGEMENT

Inhalation Injury

Etiology	Assessment Findings	Interventions
• Exposure of respiratory tract to intense heat or flames • Inhalation of noxious chemicals, smoke, or CO	• History of being trapped in an enclosed space, being in an explosion, or having clothing catch fire • Rapid, shallow respirations • Increasing hoarseness • Coughing • Singed nasal or facial hair • Darkened oral or nasal membranes • Smoky breath • Carbonaceous sputum • Productive cough with black, gray, or bloody sputum • Irritation of upper airways or burning pain in throat or chest • Difficulty swallowing • Cherry-red skin color (CO levels >20%) • Restlessness, anxiety • Altered mental status, including confusion, coma • Decreased O_2 saturation • Dysrhythmias	**Initial** • Assess airway, breathing, and circulation. • Stabilize cervical spine. • Assess for thermal burn. • Provide 100% humidified O_2. • Anticipate endotracheal intubation and mechanical ventilation with significant inhalation injury. • Monitor vital signs, level of consciousness, O_2 saturation, and heart rhythm. • Remove nonadherent clothing, jewelry, glasses, or contact lenses (if face was exposed). • Establish IV access with two large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limb(s) above heart to decrease edema. • Obtain arterial blood gas, carboxyhemoglobin levels, and chest x-ray. • Administer IV analgesia and assess effectiveness frequently. • Identify and treat other associated injuries (e.g., fractures, pneumothorax, head injury). • Cover burned areas with dry dressings or clean sheet. • Anticipate need for fiberoptic bronchoscopy or intubation. **Ongoing Monitoring** • Monitor airway. • Monitor vital signs, level of consciousness, respiratory status, O_2 saturation, and heart rhythm. • Monitor urine output.

CO, Carbon monoxide; *TBSA,* total body surface area.

TABLE 25-8 EMERGENCY MANAGEMENT

Electrical Burns

Etiology	Assessment Findings	Interventions
Alternating Current • Electric wires • Utility wires **Direct Current** • Lightning • Defibrillator	• Leathery, white, or charred skin • Burn odor • Loss of consciousness • Impaired touch sensation • Minimal or absent pain • Dysrhythmias • Cardiac arrest • Location of contact points • Diminished peripheral circulation in injured extremity • Thermal burns if clothing ignites • Fractures or dislocations from force of current • Head or neck injury if fall occurred • Depth and extent of wound difficult to visualize. Assume injury greater than what is seen	**Initial** • Remove patient from electrical source while protecting rescuer. • Assess airway, breathing, and circulation. • Stabilize cervical spine. • Provide supplemental O_2 as needed. • Monitor vital signs, heart rhythm, level of consciousness, respiratory status, and O_2 saturation. • Check pulses distal to burns. • Remove nonadherent clothing, shoes, watches, jewelry, glasses or contact lenses (if face was exposed). • Cover burned areas with dry dressings or clean sheet. • Establish IV access with two large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Obtain arterial blood gas to assess acid-base balance. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limb(s) above heart to decrease edema. • Administer IV analgesia and assess effectiveness frequently. • Identify and treat other associated injuries (e.g., fractures, head injury, thermal burns). **Ongoing Monitoring** • Monitor airway. • Monitor vital signs, heart rhythm, level of consciousness, respiratory status, O_2 saturation, and neurovascular status of injured limbs. • Monitor urine output. • Monitor urine for development of myoglobinuria secondary to muscle breakdown and hemoglobinuria secondary to RBC breakdown. • Anticipate possible administration of $NaHCO_3$ to alkalinize the urine and maintain serum pH >6.0.

$NaHCO_3$, Sodium bicarbonate; *TBSA,* total body surface area.

TABLE 25-9 EMERGENCY MANAGEMENT

Chemical Burns

Etiology	Assessment Findings	Interventions
• Acids • Alkalis • Organic compounds	• Burning • Redness, swelling of injured tissue • Degeneration of exposed tissue • Discoloration of injured skin • Localized pain • Edema of surrounding tissue • Tissue destruction continuing for up to 72 hr • Respiratory distress if chemical inhaled • Decreased muscle coordination (if organophosphate) • Paralysis	**Initial** • Assess airway, breathing, and circulation before decontamination procedures. • Stabilize cervical spine. • Provide supplemental O_2 as needed. • Brush dry chemical from skin before irrigation. • Remove nonadherent clothing, shoes, watches, jewelry, glasses or contact lenses (if face was exposed). • Flush chemical from wound and surrounding area with copious amounts of saline solution or water. • For chemical burn of the eye(s), flush from inner to outer corner of eye with water or lactated Ringer's (if available). • Cover burned areas with dry dressings or clean sheet. • Establish IV access with two large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limb(s) above heart to decrease edema. • Administer IV analgesia and assess effectiveness frequently. • Contact poison control center for assistance. **Ongoing Monitoring** • Monitor airway if exposed to chemicals. • Monitor urine output. • Consider possibility of systemic impact of identified chemical, and monitor and treat accordingly. • Monitor pH of eye if exposed to chemicals.

TBSA, Total body surface area.

Pathophysiology

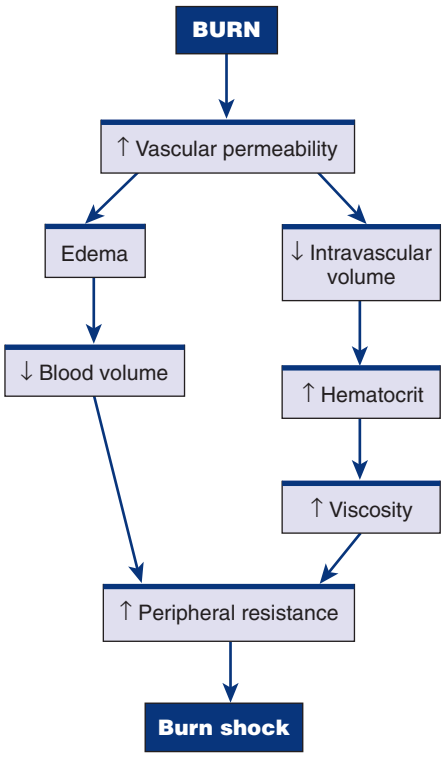
Fluid and Electrolyte Shifts. The greatest initial threat to a patient with a major burn is hypovolemic shock (Fig. 25-5). It is caused by a massive shift of fluids out of the blood vessels as a result of increased capillary permeability and can begin as early as 20 minutes postburn. As the capillary walls become more permeable, water, sodium, and plasma proteins (especially albumin) move into the interstitial spaces and other surrounding tissue. The colloidal osmotic pressure decreases with progressive loss of protein from the vascular space. This results in more fluid shifting out of the vascular space into the interstitial spaces (Fig. 25-6). Fluid accumulation in the interstitium is termed *second spacing.*

Fluid also moves to areas that normally have minimal to no fluid, a phenomenon termed *third spacing.* Examples of third spacing in burn injury are exudate and blister formation, as well as edema in nonburned areas.

Other sources of fluid loss are insensible losses by evaporation from large, denuded body surfaces and the respiratory system. The normal insensible loss of 30 to 50 mL/hr is increased in the severely burned patient. The net result of the fluid shifts and losses is termed *intravascular volume depletion.* Clinical signs of hypovolemic shock are decreased blood pressure (BP) and increased heart rate. If hypovolemic shock is not corrected, irreversible shock and death may result. (Shock is discussed in Chapter 67.)

The circulatory system is also affected by the hemolysis of RBCs from circulating factors (e.g., oxygen free radicals) released at the time of the burn, as well as by the direct insult of the burn injury. Thrombosis in the capillaries of burned tissue causes an additional loss of circulating RBCs. An elevated hematocrit is commonly caused by hemoconcentration resulting from fluid loss. After fluid balance has been restored, dilution causes the hematocrit levels to drop.

PATHOPHYSIOLOGY MAP



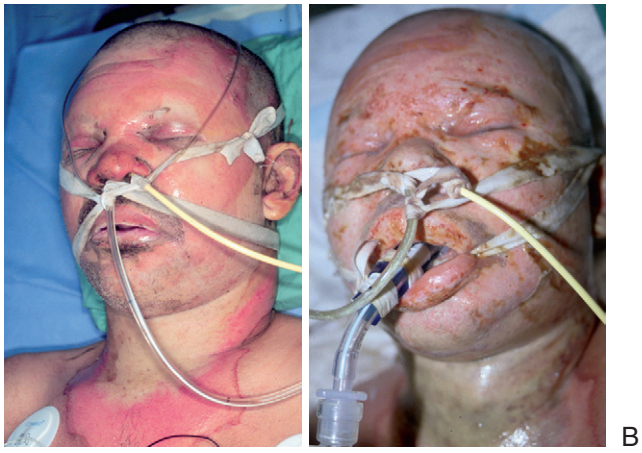


FIG. 25-5 At the time of major burn injury, there is increased capillary permeability. All fluid components of the blood begin to leak into the interstitium, causing edema and a decreased blood volume. Hematocrit increases, and the blood becomes more viscous. The combination of decreased blood volume and increased viscosity produces increased peripheral resistance. Burn shock, a type of hypovolemic shock, rapidly ensues and, if not corrected, can result in death.

Major electrolyte shifts of sodium and potassium also occur during this phase. Sodium rapidly moves to the interstitial spaces and remains there until edema formation ceases (Fig. 25-7). A potassium shift develops initially because injured cells and hemolyzed RBCs release potassium into the circulation.

Toward the end of the emergent phase, capillary membrane permeability is restored if fluid replacement is adequate. Fluid loss and edema formation end. Interstitial fluid gradually returns to the vascular space (see Fig. 25-7). Diuresis occurs, and the urine has a low specific gravity.

Inflammation and Healing. Burn injury to tissues and vessels causes coagulation necrosis. Neutrophils and monocytes accumulate at the site of injury. Fibroblasts and newly formed collagen fibrils appear and begin wound repair within the first 6 to 12 hours after injury. (The inflammatory response is discussed in Chapter 12.)

Immunologic Changes. The body's immune system is challenged when a burn injury occurs. The skin barrier to invading organisms is destroyed, bone marrow depression occurs, and circulating levels of immunoglobulins are decreased. Defects occur in the function of white blood cells (WBCs). The inflammatory cytokine cascade, triggered by tissue damage, impairs the function of lymphocytes, monocytes, and neutrophils. Thus the patient is at a greater risk for infection.

A B

FIG. 25-6 **A,** Facial edema before fluid resuscitation. **B,** Facial edema after 24 hours.

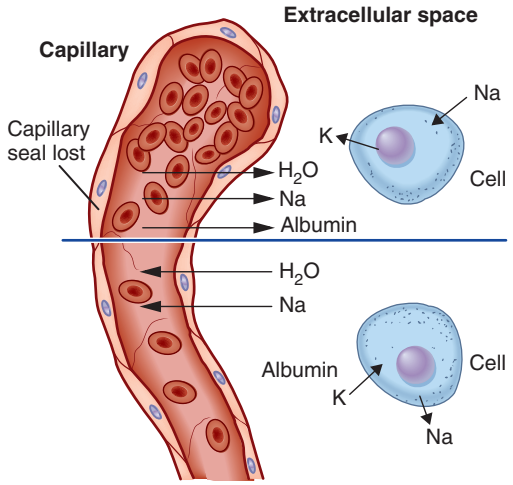

FIG. 25-7 The effects of burn shock are shown above the blue line. As the capillary seal is lost, interstitial edema develops. The cellular integrity is also altered, with sodium *(Na)* moving into the cell in abnormal amounts and potassium *(K)* leaving the cell. The shifts after the resolution of burn shock are shown below the blue line. The water and sodium move back into the circulating volume through the capillary. The albumin remains in the interstitium. Potassium is transported into the cell and sodium is transported out as the cellular integrity returns.

Clinical Manifestations

The patient with severe burns is likely to be in shock from hypovolemia. Frequently the areas of full-thickness and deep partial-thickness burns are initially anesthetic because the nerve endings have been destroyed. Superficial to moderate partial-thickness burns are very painful. Blisters, filled with fluid and protein, are common in partial-thickness burns. The patient with a larger burn area may develop a paralytic ileus, with absent or decreased bowel sounds. Shivering may occur as a result of chilling that is caused by heat loss, anxiety, or pain. The patient may be alert and able to answer questions shortly after admission or until he or she is intubated (if there is an inhalation injury). Patients are often frightened and benefit from your calm reassurances and simple explanations of what to expect as you provide care. Unconsciousness or altered mental status in a burn patient is usually not a result of the burn but of the hypoxia associated with smoke inhalation. Other possibilities include head trauma, substance abuse, or excessive amounts of sedation or pain medication.

Complications

The three major organ systems most susceptible to complications during the emergent phase of burn injury are the cardiovascular, respiratory, and urinary systems.

Cardiovascular System. Cardiovascular system complications include dysrhythmias and hypovolemic shock, which, if untreated, may progress to irreversible shock. Circulation to the extremities can be severely impaired by deep circumferential burns and subsequent edema formation, which act like a tourniquet. If untreated, ischemia, paresthesias, and necrosis can occur. An **escharotomy** (a scalpel or electrocautery incision through the full-thickness eschar) is frequently performed after transfer to a burn center to restore circulation to compromised extremities (Fig. 25-8). Initially, blood viscosity increases because of the fluid loss. Microcirculation is impaired because of the damage to skin structures that contain small capillary systems. These two events result in a phenomenon termed *sludging.* Sludging can be corrected by adequate fluid replacement.

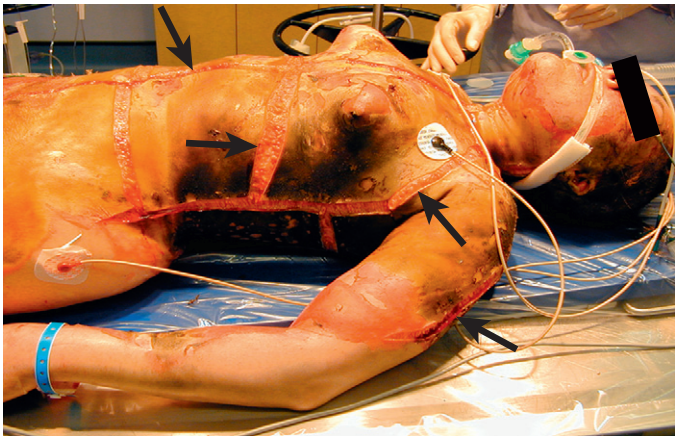

FIG. 25-8 Escharotomies of the chest and arm (indicated by *arrows*).

Respiratory System. The respiratory system is vulnerable to two types of injury: (1) upper airway burns and (2) lower airway injury (see Table 25-3). Upper airway distress may occur with or without smoke inhalation, and airway injury at either level may occur in the absence of burn injury to the skin. (Smoke and inhalation injuries are discussed earlier in this chapter on pp. 451-452.)

The patient may require a fiberoptic bronchoscopy and carboxyhemoglobin blood levels to confirm a suspected inhalation injury. Look in the prehospital notes to see if the patient was exposed to smoke or fumes. Examine any sputum for carbon. Watch for signs of impending respiratory distress, such as increased agitation, anxiety, restlessness, or a change in the rate or character of the patient's breathing, since symptoms may not be present immediately. In general, there is no correlation between the extent of TBSA burn and severity of inhalation injury. In a patient with inhalation injury, a chest x-ray may appear normal on admission, but changes usually occur over the next 24 to 48 hours. Arterial blood gas (ABG) values may also be within the normal range on admission and change over time.

Other Cardiopulmonary Problems. Patients with preexisting heart disease (e.g., myocardial infarction) or lung disease (e.g., chronic obstructive pulmonary disease) are at an increased risk for complications. If fluid replacement is too vigorous, watch for early signs of heart failure or pulmonary edema. Invasive measures (e.g., hemodynamic monitoring) may be necessary to monitor fluid resuscitation.

Patients with preexisting respiratory problems are more likely to develop a respiratory tract infection. Pneumonia, a common complication of major burns, is the leading cause of death in patients with an inhalation injury.

Burn patients are at an increased risk for venous thromboembolism (VTE) if one or more of the following conditions are present: advanced age, morbid obesity, extensive or lower-extremity burns, concomitant lower-extremity trauma, and prolonged immobility.[10] VTE prophylaxis should be started and should include medications such as enoxaparin (Lovenox) unless contraindicated.[11]

Urinary System. The most common complication of the urinary system in the emergent phase is acute tubular necrosis (ATN). If your patient becomes hypovolemic, blood flow to the kidneys is decreased, causing renal ischemia. If this continues, acute kidney injury may develop.

With full-thickness and major electrical burns, myoglobin (from muscle cell breakdown) and hemoglobin (from RBC breakdown) are released into the bloodstream and occlude renal tubules. Carefully monitor the adequacy of fluid replacement because this can counteract obstruction of the tubules.

NURSING AND COLLABORATIVE MANAGEMENT EMERGENT PHASE

In the emergent phase the patient's survival depends on rapid and thorough assessment and appropriate interventions. Usually the physician and you make an initial assessment of the depth and extent of the burn and coordinate the actions of others on the health care team. In a community hospital, determine whether the patient requires inpatient or outpatient care. In the case of inpatient care, decide whether the patient remains in the hospital or should be transferred to the closest burn center (see Table 25-4).

Nursing and collaborative management predominantly consists of airway management, fluid therapy, and wound care (Table 25-10). Patients often improve and worsen, unpredictably, on an almost daily basis.

Although physical and occupational therapy are important in both the acute and rehabilitation phases, proper positioning and splinting begin on the day of admission. Emotional support and teaching of patients and caregivers begin on admission. A nursing care plan for the patient with burn injury (eNursing Care Plan 25-1) is available on the website for this chapter.

AIRWAY MANAGEMENT

Airway management frequently involves early endotracheal (preferably orotracheal) intubation. Early intubation eliminates the need for emergency tracheostomy after respiratory problems have become apparent. In general, the patient with burns to the face and neck requires intubation within 1 to 2 hours after injury. (Intubation is discussed in Chapter 66.) After intubation the patient is placed on ventilatory support, with the delivered oxygen concentration based on ABG values. Extubation may be indicated when the edema resolves, usually 3 to 6 days after burn injury, unless severe inhalation injury is involved. Escharotomies of the chest wall may be needed to relieve respiratory distress secondary to circumferential, full-thickness burns of the neck and trunk (see Fig. 25-8).

Within 6 to 12 hours after injury in which smoke inhalation is suspected, a fiberoptic bronchoscopy should be performed to assess the lower airway. When intubation is not performed, treatment of inhalation injury includes administration of 100% humidified O_2 as needed. Place the patient in a high Fowler's position, unless contraindicated (e.g., spinal injury), and encourage deep breathing and coughing every hour. Reposition the patient every 1 to 2 hours and provide suctioning and chest physiotherapy (as ordered). If severe respiratory distress (e.g., hoarseness, shortness of breath) develops, intubation and mechanical ventilation are initiated. Positive end-expiratory pressure (PEEP) may be used to prevent collapse of the alveoli and progressive respiratory failure (see Chapters 66 and 68). Bronchodilators may be administered to treat severe bronchospasm. CO poisoning is treated by administering 100% O_2 until carboxyhemoglobin levels return to normal.

FLUID THERAPY

Establishing IV access is critical for fluid resuscitation and drug administration. At least two large-bore IV access sites must be in place for patients with burns that are 15% TBSA or more. It is critical to establish IV access that can handle large volumes of fluid. For patients with burns greater than 30% TBSA, consider a central line for fluid and drug administration and blood sampling (central lines are discussed in Chapter 17). An arterial line is often placed if frequent ABGs or invasive BP monitoring is needed.

Assess the extent of the burn wound using a standardized chart (see Fig. 25-4). Then use a standardized formula to estimate the patient's fluid resuscitation requirements. Fluid replacement is achieved with crystalloid solutions (usually lactated Ringer's), colloids (albumin), or a combination of the two.[12] Paramedics generally give IV saline until the patient's arrival at the hospital.

The Parkland (Baxter) formula for fluid replacement is the most common formula used (Table 25-11, or *www.mdcalc.com/parkland-formula-for-burns*). Remember that all formulas are

TABLE 25-10 COLLABORATIVE CARE

Burn Injury

Emergent Phase

Fluid Therapy (see Table 25-11)
- Assess fluid needs.
- Begin IV fluid replacement.
- Insert indwelling urinary catheter.
- Monitor urine output.

Wound Care
- Start daily shower and wound care.
- Debride as necessary.
- Assess extent and depth of burns.
- Administer tetanus toxoid or tetanus antitoxin.

Pain and Anxiety
- Assess and manage pain and anxiety.

Physical and Occupational Therapy
- Place patient in position that prevents contracture formation and reduces edema.
- Assess need for splints.

Nutritional Therapy
- Assess nutritional needs and begin feeding patient by most appropriate route as soon as possible.

Respiratory Therapy
- Assess oxygenation needs.
- Provide supplemental O_2 as needed.
- Intubate if necessary.
- Monitor respiratory status.

Psychosocial Care
- Provide support to patient and caregiver during initial crisis phase.

Acute Phase

Fluid Therapy
- Continue to replace fluids, depending on patient's clinical response.

Wound Care
- Continue daily shower and wound care.
- Continue debridement (if necessary).
- Assess wound daily and adjust dressing protocols as necessary.
- Observe for complications (e.g., infection).

Early Excision and Grafting
- Provide temporary allografts.
- Provide permanent autografts.
- Care for donor sites.

Pain and Anxiety
- Continue to assess for and treat pain and anxiety.

Physical and Occupational Therapy
- Begin daily therapy program for maintenance of range of motion.
- Assess need for splints and anticontracture positioning.
- Encourage and assist patient with self-care as possible.

Nutritional Therapy
- Continue to assess diet to support wound healing.

Respiratory Therapy
- Continue to assess oxygenation needs.
- Continue to monitor respiratory status.
- Monitor for signs of complications (e.g., pneumonia).

Psychosocial Care
- Provide ongoing support, counseling, and teaching to patient and caregiver about physical and emotional aspects of care and recovery.
- Begin to anticipate discharge needs.

Drug Therapy (see Table 25-13)
- Assess need for medications (e.g., antibiotics).
- Continue to monitor effectiveness and adjust dosage as needed.

Rehabilitation Phase
- Continue to counsel and teach patient and caregiver.
- Continue to encourage and assist patient in resuming self-care.
- Continue to prevent or minimize contractures and assess likelihood for scarring (surgery, physical and occupational therapy, splinting, pressure garments).
- Discuss possible reconstructive surgery.
- Prepare for discharge home or transfer to rehabilitation hospital.

TABLE 25-11 FLUID RESUSCITATION

Parkland (Baxter) Formula*

4 mL lactated Ringer's solution per kilogram (kg) of body weight per percent of total body surface area (% TBSA) burned = Total fluid requirements for first 24 hr after burn

Application

½ of total in first 8 hr
¼ of total in second 8 hr
¼ of total in third 8 hr

Example

For a 70 kg patient with a 50% TBSA burn:
4 mL × 70 kg × 50 TBSA burned = 14,000 mL in 24 hr

½ of total in first 8 hr = 7000 mL (875 mL/hr)
¼ of total in second 8 hr = 3500 mL (437 mL/hr)
¼ of total in third 8 hr = 3500 mL (437 mL/hr)

*Formulas are guidelines. Fluid is administered at a rate to produce 0.5-1.0 mL/kg/hr of urine output. The American Burn Association Consensus Fluid Resuscitation Formula of 2-4 mL lactated Ringer's solution per kg of body weight per %TBSA burned = Total fluid requirements for first 24 hr after burn has been suggested as a strategy to avoid over-resuscitation, or "fluid creep."

estimates, and fluids must be titrated based on the patient's response (e.g., hourly urine output, vital signs). Patients with an electrical injury have greater than normal fluid requirements and generally require an osmotic diuretic (mannitol [Osmitrol]) to increase their urine output and overcome high levels of hemoglobin and myoglobin in the urine. Too much fluid and overestimation of TBSA contribute to the development of "fluid creep."[13] For the first 24 hours, the recommendation is 2 to 4 mL lactated Ringer's/kg/%TBSA burned.

Colloidal solutions (e.g., 5% albumin) may also be given. However, administration is recommended after the first 12 to 24 hours postburn when capillary permeability returns to normal or near normal. After this time, the plasma remains in the vascular space and expands the circulating volume. The replacement volume is calculated based on the patient's body weight and TBSA burned (e.g., 0.3 to 0.5 mL/kg/%TBSA burned).

Hourly assessments of the adequacy of fluid resuscitation are best made using clinical parameters. Urine output, the most commonly used parameter, and cardiac parameters are defined as follows.

- *Urine output:* 0.5 to 1 mL/kg/hr; 75 to 100 mL/hr for electrical burn patient with evidence of hemoglobinuria or myoglobinuria.
- *Cardiac parameters:* Mean arterial pressure (MAP) greater than 65 mm Hg, systolic BP greater than 90 mm Hg, heart rate less than 120 beats/minute. MAP and BP are best measured by an arterial line. Manual BP measurement is often invalid because of edema and vasoconstriction.

WOUND CARE

Once a patent airway, effective circulation, and adequate fluid replacement have been established, priority is given to care of the burn wound. Partial-thickness burn wounds appear pink to cherry-red and are wet and shiny with serous exudate. These wounds may or may not have intact blisters; are painful when touched; and have only minor, localized sensation because nerve endings have been destroyed in the burned dermis.

You and appropriate personnel can perform cleansing and gentle debridement, using scissors and forceps, on a cart shower (Fig. 25-9), regular shower, or patient bed or stretcher.[14] Extensive, surgical debridement is performed in the operating room (OR) (Fig. 25-10). During **debridement,** necrotic skin is removed. Releasing escharotomies and fasciotomies are carried out in the emergent phase, usually in burn centers by burn physicians.

FIG. 25-9 Cart shower. Showering presents an opportunity for physical therapy and wound care.

Patients find the initial wound care to be both physically and psychologically demanding. Provide emotional support and begin to build trust during this activity. A once-daily shower and dressing change in the morning, with an evening dressing change in the patient's room, are part of the routine in many burn centers. Others opt to shower the patient on admission and then perform all other dressing changes in the patient's room. Some of the newer antimicrobial dressings can be left in place from 3 to 14 days, thereby decreasing the frequency of dressing changes.

Infection may cause further tissue injury and possible sepsis.[15] The source of infection in burn wounds is likely the patient's own flora, predominantly from the skin, respiratory tract, and gastrointestinal (GI) tract. The prevention of cross-contamination from one patient to another is a priority.

Two approaches to burn wound treatment are (1) the open method and (2) the use of multiple dressing changes (closed method). In the *open method* the patient's burn is covered with a topical antimicrobial and has no dressing over the wound. In the *multiple dressing change,* or *closed method,* sterile gauze dressings are impregnated with or laid over a topical antimicrobial (Fig. 25-11). These dressings are changed anywhere from every 12 to 24 hours to once every 14 days (depending on the product). Most burn centers support the concept of moist wound healing and use dressings to cover the burned areas, with the exception of facial burns.

When the patient's open burn wounds are exposed, always wear personal protective equipment (PPE) (e.g., disposable hats, masks, gowns, gloves). When removing contaminated dressings and washing the dirty wound, use nonsterile, disposable gloves. Use sterile gloves when applying ointments and sterile dressings. In addition, prevent shivering by keeping the room warm (approximately 85° F [29.4° C]). Before leaving one patient, remove your PPE. Don new equipment before you treat another patient. Perform thorough hand washing both before and after patient contact to prevent cross-contamination.

Permanent skin coverage is the primary goal for burn wound care. There is rarely enough unburned skin in the major (greater than 50% TBSA) burn patient for immediate skin grafting. This situation requires the use of temporary wound closure methods. *Allograft (homograft) skin* (from skin donor cadavers) is used, along with newer biosynthetic options. The treatment approaches vary among burn centers (Table 25-12).

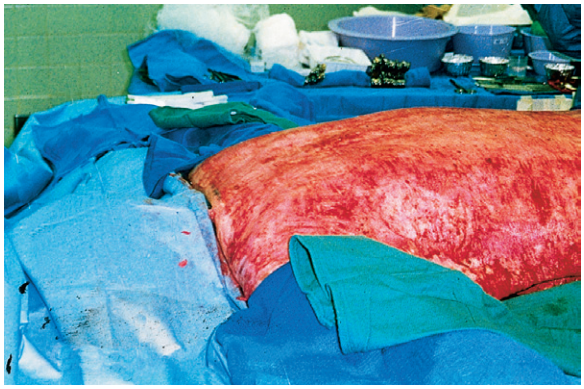

FIG. 25-10 Surgical debridement of full-thickness burns is necessary to prepare the wound for grafting.

FIG. 25-11 Application of silver sulfadiazine cream to saline-moistened gauze.

TABLE 25-12 SOURCES OF GRAFTS

Source	Graft Name	Coverage
Porcine skin	Xenograft (or heterograft) (different species)	Temporary (3 days to 2 wk)
Cadaveric skin	Allograft (or homograft) (same species)	Temporary (3 days to 2 wk)
Patient's own skin	Autograft	Permanent
Patient's own skin and cell cultures	Cultured epithelial autograft (CEA)	Permanent
Porcine collagen bonded to silicone membrane	Biobrane	Temporary (10-21 days)
Bovine collagen and glycosaminoglycan bonded to silicone membrane	Integra	Permanent
Acellular dermal matrix derived from donated human skin	AlloDerm	Permanent

OTHER CARE MEASURES

Certain parts of the body (e.g., face, eyes, hands, arms, ears, perineum) require particularly vigilant nursing care. The face is highly vascular and can become very swollen. It is often covered with ointments and gauze but not wrapped to limit pressure on delicate facial structures. Eye care for corneal burns or edema includes antibiotic ointments. An ophthalmology examination should occur soon after admission for all patients with facial burns. Periorbital edema can prevent eye opening and is often frightening for the patient. Provide assurance that the swelling is not permanent. Instill methylcellulose drops or artificial tears into the eyes for moisture and additional comfort.

Ears should be kept free from pressure because of their poor vascularization and tendency to become infected. Do not use pillows for the patient with ear burns. The pressure on the cartilage may cause chondritis. Further, the ear may stick to the pillowcase, causing pain and bleeding. Elevate your patient's head using a rolled towel placed under the shoulders, being careful to avoid pressure necrosis. Follow the same strategy for the patient with neck burns to hyperextend the neck and prevent neck wound contracture.

Extend your patient's burned hands and arms and elevate them on pillows or plastic-covered foam wedges to minimize edema. Ask the occupational therapist and the physician if splints need to be applied to burned hands and feet to maintain them in positions of function. Remove the splints frequently and inspect the skin and bony prominences to avoid areas of pressure from inappropriate or prolonged application.

Keep your patient's perineum as clean and dry as possible after each voiding or bowel movement. In addition to monitoring hourly urine outputs, an indwelling catheter prevents urine contamination of the perineal area. Regular once- or twice-daily perineal and catheter care, in the presence or absence of a perineal burn wound, is essential. Assess the need for an indwelling urinary catheter on a daily basis and remove when no longer necessary to avoid development of a urinary tract infection. If your patient has frequent, loose stools, consider the temporary insertion of a fecal diversion device.

Perform necessary laboratory tests to monitor fluid and electrolyte balance. Draw ABGs, as necessary, to determine adequacy of ventilation and perfusion in patients with suspected or confirmed inhalation or electrical injury.

Work in collaboration with the physical therapist to perform range-of-motion (ROM) exercises during dressing changes and throughout the day. Movement facilitates mobilization of the leaked fluid back into the vascular bed. Active and passive exercise of body parts also maintains function, prevents contractures, and reassures the patient that movement is still possible.

DRUG THERAPY

ANALGESICS AND SEDATIVES. Promote the use of analgesics for the patient's comfort.[16] Early in the postburn period, IV pain medications should be given because (1) onset of action is fastest with this route; (2) oral medications have a slower onset of action and are not as effective when GI function is slowed or impaired because of shock or paralytic ileus; and (3) intramuscular (IM) injections will not be absorbed adequately in burned or edematous areas, causing pooling of medications in the tissues. Consequently, when fluid mobilization begins, the patient could be inadvertently overdosed from the interstitial accumulation of previous IM medications.

Common opioids used for pain control are listed in Table 25-13. Reevaluate analgesic requirements, since the patient's needs may change and tolerance to medications may develop over time. Initially, opioids are the drug of choice for pain control. When given appropriately, these drugs should provide adequate pain relief. Sedatives/hypnotics and antidepressants can also be given with analgesics to control the anxiety, insomnia, or depression that patients may experience (see Table 25-13). Analgesic requirements can vary widely from one patient to another, so consider a multimodal approach to pain management.[17] Remember that the patient's pain intensity may not directly correlate with the extent and depth of burn.

TETANUS IMMUNIZATION. Tetanus toxoid is given routinely to all burn patients because of the likelihood of anaerobic burn wound contamination. If the patient has not received an active immunization within 10 years before the burn injury, tetanus immunoglobulin should be considered. (Tetanus immunization is discussed in Table 69-6.)

ANTIMICROBIAL AGENTS. After the wound is cleansed, topical antimicrobial agents may be applied (see Fig. 25-11) and covered with a light dressing.[18] Systemic antibiotics are not routinely used to control burn wound flora because the burn eschar has little or no blood supply and consequently little antibiotic is delivered to the wound. In addition, the routine use of systemic antibiotics increases the chance of developing multidrug-resistant organisms. Some topical burn agents penetrate the eschar and inhibit bacterial invasion of the wound. Silver-impregnated dressings (e.g., Acticoat, Silverlon, Aquacel AG) can be left in place from 3 to 14 days, depending on the patient's clinical situation and the particular product. Silver sulfadiazine (Silvadene, Flamazine) and mafenide acetate (Sulfamylon) creams are also used.

SAFETY ALERT

- Check the patient for any allergies to sulfa, since many burn antimicrobial creams contain sulfa.

Sepsis remains a primary cause of death in the patient with major burns and may lead to multiple organ dysfunction syndrome (see Chapter 67). Systemic antibiotic therapy is initiated when the diagnosis of sepsis is made, or when some other source of infection is identified (e.g., pneumonia).[19]

TABLE 25-13 DRUG THERAPY

Burn Care

Drugs	Purpose
Analgesics	
morphine (Avinza) sustained-release morphine (MS Contin) hydromorphone (Dilaudid) sustained-release hydromorphone (Dilaudid CR) fentanyl (Sublimaze) oxycodone and acetaminophen (Percocet) methadone (Dolophine) Nonsteroidal antiinflammatory (e.g., ketorolac [Toradol]) Adjuvant analgesics (e.g., gabapentin [Neurontin])	Relieve pain
Sedatives/Hypnotics	
lorazepam (Ativan)	Reduce anxiety
midazolam (Versed)	Provide short-acting amnesic effects
zolpidem (Ambien)	Promote sleep
Antidepressants	
sertraline (Zoloft) citalopram (Celexa)	Reduce depression, improve mood
Anticoagulants	
enoxaparin (Lovenox) heparin	Prevent venous thromboembolism
Nutritional Support	
Vitamins A, C, E, and multivitamins	Promote wound healing
Minerals: zinc, iron (ferrous sulfate)	Promote cell integrity and hemoglobin formation
oxandrolone (Oxandrin)	Promote weight gain and preservation of lean body mass
Gastrointestinal Support	
ranitidine (Zantac) esomeprazole (Nexium)	Decrease stomach acid and risk of Curling's ulcer
calcium carbonate and magnesium carbonate (Mylanta), aluminum hydroxide and magnesium hydroxide (Maalox)	Neutralize stomach acid
nystatin (Mycostatin)	Prevent overgrowth of *Candida albicans* in oral mucosa

Fungal infections may develop in the patient's mucous membranes (mouth and genitalia) as a result of systemic antibiotic therapy and low resistance. The offending organism is usually *Candida albicans*. Oral infection is treated with nystatin (Mycostatin) mouthwash. When a normal diet is resumed, yogurt or *Lactobacillus* (Lactinex) may be given by mouth to reintroduce the normal intestinal flora that was destroyed by antibiotic therapy.

VENOUS THROMBOEMBOLISM PROPHYLAXIS. Burn patients are at risk for VTE. If there are no contraindications, it is recommended that low-molecular-weight heparin (enoxaparin) or low-dose unfractionated heparin be started as soon as it is considered safe. For burn patients who have a high bleeding risk, VTE prophylaxis with sequential compression devices and/or graduated compression stockings are used until the bleeding risk decreases and heparin can be started (see Table 25-13). (VTE prophylaxis is discussed in Chapter 38.)

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Does the Type of Enteral Feeding Affect Outcomes in Burn Patients?

Clinical Question

In patients with burns (P), what is the effect of high-carbohydrate enteral feeding (I) versus high-fat enteral feeding (C) in reducing mortality, days on ventilator, and incidence of pneumonia (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Two RCTs ($n = 93$) of hospitalized patients in the immediate postburn period, with burns covering ≥10% of the total body surface area (TBSA).
- Two types of enteral feeding were compared: high-carbohydrate, high-protein, low-fat feeding (high-carbohydrate formula) and low-carbohydrate, high-protein, high-fat feeding (high-fat formula).
- High-carbohydrate enteral feeding resulted in a reduced incidence of pneumonia compared with high-fat enteral feeding.
- Inconclusive results on type of enteral feeding and patient outcomes of mortality and days on ventilator.

Conclusion

- High-carbohydrate enteral feedings may be of benefit in reducing the risk of pneumonia.

Implications for Nursing Practice

- Further research is needed to determine if enteral feeds are significantly different related to patient outcomes.

NUTRITIONAL THERAPY

Once fluid replacement needs have been addressed, nutrition takes priority in the initial emergent phase.[20] Early and aggressive nutritional support within several hours of the burn injury can decrease mortality risks and complications, optimize healing of the burn wound, and minimize the negative effects of hypermetabolism and catabolism.[21] Nonintubated patients with a burn of less than 20% TBSA will generally be able to eat enough to meet their nutritional needs.

Intubated patients and those with larger burns require additional support. Enteral feedings (gastric or intestinal) have almost entirely replaced parenteral feeding. Early enteral feeding, usually with smaller-bore tubes, preserves GI function, increases intestinal blood flow, and promotes optimal conditions for wound healing. In general, begin the feedings slowly at a rate of 20 to 40 mL/hr and increase to the goal rate within 24 to 48 hours. If a large nasogastric tube is inserted, gastric residuals should be checked to rule out delayed gastric emptying. Assess bowel sounds every 8 hours.

A *hypermetabolic state* proportional to the size of the wound occurs after a major burn injury.[21] Resting metabolic expenditure may be increased by 50% to 100% above normal in patients with major burns. Core temperature is elevated. Catechol-

amines, which stimulate catabolism and heat production, are increased. Massive catabolism can occur and is characterized by protein breakdown and increased gluconeogenesis. Failure to supply adequate calories and protein leads to malnutrition and delayed healing. Calorie-containing nutritional supplements and milkshakes are often given to meet the caloric needs. Protein powder can also be added to food and liquids. Supplemental vitamins may be started in the emergent phase, with iron supplements often given in the acute phase (see Table 25-13).

ACUTE PHASE

The *acute phase* of burn care begins with the mobilization of extracellular fluid and subsequent diuresis. It concludes when partial-thickness wounds are healed or full-thickness burns are covered by skin grafts. This may take weeks or months.

Pathophysiology

A healing burn injury causes many pathophysiologic changes in the body. Diuresis from fluid mobilization occurs, and the patient is less edematous. Bowel sounds return. The depth of the burn wounds may be more apparent as they "declare" themselves as partial or full thickness. The patient may now become more aware of the enormity of his or her situation and will benefit from psychosocial support and information.

Some healing begins as WBCs surround the burn wound and phagocytosis occurs. Necrotic tissue begins to slough. Fibroblasts lay down matrices of the collagen precursors that eventually form granulation tissue. A partial-thickness burn will heal, from both the wound edges and the dermal bed below, if kept free from infection and *desiccation* (dryness). However, full-thickness burn wounds, unless extremely small, must have the burn eschar surgically removed (excised) and skin grafts applied in order to heal. In some cases, healing time and length of hospitalization are decreased by early excision and grafting.

Clinical Manifestations

Partial-thickness wounds form eschar, which begins separating fairly soon after injury. Once the eschar is removed, reepithelialization begins at the wound margins and appears as red or pink scar tissue. Epithelial buds, from the hair follicles and glands in the dermal bed, eventually close the wound. Healing is spontaneous and usually occurs within 10 to 21 days.

Margins of full-thickness eschar take longer to separate. As a result, full-thickness burn wounds require surgical debridement and skin grafting to heal.

Laboratory Values

Because the body is attempting to reestablish fluid and electrolyte balance in the initial acute phase, it is important to follow serum electrolyte levels closely.

Sodium. *Hyponatremia* can develop from excessive GI suction, diarrhea, and water intake. Manifestations of hyponatremia include weakness, dizziness, muscle cramps, fatigue, headache, tachycardia, and confusion. The patient may also develop a dilutional hyponatremia called *water intoxication*. To avoid this condition, encourage the patient to drink fluids other than water, such as juice or nutritional supplements.

Hypernatremia may be seen after successful fluid resuscitation if copious amounts of hypertonic solutions were required. Hypernatremia may also be related to tube feeding therapy or inappropriate fluid administration. Manifestations of hypernatremia include thirst; dried, furry tongue; lethargy; confusion; and possibly seizures. Sodium restrictions may be applied to IV fluids and enteral or oral feedings until levels return to safe limits.

Potassium. *Hyperkalemia* may occur if the patient has renal failure, adrenocortical insufficiency, or massive deep muscle injury (e.g., electrical burn) with large amounts of potassium released from damaged cells. Cardiac dysrhythmias and arrest can occur with elevated potassium levels. Muscle weakness, cramping, and paralysis are found clinically (see Chapters 17 and 36).

Hypokalemia occurs with vomiting, diarrhea, prolonged GI suction, and IV therapy without potassium supplementation. Potassium is also lost through the patient's burn wounds. Signs and symptoms of hypokalemia include fatigue, muscle weakness, leg cramps, cardiac dysrhythmias (e.g., premature ventricular contractions), paresthesias, and decreased reflexes (see Chapter 17).

Complications

Infection. The body's first line of defense, the skin, is destroyed by a burn injury. The burn wound is now colonized with the person's own organisms that were on the skin before the burn. If the levels of bacteria between the eschar and the viable wound bed rise to greater than 10^5/g of tissue, the patient has a burn wound infection. Localized inflammation, induration, and sometimes suppuration can be seen at the burn wound margins. Partial-thickness burns can convert to full-thickness wounds when these organisms invade viable, adjacent, unburned tissue. Invasive wound infections may be treated with systemic antibiotics based on culture and sensitivity wound swab results.

Watch for signs and symptoms, including hypothermia or hyperthermia, increased heart and respiratory rate, decreased BP, and decreased urine output. The patient may have mild confusion, chills, malaise, and loss of appetite. The WBC count usually is between 10,000/μL (10×10^9/L) and 20,000/μL (20×10^9/L). The WBCs have functional defects and the patient remains immunosuppressed for many months after the burn injury.

The causative organisms of sepsis are usually gram-negative bacteria (e.g., *Pseudomonas, Proteus* organisms), putting the patient at further risk for septic shock. When sepsis is suspected, immediately obtain cultures from all possible sources, including the burn wound, blood, urine, sputum, oropharynx and perineal regions, and IV site. Treatment immediately begins with antibiotics appropriate for the usual residual flora of the particular burn center. When the culture and sensitivity results are known, the antibiotic in use may be continued or changed based on the results. At this stage the patient's condition is considered critical, requiring close monitoring of vital signs.

Cardiovascular and Respiratory Systems. The same cardiovascular and respiratory system complications present in the emergent phase may continue into the acute phase of care. In addition, new problems might arise, requiring timely intervention.

Neurologic System. Neurologically, the patient probably has no physical symptoms unless severe hypoxia from respiratory injuries or complications from electrical injuries occur. Probable causes of neurologic complications include electrolyte imbalance, stress, cerebral edema, sepsis, sleep disturbances, and the use of analgesics and antianxiety drugs. However, some patients may demonstrate certain behaviors that are not com-

pletely understood. The patient can become extremely disoriented, may withdraw or become combative, and may have hallucinations and frequent nightmare-like episodes. Delirium is more acute at night and occurs more often in the older patient. Use a screening tool to diagnose delirium (see Table 60-16) and initiate appropriate nursing interventions to prevent delirium, whenever possible. Focus on nursing strategies to orient and reassure your patient if he or she is confused or agitated. This state is usually transient, lasting from a day or two to several weeks, but complications and sequelae can last for years and be quite serious.

Musculoskeletal System. The musculoskeletal system is particularly prone to complications during the acute phase, and the involvement of both the physical and occupational therapist is vitally important.[22] As the burns begin to heal and scar tissue forms, the skin is less supple and pliant. ROM may be limited, and contractures can occur. Because of pain, the patient likely prefers a flexed position for comfort. Encourage the patient to stretch and move the burned body parts as much as possible. Consult with the occupational therapist about proper positioning and splinting to prevent or reduce contracture formation.

Gastrointestinal System. The GI system may also experience complications during this phase. Paralytic ileus can be caused by sepsis. Diarrhea may result from the use of enteral feedings or antibiotics. Constipation can occur as a side effect of opioid analgesics, decreased mobility, and a low-fiber diet. *Curling's ulcer* is a type of gastroduodenal ulcer characterized by diffuse superficial lesions (including mucosal erosion). It is caused by a generalized stress response to decreased blood flow to the GI tract. The patient has increased gastric acid secretion. Aim to prevent Curling's ulcer by feeding the patient as soon as possible after the burn injury. Antacids, H_2-histamine blockers (e.g., ranitidine [Zantac]), and proton pump inhibitors (e.g., esomeprazole [Nexium]) are used prophylactically to neutralize stomach acids and inhibit histamine and the secretion of hydrochloric acid (see Table 25-13). Patients with major burns may also have occult blood in their stools during the acute phase and require close monitoring for bleeding.

Endocrine System. Observe for transient increases in the patient's blood glucose levels as a result of stress-mediated cortisol and catecholamine release. There is an increased mobilization of glycogen stores and gluconeogenesis. Subsequently, glucose is produced, along with an increase in insulin production. However, insulin's effectiveness is decreased because of relative insulin insensitivity. This results in an elevated blood glucose level. Hyperglycemia may also be caused by the increased caloric intake necessary to meet some patients' metabolic requirements. When this occurs, the treatment is supplemental IV insulin, not decreased feeding. Check blood glucose levels frequently and give insulin as ordered. Point-of-care testing of glucose can be done, but serum glucose testing is more accurate. As the patient's metabolic demands are met and less stress is placed on the entire system, this stress-induced condition is reversed.

NURSING AND COLLABORATIVE MANAGEMENT ACUTE PHASE

The predominant therapeutic interventions in the acute phase are (1) wound care, (2) excision and grafting, (3) pain management, (4) physical and occupational therapy, and (5) nutritional therapy.

WOUND CARE

The goals of wound care are to (1) prevent infection by cleansing and debriding the area of necrotic tissue that would promote bacterial growth and (2) promote wound re-epithelialization and/or successful skin grafting.

Wound care consists of ongoing observation, assessment, cleansing, debridement, and dressing reapplication. Nonsurgical debridement, dressing changes, topical antimicrobial therapy, graft care, and donor site care are performed as often as necessary, depending on the topical cream or dressing ordered. Enzymatic debriders made of natural ingredients, such as collagen, may be used for *enzymatic debridement* of burn wounds, which speeds up the removal of dead tissue from the healthy wound bed.

Cleanse wounds with soap and water or normal saline-moistened gauze to gently remove the old antimicrobial agent and any loose necrotic tissue, scabs, or dried blood. During the debridement phase, cover the wound with topical antimicrobial creams (e.g., silver sulfadiazine) or silver-impregnated dressings. When the partial-thickness burn wounds have been fully debrided, a protective, coarse or fine-meshed, greasy-based (paraffin or petroleum) gauze dressing is applied to protect the re-epithelializing keratinocytes as they resurface and close the open wound bed.

If grafting is necessary, protect the skin graft (discussed below) with the same greasy gauze dressings next to the graft, followed by saline-moistened middle, and dry gauze outer dressings. With facial grafts the unmeshed sheet graft is left open, so it is possible for *blebs* (serosanguineous exudate) to form between the graft and the recipient bed. Blebs prevent the graft from permanently attaching to the wound bed. The evacuation of blebs is best performed by aspiration with a tuberculin syringe and only by those who have received instruction in this specialized skill. (Dressings are discussed in Table 12-10.)

EXCISION AND GRAFTING

Management of full-thickness burn wounds involves early removal (surgical excision) of the necrotic tissue followed by application of split-thickness autograft skin.[23] This aggressive and definitive approach has improved the management and survival rate of burn patients. In the past, patients with major burns had low rates of survival because healing and wound coverage took so long that the patient usually died of sepsis or malnutrition.

Many patients, especially those with major burns, are taken to the OR for wound excision on day 1 or 2 (emergent phase). The wounds are covered with a biologic dressing or allograft for temporary coverage until permanent grafting can occur (see Table 25-12).

During the procedure of **excision and grafting,** devitalized tissue (eschar) is excised down to the subcutaneous tissue or fascia, depending on the degree of injury. Surgical excision can result in massive blood loss.[24] To decrease surgical blood loss, topical application of epinephrine or thrombin, injection of saline and epinephrine, application of extremity tourniquets, or application of a new fibrin sealant (Artiss) is used. Once hemostasis has been achieved, a graft is then placed on clean, viable tissue to achieve good adherence. Whenever possible, the freshly excised wound is covered with *autograft* (the person's own) skin (see Table 25-12). Recently, fibrin sealant has been used to attach skin grafts to the wound bed. Grafts can also be stapled or sutured into place (Fig. 25-12, *A*). A temporary

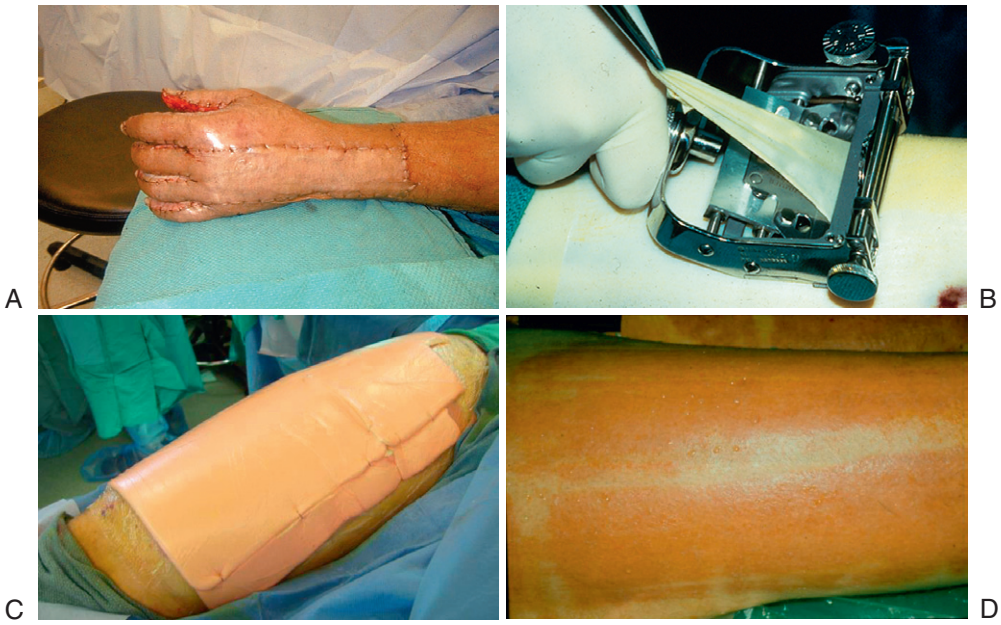

FIG. 25-12 **A,** Freshly applied split-thickness sheet skin graft to the hand. **B,** Split-thickness skin graft is harvested from a patient's thigh using a dermatome. **C,** Donor site is covered with a hydrophilic foam dressing after harvesting. **D,** Healed donor site.

allograft can be used to test the suitability of the recipient site to accept a graft.[25] The allograft is then removed several days later in the OR and an autograft applied.

With early excision, function is restored and scar tissue formation is minimized. Clots between the graft and the wound keep the graft from adhering to the wound. Outer occlusive dressings apply just enough pressure to promote adherence of the graft to the wound bed and help control bleeding. Protect the grafted area from shearing, friction, and pressure. Facial, neck, and hand burns require skillful nursing care to identify and manage clots quickly for the best functional and esthetic outcomes.

Donor skin is taken from the patient for grafting by means of a *dermatome,* which removes a thin (14/1000 to 16/1000 inch) split-thickness layer of skin from an unburned site (Fig. 25-12, *B*). The donor skin can be meshed (usually ratio of 1.5:1) to allow for greater wound coverage, or it may be applied as an unmeshed sheet for a better cosmetic result when grafting the face, neck, and hands. The donor site now becomes a new open wound.

The goals of donor site care are to promote rapid, moist wound healing; decrease pain at the site; and prevent infection. The choices of dressings for donor sites vary among burn centers and include transparent dressings (e.g., Opsite), xenograft, silver sulfadiazine, silver-impregnated dressings, calcium alginate, and hydrophilic foam dressings (Fig. 25-12, *C*). Nursing care of the donor site is specific to the dressing selected.[26] Several of the newer dressing materials offer decreased healing time, which facilitates earlier reharvesting of skin at the same site. The average healing time for a donor site is 10 to 14 days (Fig. 25-12, *D*).

CULTURED EPITHELIAL AUTOGRAFTS. In the patient with large body burns, only a limited amount of unburned skin may be available as donor sites for grafting, and some of that skin may be unsuitable for harvesting. **Cultured epithelial autograft (CEA)** is a method of obtaining permanent skin from a person with limited skin available for harvesting. CEA is grown from biopsy specimens obtained from the patient's own unburned skin.[27] This procedure is performed in suitable patients in some burn centers as soon as possible. The specimens are sent to a commercial laboratory, where the biopsied keratinocytes are grown in a culture medium containing epidermal growth factor. After approximately 18 to 25 days, the keratinocytes have expanded up to 10,000 times and form sheets that can be used as skin grafts. The cultured skin is returned to the burn center, where it is placed on the patient's excised burn wounds (Fig. 25-13, *A*). CEA grafts generally form a seamless, smooth replacement skin tissue (Fig. 25-13, *B*). Problems related to CEA include a poor graft take because of thin epidermal skin, graft loss during healing, infection, and contracture development.

ARTIFICIAL SKIN. Artificial skin must replace all functions of the skin and consist of both dermal and epidermal elements.[27] The Integra artificial skin dermal regeneration template is an example of a skin replacement system. As with CEA, it is indicated for use in the treatment of life-threatening, full-thickness or deep partial-thickness burn wounds when conventional autograft is not available or advisable, as in older or high anesthetic-risk patients. It has also been successfully used in reconstructive burn surgery procedures. It needs to be applied within a few days postburn for greatest success.

Integra artificial skin has a bilayer membrane composed of acellular dermis and silicone. The wound is excised, the bilayer membrane is placed dermal layer down, and the wound is wrapped with dressings in the OR. The dermal layer functions as a biodegradable template that induces organized regeneration of new dermis by the body. The silicone layer remains intact for 3 weeks as the dermal layer degrades and epidermal autografts become available. At this point, the silicone is removed during a second surgical procedure and replaced by the patient's own epidermal autografts. Some burn centers use CEA as the source of the epidermis.

Another dermal replacement is AlloDerm, a cryopreserved allogenic dermis. Human allograft dermis, harvested from

A B

FIG. 25-13 Patient with cultured epithelial autograft (CEA). **A,** Intraoperative application of CEA. **B,** Appearance of healed CEA.

cadavers, is decellularized to render it immunogenic and then freeze-dried. Once thawed, AlloDerm is rehydrated with ultrathin epidermal autografts immediately before placement on a freshly excised wound.

PAIN MANAGEMENT

Many aspects of burn care cause pain. However, patients experience moments of relative comfort if they receive adequate analgesia. To provide effective pain management, you must understand both the physiologic and psychologic aspects of pain. (Pain management is discussed in Chapter 9.)

Burn patients experience two kinds of pain: (1) *continuous, background pain* that might be present throughout the day and night; and (2) *treatment-induced pain* associated with dressing changes, ambulation, and rehabilitation activities. The first line of treatment is drugs (see Table 25-13). With background pain, a continuous IV infusion of an opioid (e.g., hydromorphone [Dilaudid]) allows for a steady, therapeutic level of medication. If an IV infusion is not present, slow-release, twice-a-day opioid medications (e.g., morphine [MS Contin]) are indicated. Around-the-clock oral analgesics can also be used. Breakthrough doses of pain medication need to be available regardless of the regimen selected. Anxiolytics, which can potentiate analgesics, are also indicated and include lorazepam (Ativan) and midazolam (Versed). Adjuvant analgesics, such as gabapentin (Neurontin) and pregabalin (Lyrica), also potentiate opioids. The use of these drugs can help reduce the opioid dosage and undesirable side effects.

For treatment-induced pain, premedicate with an analgesic and an anxiolytic via the IV or oral route. For patients with an IV infusion, a potent, short-acting analgesic, such as fentanyl (Sublimaze), is often effective. During treatment and activity, small doses should be given to keep the patient as comfortable as possible. Elimination of all the pain is difficult, and most patients indicate acceptance of "tolerable" levels of discomfort.

Pain management is complex and ever-changing throughout the patient's hospital stay and after discharge.[28] Some pain can be managed using nondrug strategies. Mind-body interventions, such as relaxation breathing, guided imagery, hypnosis, biofeedback, and music therapy, can be effective in helping patients cope with pain (see Chapters 6 and 7).

Remember, the more control the patient has in managing pain, the more successful the chosen strategies will be. Active participation in requesting time-outs and scheduling treatments and rest periods can help the patient manage feelings of anticipatory pain. Patient-controlled analgesia (PCA) is used in selected circumstances in some burn centers, with varying degrees of success. (PCA is discussed in Chapter 9.)

PHYSICAL AND OCCUPATIONAL THERAPY

Continuous physical therapy, throughout burn recovery, is imperative if the patient is to regain and maintain muscle strength and optimal joint function. A good time for exercise is during and after wound cleansing, when the skin is softer and bulky dressings are removed. Passive and active ROM should be performed on all joints. Ensure that the patient with neck burns continues to sleep without pillows or with the head hanging slightly over the top of the mattress to encourage hyperextension. Maintain the occupational therapy schedule for wearing custom-fitted splints, which are designed to keep joints in functional position. Examine the splints frequently to ensure an optimal fit, with no undue pressure that might lead to skin breakdown or nerve damage.

NUTRITIONAL THERAPY

The goal of nutritional therapy during the acute burn phase is to provide adequate calories and protein to promote healing. When the wounds are still open, the burn patient is in a hypermetabolic and highly catabolic state.

The patient may benefit from an antioxidant protocol, which includes selenium, acetylcysteine, ascorbic acid, vitamin E, zinc, and a multivitamin. Meeting daily caloric requirements is crucial and should begin within the first 1 to 2 days postburn. The daily estimated caloric needs must be regularly calculated by a dietitian and readjusted as the patient's condition changes (e.g., wound healing improves, sepsis develops). Monitor laboratory values (e.g., albumin, prealbumin, total protein, transferrin) on a regular basis.

If the patient is on a mechanical ventilator or unable to consume adequate calories by mouth, a small-bore feeding tube is placed and enteral feedings are initiated. When the patient is extubated, contact the speech pathologist to perform a swallowing assessment before an oral diet is started.[29] Encourage the patient to eat high-protein, high-carbohydrate foods to meet caloric needs. Ask caregivers to bring in favorite foods from home. Appetite is usually diminished, and you will need to reinforce whatever steps are necessary to achieve adequate intake. Ideally, weight loss should not be more than 10% of

preburn weight. Record the patient's daily caloric intake using calorie count sheets, which are monitored by the dietitian. Weigh your patient weekly to evaluate progress.

REHABILITATION PHASE

The formal *rehabilitation phase* begins when the patient's wounds have healed and he or she is engaging in some level of self-care. This may happen as early as 2 weeks or as long as 7 to 8 months after the burn injury. Goals for the patient now are to (1) work toward resuming a functional role in society and (2) rehabilitate from any functional and cosmetic postburn reconstructive surgery that may be necessary.[30]

Pathophysiologic Changes and Clinical Manifestations

Burn wounds heal either by spontaneous re-epithelialization or by skin grafting. Layers of keratinocytes begin rebuilding the tissue structure destroyed by the burn injury. Collagen fibers, present in the new scar tissue, assist with healing and add strength to weakened areas. The new skin appears flat and pink. In approximately 4 to 6 weeks, the area becomes raised and hyperemic. If adequate ROM is not instituted, the new tissue will shorten, causing a contracture. Mature healing is reached in about 12 months when suppleness has returned, and the pink or red color has faded to a slightly lighter hue than the surrounding unburned tissue.

Counsel patients who have more heavily pigmented skin that it will take longer for it to regain its dark color because many of the melanocytes have been destroyed. Frequently, the skin does not regain its original color. Provide teaching and psychosocial support to assist the patient with grieving about these changes to his or her body image. In particular, teenagers and female patients may need more support, but explore potential body image concerns with everyone.[31] Cosmetic camouflage, the implantation of pigment within the skin, can help even out unequal skin tones and improve the patient's overall appearance and self-image.

Scarring has two characteristics: discoloration and contour. The discoloration of scars fades somewhat with time. However, scar tissue tends to develop altered contours; that is, it is no longer flat or slightly raised but becomes elevated and enlarged above the original burned area. Some burn care providers believe that pressure can eventually help keep a scar flat.[32] Gentle pressure is maintained on the healed burn with custom-fitted pressure garments and clear, thermoplastic face masks. Pressure garments and masks should never be worn over unhealed wounds and, once a wearing schedule has been established, are removed only for short periods while bathing. Pressure garments are worn up to 24 hours a day for as long as 12 to 18 months.

The patient typically experiences discomfort from itching where healing is occurring. Teach your patient about the application of water-based moisturizers and selective, short-term use of oral antihistamines (e.g., hydroxyzine [Atarax]) to help reduce the itching. Massage oil, silicone gel sheeting (e.g., Biodermis), gabapentin, and injectable corticosteroids also may be helpful.[33]

As "old" epithelium is replaced by new cells, flaking occurs. The newly formed skin is extremely sensitive to trauma. Blisters and skin tears are likely to develop from slight pressure or friction. Additionally, these newly healed areas can be hypersensitive or hyposensitive to cold, heat, and touch. Grafted areas are more likely to be hyposensitive until peripheral nerve regeneration occurs. Teach your patients to protect healed burn areas from direct sunlight for about 3 months to prevent hyperpigmentation and sunburn injury. They should always wear sunscreen when they are outside.[34]

FIG. 25-14 Neck contractures.

Complications

The most common complications during the rehabilitation phase are skin and joint contractures and hypertrophic scarring (Fig. 25-14) and eFig. 25-1 (available on the website for this chapter). A **contracture** (an abnormal condition of a joint characterized by flexion and fixation) develops as a result of the shortening of scar tissue in the flexor tissues of a joint. Areas that are most susceptible to contracture formation include the anterior and lateral neck areas, axillae, antecubital fossae, fingers, groin areas, popliteal fossae, knees, and ankles. Some areas encompass major joints. Not only does the skin over these areas develop contractures, but the underlying tissues, such as the ligaments and tendons, also have a tendency to shorten during the healing process.

Carefully observe the patient for these potential problems. Encourage proper positioning, splinting, and exercise to minimize this complication. Tell the patient to continue with these strategies until the skin matures at around 1 year posthealing. Rehabilitative therapy is aimed at the extension of body parts because the flexors are stronger than the extensors. Burned legs may first be wrapped with elastic (e.g., tensor, Ace) bandages to assist with circulation to leg-graft and donor sites before ambulation. Burned arms can be wrapped with a layer of tubular elastic gauze (e.g., Tubigrip). This interim pressure prevents blister formation, promotes venous return, and decreases pain and itchiness. Once the skin is completely healed and less fragile, custom-fitted pressure garments replace the elastic bandages and tubular gauze.

NURSING AND COLLABORATIVE MANAGEMENT REHABILITATION PHASE

During the rehabilitation phase, encourage both the patient and the caregiver to participate in care. Since the patient may go home with small, unhealed wounds, teach your patient and caregiver the skills for dressing changes and wound care.[34] Pain management and nutritional needs continue to be based on

individual patient status. If needed, arrange home care nursing services to assist with care after discharge. Water-based creams that penetrate into the dermis (e.g., Vaseline Intensive Rescue, Sween, Complex 15) should be used routinely on healed areas to keep the skin supple and well moisturized, which will decrease itching and flaking. Occasionally low-dose antihistamines may be used at bedtime if itching persists.

Postburn reconstructive surgery is frequently required after a major burn. The need for further surgery is reviewed at the outpatient burn clinic appointments after discharge.

Continue to encourage the patient to perform the physical and occupational therapy routines. Constant encouragement and reassurance are necessary to maintain a patient's morale, particularly once the patient realizes that recovery can be slow. Rehabilitation may need to be a primary focus for at least the next 6 to 12 months.

GERONTOLOGIC CONSIDERATIONS

BURNS

The older patient presents many challenges for the burn team. The normal aging process puts the patient at risk for injury because of unsteady gait, limited eyesight, and diminished hearing. As people age, skin becomes drier and more wrinkled. Older adults have thinning of the dermal layer, a loss of elastic fibers, a reduction in subcutaneous adipose tissue, and a decrease in vascularity. As a result, the thinner dermis, with reduced blood flow, sustains deeper burns with poorer rates of healing.[35]

Once injured, the older adult has more complications in the emergent and acute phases of burn resuscitation because of preexisting medical conditions. For example, older patients with diabetes, heart failure, or chronic obstructive pulmonary disease have morbidity and mortality rates exceeding those of healthy, younger patients. In older patients, pneumonia is a frequent complication, burn wounds and donor sites take longer to heal, and surgical procedures are less well tolerated. Weaning from a ventilator can be a challenge. Although usually self-limiting, delirium, if it develops, may be distressing. It usually takes longer for these patients to rehabilitate to the point where they can safely return home.[36] For some, a return home to independent living may not be possible. As the population ages, developing strategies to prevent burn injuries in older adults is a priority.

EMOTIONAL/PSYCHOLOGIC NEEDS OF PATIENTS AND CAREGIVERS

Patients and caregivers have many emotional/psychologic needs during the often lengthy, unpredictable, and complex course of care.[37,38] You have an important supportive and counseling role as patients struggle to get their lives back on track.

To manage the enormous range of emotional responses that the burn patient may exhibit, assess the circumstances of the burn (e.g., cause, people involved), family relationships, and previous coping experiences with stressful stimuli. At any time the patient may experience a variety of emotions such as fear, anxiety, anger, guilt, and depression (Table 25-14).

Burn survivors frequently experience thoughts and feelings that are frightening and disturbing, such as guilt about the burn incident, reliving of the frightening burn experience, fear of dying, concern about future therapy and surgery, frustrations with ongoing discomfort and treatment, and hopelessness about the future. During recovery, as more independence is expected from the patient, new fears may occur: "Can I really do this?" "Am I a desirable person?" "How can I go outside looking like this?" These challenges confront patients throughout their recovery and perhaps for years to come.

TABLE 25-14 EMOTIONAL RESPONSES OF BURN PATIENTS*

Emotion	Possible Verbal Expression
Fear	Will I die?
	What will happen next?
	Will I be disfigured?
	Will my family and friends still love me?
Anxiety	I feel out of control.
	What's going to happen to me?
	When will I look normal again?
Anger	Why did this happen to me?
	The nurses enjoy hurting me.
	I hope the person who did this to me dies.
Guilt	If only I'd been more careful.
	I'm being punished because I did something wrong.
Depression	It's no use going on like this.
	I don't care what happens to me.
	I wish people would leave me alone.

*List is not all-inclusive.

A person's self-esteem may be adversely affected by a burn injury. Some individuals may fear the loss of relationships because of perceived or actual physical disfigurement. In a society that values physical beauty, alterations in body image can result in psychologic distress.

Open and frequent communication among the patient, caregivers, close friends, and burn team members is essential. Because of the tremendous psychologic impact of a burn injury, be particularly sensitive to the patient's emotions and concerns. Encourage the patient to discuss fears regarding loss of life as he or she once knew it, loss of function, temporary or permanent deformity and disfigurement, return to work and home life, and financial burdens resulting from a long and costly hospitalization and rehabilitation.[39]

Encourage appropriate independence and an eventual return to preburn activities, such as school or work.[40] Peer counseling and informal interactions with other burn survivors may bring comfort and help to restore confidence. Reassure patients that their feelings, during this period of adjustment, are a normal reaction to an extraordinary life event. Their frustration and impatience are to be expected as they work to establish a new life. Assist patients in adapting to a realistic, yet positive appraisal of their particular situation, emphasizing what they *can* do instead of what they *cannot* do.

Caregivers may share some or all of these challenges and feelings. At times, they may feel helpless or too exhausted to assist their loved one. Continued support from trusted and familiar burn team members is essential. Helping caregivers assist with aspects of the patient's care helps them to reconnect with their loved one and eases the transition home. Many burn survivors and their caregivers remark on the powerful learning experience of the burn and a renewed appreciation of life, despite the ongoing challenges of a prolonged recovery. You need to acknowledge that their feelings are real and common. Most burn survivors speak of a real satisfaction with their postburn life and are more empowered as time goes on.

It is important to address individual spiritual and cultural needs because both have a role in treatment decisions and recovery. Pastoral care may be a helpful resource for the patient and the caregiver. The need for support, information, and family involvement may vary among cultures. Identify what is important to your patient and caregiver, and communicate that information in the patient's plan of care. Encourage the burn care team to remain culturally aware of and sensitive to the individual patient's and caregiver's cultural needs.

The difficult issue of sexuality must be met with honesty.[41] Physical appearance is altered in the patient who has sustained a major burn. Acceptance of any changes is difficult at first for the patient and significant other. The nature of skin injury in itself can cause modifications in processing sexual stimuli. Touch is an important part of sexuality, and immature scar tissue may make the sensation of touch unpleasant or may dull it. This may only be transient, but the patient and partner need to know that it is normal and receive anticipatory guidance from the burn team to avoid undue emotional strain.

The stress of the burn injury occasionally precipitates a psychologic crisis. Many patients realize this experience is beyond their ability to cope. Assessment by a psychiatrist who can prescribe appropriate medication, if needed, and begin short-term counseling is frequently helpful. Early psychiatric intervention is essential if the patient has been previously treated for a psychiatric illness or if the injury was a suicide attempt. The diagnosis of posttraumatic stress disorder is made in a number of burn patients. Treatment typically begins in the hospital, but links to community resources must be made before discharge to ensure continuity of psychologic care. A referral to a psychiatrist, psychologist, mental health counselor, social worker, or psychiatric advanced practice nurse (APN) should be discussed if concerns are raised at burn clinic follow-up.

Caregiver and patient support groups may be beneficial in meeting the patient's and caregiver's emotional needs at any phase of the recovery process.[42] Speaking with others who have experienced burn trauma can be beneficial, both in terms of reaffirming that the patient's feelings are normal and in sharing helpful advice. The Phoenix Society *(www.phoenix-society.org)* is an international, highly respected burn survivors' support group. For many years the society has offered invaluable support and resources (e.g., annual World Burn Congress conference) to burn survivors, caregivers, and burn team personnel.

SPECIAL NEEDS OF NURSES

Warm, trusting, and mutually satisfying relationships frequently develop between burn patients and nursing staff, not only during hospitalization but also during the long-term rehabilitation period.[43] Sometimes the bond can be so strong that the patient has difficulty separating from the hospital and staff. The frequency and intensity of family contact can be rewarding as well as draining to you. You may find it difficult to cope with the deformities caused by the burn injury, the odors, the unpleasant sight of the wound, and the reality of the pain that accompanies the burn and its treatment. Do not hesitate to seek help from co-workers, a manager, or the employee assistance program should you feel the need.

In time, you will come to know that the specialized burn care you provide makes a critical difference in helping patients not only survive, but also cope with and triumph over an intense and multifaceted injury.

Ongoing support services or critical incident stress debriefings led by a psychiatrist, psychologist, psychiatric APN, or social worker may also be helpful. Peer support groups (e.g., ABA, International Society for Burn Injuries) can serve a similar purpose by helping you cope with difficult feelings experienced when caring for burn patients. Because burn nursing is physically, psychologically, and intellectually demanding, it has many challenges and inherent rewards. Attention to your own self-care is important to maintain a positive attitude and healthy work-life balance.[44] Time with family and friends and rest and relaxation at home are essential parts of self-care and a balanced life with purpose and meaning.

CASE STUDY

Burn Injury

Comstock/Thinkstock

Patient Profile

G.M., a 52-year-old married white man, arrives at the emergency department with burns to his face, neck, chest, right arm and hand, and right foot. He was burning brush on his farm when the fire went out of control. He has an 18-gauge IV with NSS running at 100 mL/hr, and he is receiving 100% humidified O_2 by mask.

Subjective Data

- Complains of blurry vision and trouble swallowing
- States his burns are painful and that he is scared
- States he is a "diabetic" and has "high blood pressure"

Objective Data

Physical Examination

- Is awake, alert, and oriented, but in some distress
- Eyes are red, irritated
- Voice is hoarse; nasal hair is singed
- Face is reddened with blisters noted on the nose and forehead
- Right arm, right hand, chest, neck, and right foot have shiny, bright red, wet wounds
- Patient is shivering

Discussion Questions

1. ***Priority Decision:*** What are the priorities of care in the prehospital environment? How should his airway, breathing, and circulation be managed?
2. ***Priority Decision:*** What factors place G.M. at high risk for an inhalation injury? What priority interventions can be anticipated?
3. What pain medications might be considered to relieve his pain?
4. Which of the criteria for burn center referral does G.M. meet for admission to the hospital burn unit?
5. What metabolic disturbances would be expected soon after G.M.'s admission? Explain the physiologic basis for these changes.
6. How might G.M.'s co-morbidities affect his burn care and rehabilitation?
7. What measures should be taken to support G.M.'s caregivers?
8. ***Priority Decision:*** Based on the assessment data presented, develop three priority nursing diagnoses. Identify any collaborative problems.
9. ***Evidence-Based Practice:*** What are the most effective wound care strategies to manage G.M.'s burn wounds?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Knowing the most common causes of household fires, which prevention strategy would the nurse focus on when teaching about fire safety?
   - **a.** Set hot water temperature at 140° F (60° C).
   - **b.** Use only hardwired smoke detectors.
   - **c.** Encourage regular home fire exit drills.
   - **d.** Never permit older adults to cook unattended.
2. The injury that is least likely to result in a full-thickness burn is
   - **a.** sunburn.
   - **b.** scald injury.
   - **c.** chemical burn.
   - **d.** electrical injury.
3. When assessing a patient with a partial-thickness burn, the nurse would expect to find *(select all that apply)*
   - **a.** blisters.
   - **b.** exposed fascia.
   - **c.** exposed muscles.
   - **d.** intact nerve endings.
   - **e.** red, shiny, wet appearance.
4. A patient is admitted to the burn center with burns of his head and neck, chest, and back after an explosion in his garage. On assessment, the nurse auscultates wheezes throughout the lung fields. On reassessment, the wheezes are gone and the breath sounds are greatly diminished. Which action is the most appropriate for the nurse to take next?
   - **a.** Obtain vital signs and a STAT arterial blood gas.
   - **b.** Encourage the patient to cough and auscultate the lungs again.
   - **c.** Document the findings and continue to monitor the patient's breathing.
   - **d.** Anticipate the need for endotracheal intubation and notify the physician.
5. Fluid and electrolyte shifts that occur during the early emergent phase of a burn injury include
   - **a.** adherence of albumin to vascular walls.
   - **b.** movement of potassium into the vascular space.
   - **c.** sequestering of sodium and water in interstitial fluid.
   - **d.** hemolysis of red blood cells from large volumes of rapidly administered fluid.
6. To maintain a positive nitrogen balance in a major burn, the patient must
   - **a.** eat a high-protein, low-fat, high-carbohydrate diet.
   - **b.** increase normal caloric intake by about three times.
   - **c.** eat at least 1500 calories/day in small, frequent meals.
   - **d.** eat rice and whole wheat for the chemical effect on nitrogen balance.
7. A patient has 25% TBSA burned from a car fire. His wounds have been debrided and covered with a silver-impregnated dressing. The nurse's priority intervention for wound care would be to
   - **a.** reapply a new dressing without disturbing the wound bed.
   - **b.** observe the wound for signs of infection during dressing changes.
   - **c.** apply cool compresses for pain relief in between dressing changes.
   - **d.** wash the wound aggressively with soap and water three times a day.
8. Pain management for the burn patient is most effective when *(select all that apply)*
   - **a.** a pain rating tool is used to monitor the patient's level of pain.
   - **b.** painful dressing changes are delayed until the patient's pain is completely relieved.
   - **c.** the patient is informed about and has some control over the management of the pain.
   - **d.** a multimodal approach is used (e.g., sustained-release and short-acting opioids, NSAIDs, adjuvant analgesics).
   - **e.** nonpharmacologic therapies (e.g., music therapy, distraction) replace opioids in the rehabilitation phase of a burn injury.
9. A therapeutic measure used to prevent hypertrophic scarring during the rehabilitation phase of burn recovery is
   - **a.** applying pressure garments.
   - **b.** repositioning the patient every 2 hours.
   - **c.** performing active ROM at least every 4 hours.
   - **d.** massaging the new tissue with water-based moisturizers.
10. A patient is recovering from second- and third-degree burns over 30% of his body and is now ready for discharge. The first action the nurse should take when meeting with the patient would be to
    - **a.** arrange a return-to-clinic appointment and prescription for pain medications.
    - **b.** teach the patient and the caregiver proper wound care to be performed at home.
    - **c.** review the patient's current health care status and readiness for discharge to home.
    - **d.** give the patient written discharge information and websites for additional information for burn survivors.

1. c, 2. a, 3. a, d, e, 4. d, 5. c, 6. a, 7. b, 8. a, c, d, 9. a, 10. c

CASE STUDY

Managing Multiple Patients

Introduction

You are working the day shift on a medical-surgical unit and have been assigned to care for the following five patients. You have 1 UAP who is assigned to work with you. There are 15 other patients on the unit being cared for by an additional 3 RNs and 3 UAPs.

Patients

Jack Hollingsworth/ Photodisc/Thinkstock

F.M., an 81-year-old Hispanic woman, had pneumatic retinopexy surgery yesterday to repair a partially detached retina. She has a history of diabetes, hypothyroidism, and hypertension. She is scheduled to be discharged today, but the night nurse is concerned because her blood pressure is elevated at 150/94 mm Hg.

Kevin Peterson/Stockbyte/ Thinkstock

J.K., a 68-year-old African American woman with osteoarthritis and type 2 diabetes mellitus for the past 15 years, now has diabetic retinopathy. She had argon laser therapy to her right eye yesterday to seal leaking microaneurysms from macular edema. She was admitted with uncontrolled postoperative hyperglycemia.

iStockphoto/Thinkstock

D.A., a 74-year-old woman, is admitted to the hospital with complaints of chest tightness and shortness of breath. Her past medical history is negative except for a recent diagnosis of basal cell carcinoma (BCC) on her face. She was scheduled to have the BCC surgically removed tomorrow. The health care provider suspects D.A.'s symptoms are caused by anxiety but first needs to rule out any coronary artery disease before surgery.

Hemera/Thinkstock

G.L., a 59-year-old white man, just arrived for admission. He is scheduled for surgical removal of malignant melanoma lesions on his face at 1200. He is worried that the surgery will be disfiguring.

Comstock/Thinkstock

G.M., a 52-year-old white man, is transferred from the ICU following burns to his face, neck, chest, right arm and hand, and right foot. He has a tracheostomy and is receiving 35% O_2 via a humidified trach collar. He has a history of diabetes and hypertension. In the ICU he had been on a mechanical ventilator for respiratory failure caused by inhalation injury. His burns are shiny, bright red, and wet. There are a few blisters on his face.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide rationale.
2. ***Delegation Decision:*** Which tasks could you delegate to the UAP *(select all that apply)?*
   a. Obtain vital signs on F.M.
   b. Take a blood pressure reading on G.M.
   c. Perform an admission assessment on G.L.
   d. Explain planned diagnostic testing to D.A.
   e. Obtain a capillary blood glucose reading on J.K.
3. ***Priority and Delegation Decision:*** When you enter G.M.'s room, he tells you he is not feeling well. He says he has a headache and his legs are "cramping up." He is also somewhat confused as he is unaware that he is in the hospital. What initial action would be most appropriate?
   a. Administer acetaminophen for headache relief.
   b. Have the UAP obtain a stat capillary blood glucose reading.
   c. Notify G.M.'s health care provider of his altered level of consciousness.
   d. Have the UAP obtain vital signs on G.M. while you look at his most recent laboratory test results.

Case Study Progression

G.M.'s vital signs are BP 154/88 mm Hg, his heart rate is 112 bpm, his respirations are 18 breaths/min, and his temperature is 98° F (36.8° C). His most recent lab work reveals a serum sodium level of 125 mEq/L (125 mmol/L). You notify his health care provider, who orders a normal saline IV to infuse at 100 mL/hr.

4. G.M. complains of thirst and asks for something to drink. Which fluid would be appropriate to give him *(select all that apply)?*
   a. Gatorade
   b. Tap water
   c. Cola soda
   d. Apple juice
   e. Orange juice
5. In addition to teaching F.M. how to administer postoperative eye drops, you will also explain
   a. position and activity restrictions.
   b. how to change the dressing on her eye.
   c. the necessity for restricting fluid intake.
   d. that protective eyewear will no longer be required.
6. When giving report to your UAP regarding your assigned patients, she asks if there is a significant difference between D.A. and G.L.'s skin cancers. You reply based on knowledge that
   a. basal cell carcinoma is the most deadly form of skin cancer.
   b. malignant melanoma typically appears as red, rough patches on the skin.
   c. basal cell carcinoma typically presents during the second and third decades of life.
   d. melanoma has the ability to metastasize to any organ, including the brain and heart.
7. ***Management Decision:*** Another RN offers to help you by providing wound care for G.M. Which observed action by the RN would require your immediate intervention?
   a. G.M.'s hands are elevated on pillows.
   b. G.M.'s burns are cleansed with soap and water.
   c. G.M. is promised analgesia as soon as wound care is complete.
   d. G.M.'s burns are covered with a very thin layer of prescribed ointment.

LEARNING OUTCOMES

1. Differentiate among the structures and functions of the upper respiratory tract, the lower respiratory tract, and the chest wall.
2. Describe the process that initiates and controls inspiration and expiration.
3. Describe the process of gas diffusion within the lungs.
4. Identify the respiratory defense mechanisms.
5. Describe the significance of arterial blood gas values in relation to respiratory function.
6. Relate the signs and symptoms of inadequate oxygenation to implications of these findings.
7. Link the age-related changes of the respiratory system to the differences in assessment findings.
8. Select the significant subjective and objective data related to the respiratory system that should be obtained from a patient.
9. Select appropriate techniques to use in the physical assessment of the respiratory system.
10. Differentiate normal from common abnormal findings in a physical assessment of the respiratory system.
11. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the respiratory system.

STRUCTURES AND FUNCTIONS OF RESPIRATORY SYSTEM

The primary purpose of the respiratory system is gas exchange. This involves the transfer of oxygen (O_2) and carbon dioxide (CO_2) between the atmosphere and the blood. The respiratory system is divided into two parts: the upper respiratory tract and the lower respiratory tract (Fig. 26-1).

Upper Respiratory Tract

The *upper respiratory tract* includes the nose, mouth, pharynx, epiglottis, larynx, and trachea. Air enters into the respiratory tract through the nose. The nose is made of bone and cartilage and is divided into two nares by the nasal septum. The inside of the nose is shaped into three passages by projections called *turbinates*. The turbinates increase the surface area of the nasal

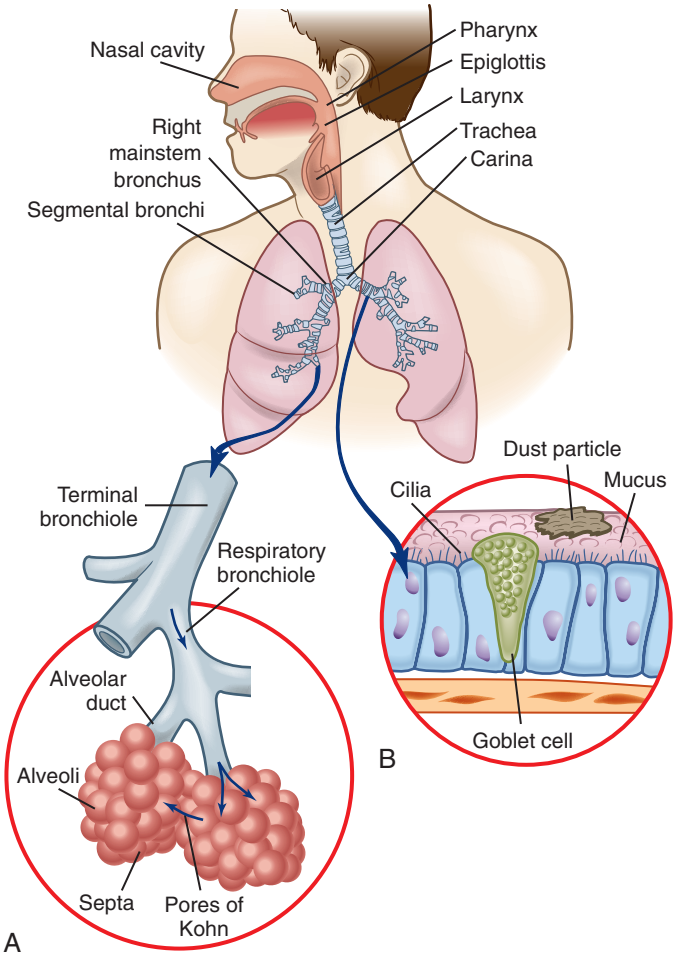

FIG. 26-1 Structures of the respiratory tract. **A,** Pulmonary functional unit. **B,** Ciliated mucous membrane.

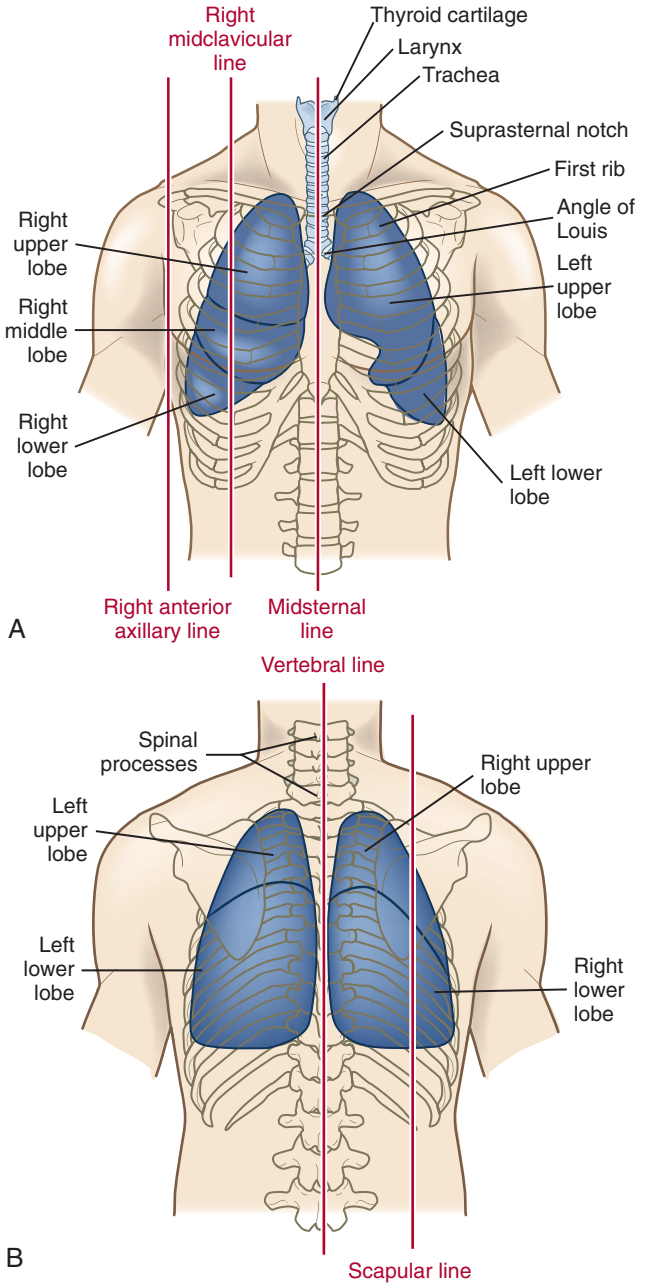

FIG. 26-2 Landmarks and structures of the chest wall. **A,** Anterior view. **B,** Posterior view.

mucosa, which warms and moistens the air as it enters the nose. The internal nose opens directly into the sinuses. The nasal cavity connects with the pharynx, a tubular passageway that is subdivided into three parts: the *nasopharynx, oropharynx,* and *laryngopharynx*.

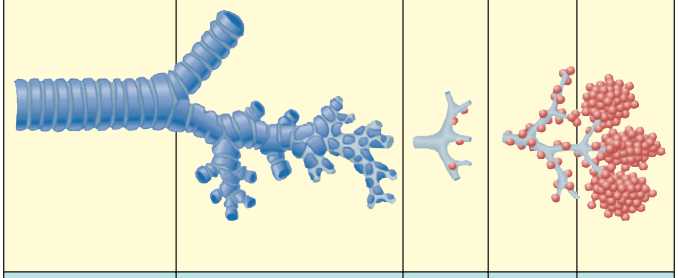
The nose functions to protect the lower airway by warming and humidifying air and filtering small particles before air enters the lungs. Olfactory nerve endings, located in the roof of the nose, are responsible for the sense of smell.

Air moves through the oropharynx to the laryngopharynx. It then travels through the epiglottis to the larynx before moving into the trachea. The *epiglottis* is a small flap located behind the tongue that closes over the larynx during swallowing. This prevents solids and liquids from entering the lungs. The vocal cords are located in the larynx. Vibrational sounds are made during respiration leading to vocalization. Air passes through the glottis, the opening between the vocal cords, and into the trachea. The trachea is a cylindric tube about 5 in (10 to 12 cm) long and 1 in (1.5 to 2.5 cm) in diameter. U-shaped cartilages keep the trachea open but allow the adjacent esophagus to expand for swallowing. The trachea bifurcates into the right and left mainstem bronchi at a point called the *carina.* The carina is located at the level of the manubriosternal junction, also called the *angle of Louis.* The carina is highly sensitive, and touching it during suctioning causes vigorous coughing.[1]

Lower Respiratory Tract

The *lower respiratory tract* consists of the bronchi, bronchioles, alveolar ducts, and alveoli. With the exception of the right and left mainstem bronchi, all lower airway structures are located inside the lungs. The right lung is divided into three lobes (upper, middle, and lower) and the left lung into two lobes (upper and lower) (Fig. 26-2). The structures of the chest wall (ribs, pleura, muscles of respiration) are also important for respiration.

Once air passes the carina, it is in the lower respiratory tract. The mainstem bronchi, pulmonary vessels, and nerves enter the lungs through a slit called the *hilus.* The right mainstem bronchus is shorter, wider, and straighter than the left mainstem bronchus. For this reason, aspiration is more likely to occur in the right lung than in the left lung.



Conducting airways					Respiratory unit
Trachea	Bronchi, segmental bronchi	Sub-segmental bronchi	Bronchioles: Non-respiratory	Bronchioles: Respiratory	Alveolar ducts, alveoli
					
Generations	8	15	21-22	24	28

FIG. 26-3 Structures of lower airways.

The mainstem bronchi subdivide several times to form the lobar, segmental, and subsegmental bronchi. Further divisions form the bronchioles. The most distant bronchioles are called the respiratory bronchioles. Beyond these lie the alveolar ducts and alveolar sacs (Fig. 26-3). The bronchioles are encircled by smooth muscles that constrict and dilate in response to various stimuli. The terms *bronchoconstriction* and *bronchodilation* refer to a decrease or increase in the diameter of the airways caused by contraction or relaxation of these muscles.

Oxygen and carbon dioxide exchange takes place in the alveoli. The trachea and bronchi act as a pathway to conduct gases to the alveoli. The trachea plus the bronchi are called *anatomic dead space* (V_D).The air filling this space with every breath is not available for gas exchange. In adults a normal **tidal volume (V_T),** or volume of air exchanged with each breath, is about 500 mL (in a 150 lb man). Of each 500 mL inhaled, about 150 mL is V_D.

After moving through the V_D, air reaches the respiratory bronchioles and alveoli (Fig. 26-4). *Alveoli* are small sacs that are the primary site of gas exchange in the lungs. The alveoli are interconnected by pores of Kohn, which allow movement of air from alveolus to alveolus (see Fig. 26-1). Deep breathing promotes air movement through these pores and assists in moving mucus out of the respiratory bronchioles. Bacteria can also move through these pores, spreading infection to previously uninfected areas. The adult lung has 300 million alveoli. Alveoli have a total volume of about 2500 mL and a surface area for gas exchange that is about the size of a tennis court.

Gases are exchanged at the alveolar-capillary membrane where the alveoli come in contact with pulmonary capillaries (Fig. 26-5). In conditions such as pulmonary edema, excess fluid fills the interstitial space and alveoli, markedly reducing gas exchange.

Surfactant. The lungs are a collection of 300 million alveoli, each 0.3 mm in diameter. Because alveoli are unstable, they have a natural tendency to collapse. Alveolar cells secrete surfactant. **Surfactant** is a lipoprotein that lowers the surface tension in the alveoli. It reduces the amount of pressure needed to inflate the alveoli and makes them less likely to collapse. Normally, each person takes a slightly larger breath, termed a *sigh*, after every five or six breaths. This sigh stretches the alveoli and promotes surfactant secretion.

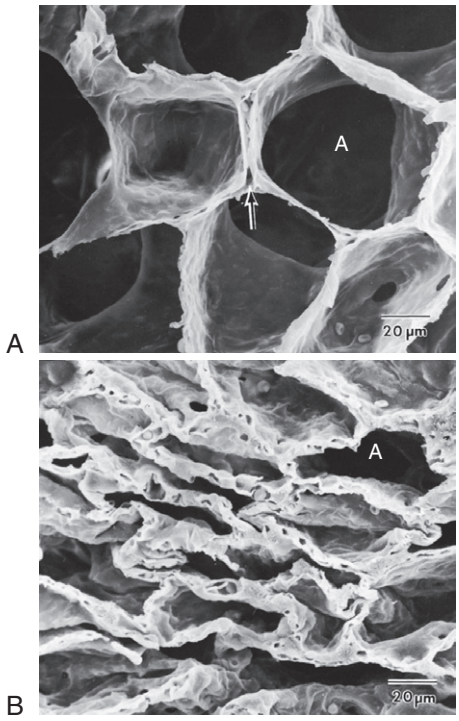


FIG. 26-4 Scanning electron micrograph of lung parenchyma. **A,** Alveoli *(A)* and alveolar-capillary membrane *(arrow)*. **B,** Effects of atelectasis. Alveoli *(A)* are partially or totally collapsed.

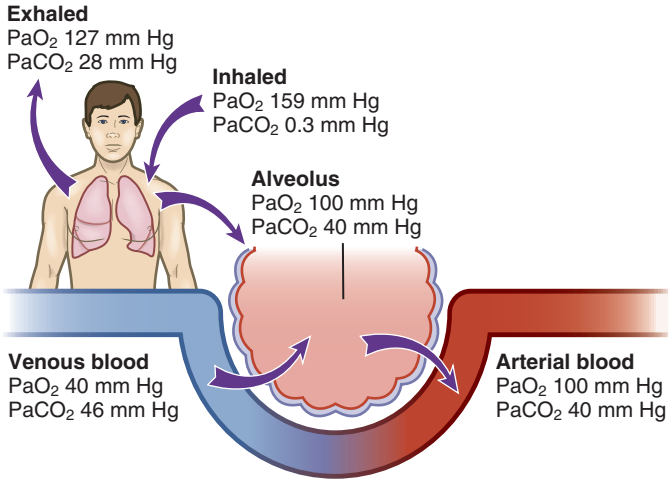

FIG. 26-5 Partial pressure of respiratory gases in normal respiration. The pressures are shown in inhaled and exhaled air from the lungs and at the level of the alveoli and pulmonary venous and arterial blood vessels.

When not enough surfactant is present, the alveoli collapse. The term *atelectasis* refers to collapsed, airless alveoli (see Fig. 26-4, *B*). The postoperative patient is at risk for atelectasis because of the effects of anesthesia and restricted breathing with pain (see Chapter 20). In acute respiratory distress syndrome (ARDS), lack of surfactant contributes to widespread atelectasis (see Chapter 68).

Blood Supply. The lungs have two different types of circulation: pulmonary and bronchial. The *pulmonary circulation* provides the lungs with blood that participates in gas exchange. The pulmonary artery receives deoxygenated blood from the right ventricle of the heart and delivers it to pulmonary capillaries that are directly connected with alveoli. Oxygen–carbon dioxide

exchange occurs at this point. The pulmonary veins return oxygenated blood to the left atrium, which then delivers it to the left ventricle. This oxygenated blood is pumped by the left ventricle into the aorta, which supplies the arteries of the systemic circulation. Venous blood is collected from capillary networks of the body and returned to the right atrium by way of the venae cavae.

The *bronchial circulation* starts with the bronchial arteries, which arise from the thoracic aorta. The bronchial circulation provides oxygen to the bronchi and other pulmonary tissues. Deoxygenated blood returns from the bronchial circulation through the azygos vein into the superior vena cava.

Chest Wall

The chest wall is shaped, supported, and protected by 24 ribs (12 on each side). The ribs and the sternum protect the lungs and the heart from injury and are called the *thoracic cage.*

The chest cavity is lined with a membrane called the *parietal pleura,* and the lungs are lined with a membrane called the *visceral pleura.* The parietal and visceral pleurae join to form a closed, double-walled sac. The visceral pleura does not have any sensory pain fibers or nerve endings, whereas the parietal pleura does have sensory pain fibers. Therefore irritation of the parietal pleura causes pain with each breath.

The space between the pleural layers is called the *intrapleural space.* Normally this space contains 20 to 25 mL of fluid. This fluid serves two purposes: (1) it provides lubrication, allowing the pleural layers to slide over each other during breathing; and (2) it increases cohesion between the pleural layers, thereby facilitating expansion of the pleurae and lungs during inspiration.

Fluid drains from the pleural space by the lymphatic circulation. Several pathologic conditions may cause the accumulation of greater amounts of fluid, termed a *pleural effusion.* Pleural fluid may accumulate because of blockage of lymphatic drainage (e.g., from malignant cells) or because of an imbalance between intravascular and oncotic fluid pressures, as in heart failure. Purulent pleural fluid with bacterial infection is called *empyema.*

The *diaphragm* is the major muscle of respiration. During inspiration the diaphragm contracts, increasing intrathoracic volume and pushing the abdominal contents downward. At the same time the external intercostal muscles and scalene muscles contract, increasing the lateral and anteroposterior (AP) dimension of the chest. This causes the size of the thoracic cavity to increase and intrathoracic pressure to decrease, so air enters the lungs.

The diaphragm is made up of two hemidiaphragms, each innervated by the right and left phrenic nerves. The phrenic nerves arise from the spinal cord between C3 and C5, the third and fifth cervical vertebrae. Injury to the phrenic nerve results in hemidiaphragm paralysis on the side of the injury. Complete spinal cord injuries above the level of C3 result in total diaphragm paralysis and dependence on a mechanical ventilator.

Physiology of Respiration

Ventilation. **Ventilation** involves *inspiration,* or inhalation (movement of air into the lungs), and *expiration,* or exhalation (movement of air out of the lungs). Air moves in and out of the lungs because intrathoracic pressure changes in relation to pressure at the airway opening. Contraction of the diaphragm and intercostal and scalene muscles increases chest dimensions, thereby decreasing intrathoracic pressure. Gas flows from an area of higher pressure (atmospheric) to one of lower pressure (intrathoracic).[2] When **dyspnea** (shortness of breath) occurs, neck and shoulder muscles can assist the effort. Some conditions (e.g., phrenic nerve paralysis, rib fractures, neuromuscular disease) may limit diaphragm or chest wall movement and cause the patient to breathe with smaller tidal volumes. As a result, the lungs do not fully inflate, and gas exchange is impaired.

In contrast to inspiration, expiration is passive. **Elastic recoil** is the tendency for the lungs to relax after being stretched or expanded. The elasticity of lung tissue is due to the elastin fibers found in the alveolar walls and surrounding the bronchioles and capillaries. The elastic recoil of the chest wall and lungs allows the chest to passively decrease in volume. Intrathoracic pressure rises, causing air to move out of the lungs.

Exacerbations of asthma or chronic obstructive pulmonary disease (COPD) cause expiration to become an active, labored process (see Chapter 29). Abdominal, intercostal, and accessory muscles (e.g., scalene, trapezius) assist in expelling air during labored breathing.

Compliance. **Compliance** (distensibility) is a measure of the ease of expansion of the lungs. This is a product of the elasticity of the lungs and the elastic recoil of the chest wall. When compliance is decreased, the lungs are more difficult to inflate. Examples include conditions that increase fluid in the lungs (e.g., pulmonary edema, ARDS, pneumonia), conditions that make lung tissue less elastic or distensible (e.g., pulmonary fibrosis, sarcoidosis), and conditions that restrict lung movement (e.g., pleural effusion). Compliance is increased when there is destruction of alveolar walls and loss of tissue elasticity, as in COPD.

Diffusion. Oxygen and carbon dioxide move back and forth across the alveolar-capillary membrane by diffusion. The overall direction of movement is from the area of higher concentration to the area of lower concentration. Thus oxygen moves from alveolar gas (atmospheric air) into the arterial blood and carbon dioxide from the arterial blood into the alveolar gas. Diffusion continues until equilibrium is reached.

The lungs' ability to oxygenate arterial blood adequately is assessed by examination of the partial pressure of oxygen in arterial blood (PaO_2) and arterial oxygen saturation (SaO_2). Oxygen is carried in the blood in two forms: dissolved oxygen and hemoglobin-bound oxygen. The PaO_2 represents the amount of oxygen dissolved in the plasma and is expressed in millimeters of mercury (mm Hg). The SaO_2 is the amount of oxygen bound to hemoglobin in comparison with the amount of oxygen the hemoglobin can carry. The SaO_2 is expressed as a percentage. For example, if the SaO_2 is 90%, this means that 90% of the hemoglobin attachments for oxygen have oxygen bound to them.

Arterial Blood Gases. Two methods are used to assess the efficiency of gas transfer in the lung and tissue oxygenation: analysis of *arterial blood gases* (ABGs) and pulse oximetry. ABGs are measured to determine oxygenation status and acid-base balance. ABG analysis includes measurement of the PaO_2, $PaCO_2$, acidity (pH), and bicarbonate (HCO_3^-) in arterial blood. The SaO_2 is either calculated or measured during this analysis. Normal values for ABGs are given in Table 26-1.

Blood for ABG analysis can be obtained by arterial puncture or from an arterial catheter, usually in the radial or femoral artery. Both techniques allow only intermittent analysis. Con-

TABLE 26-1 NORMAL ARTERIAL AND VENOUS BLOOD GAS VALUES*

tinuous intraarterial blood gas monitoring is also possible via a fiberoptic sensor or an oxygen electrode inserted into an arterial catheter. An arterial catheter permits ABG sampling without repeated arterial punctures.

The normal PaO_2 decreases with advancing age. It also varies in relation to the distance above sea level. At higher altitudes the barometric pressure is lower, resulting in a lower inspired oxygen pressure and a lower PaO_2 (see Table 26-1).

Mixed Venous Blood Gases. For the patient with a normal or near-normal cardiac status, an assessment of PaO_2 or SaO_2 is usually sufficient to determine the level of oxygenation. The patient with impaired cardiac output or hemodynamic instability may have inadequate tissue oxygen delivery or abnormal oxygen consumption.[3]

The amount of oxygen delivered to the tissues or consumed can be calculated. A catheter positioned in the pulmonary artery, termed a *pulmonary artery (PA) catheter,* is used for mixed venous sampling (see Chapter 66). Blood drawn from a PA catheter is termed a *mixed venous blood gas* sample because it consists of venous blood that has returned to the heart and "mixes" in the right ventricle. Normal mixed venous values are given in Table 26-1. When tissue oxygen delivery is inadequate or when inadequate oxygen is transported to the tissues by the hemoglobin, the PvO_2 and SvO_2 fall.

Oximetry. Arterial oxygen saturation can be monitored noninvasively and continuously using a *pulse oximetry* probe on the finger, toe, ear, or bridge of the nose[4] (see eFig. 26-2 available on the website). The abbreviation SpO_2 is used to indicate the oxygen saturation of hemoglobin as measured by pulse oximetry. SpO_2 and heart rate are displayed on the monitor as digital readings (see eFig. 26-2).

Pulse oximetry is particularly valuable in intensive care and perioperative situations, in which sedation or decreased consciousness might mask hypoxia (Table 26-2). SpO_2 is assessed with each routine vital sign check in many inpatient areas. Changes in SpO_2 can be detected quickly and treated (Table 26-3). Oximetry is also used during exercise testing and when adjusting flow rates during long-term oxygen therapy.

Values obtained by pulse oximetry are less accurate if the SpO_2 is less than 70%. At this level the oximeter may display a value that is ±4% of the actual value. For example, if the SpO_2 reading is 70%, the actual value can range from 66% to 74%. Pulse oximetry is also inaccurate if hemoglobin variants (e.g., carboxyhemoglobin, methemoglobin) are present. Other factors that can alter the accuracy of pulse oximetry include motion, low perfusion, anemia, cold extremities, bright fluorescent lights, intravascular dyes, thick acrylic nails, and dark skin color. If there is doubt about the accuracy of the SpO_2 reading, obtain an ABG analysis to verify the results.

Oximetry can also be used to monitor SvO_2 via a PA catheter. A decrease in SvO_2 suggests that less oxygen is being delivered to the tissues or that more oxygen is being consumed. Changes in SvO_2 provide an early warning of a change in cardiac output or tissue oxygen delivery. Normal SvO_2 is 60% to 80%.

Carbon Dioxide Monitoring. Carbon dioxide can be monitored using transcutaneous CO_2 ($PTCCO_2$) and end-tidal CO_2

TABLE 26-3 CRITICAL VALUES FOR PaO_2 AND SpO_2*

PaO_2 (%)	SpO_2 (%)	Significance
≥70	≥94	Adequate unless patient is hemodynamically unstable or hemoglobin (Hgb) has difficulty releasing O_2 to the tissues.
60	90	Adequate in almost all patients. Provides adequate oxygenation but with less margin for error than above.
55	88	Adequate for patients with chronic hypoxemia if no cardiac problems occur. These values are also used as criteria for prescription of continuous O_2 therapy.
40	75	Inadequate but may be acceptable on a short-term basis if the patient also has CO_2 retention. In this situation, respirations may be stimulated by a low PaO_2. Thus the PaO_2 cannot be raised rapidly.
<40	<75	Inadequate. Tissue hypoxia and cardiac dysrhythmias can be expected.

*The same critical values apply for SpO_2 and SaO_2. Values pertain to rest or exertion.

($PETCO_2$) (capnography). Transcutaneous measurement of CO_2 is a noninvasive method of estimating arterial pressure of CO_2 ($PaCO_2$) using an electrode placed on the skin.

$PETCO_2$ is the noninvasive measurement of alveolar CO_2 at the end of exhalation when CO_2 concentration is at its peak. It is used to monitor and assess trends in the patient's ventilatory status. Expired gases are sampled from the patient's airway and are analyzed by a CO_2 sensor that uses infrared light to measure exhaled CO_2. The sensor may be attached to an adaptor on the endotracheal tube or the tracheostomy tube. A nasal cannula with a sidestream capnometer can be used in patients without an artificial airway. Capnography is usually presented as a graph of expiratory CO_2 plotted against time.

In the past, capnography was used mainly intraoperatively, postoperatively, and in critical care units. Today's monitors are portable and practical for use on inpatient units and emergency departments.

Measurement of oxygen saturation (oximetry) is primarily used to assess for hypoxia. CO_2 monitoring assesses for hypoventilation. The use of both measures together is important in determining patients' oxygenation and ventilatory status.

Control of Respiration

The respiratory center in the medulla (located in the brainstem) responds to chemical and mechanical signals. Impulses are sent from the medulla to the respiratory muscles through the spinal cord and the phrenic nerves.

Chemoreceptors. A **chemoreceptor** is a receptor that responds to a change in the chemical composition ($PaCO_2$ and pH) of the fluid around it. Central chemoreceptors are located in the medulla and respond to changes in the hydrogen ion (H^+) concentration. An increase in the H^+ concentration *(acidosis)* causes the medulla to increase the respiratory rate and tidal volume (V_T). A decrease in H^+ concentration *(alkalosis)* has the opposite effect. Changes in $PaCO_2$ regulate ventilation primarily by their effect on the pH of the cerebrospinal fluid. When the $PaCO_2$ level is increased, more CO_2 is available to combine with H_2O and form carbonic acid (H_2CO_3). This lowers the cerebrospinal fluid pH and stimulates an increase in respiratory rate. The opposite process occurs with a decrease in $PaCO_2$ level.

Peripheral chemoreceptors are located in the carotid bodies at the bifurcation of the common carotid arteries and in the aortic bodies above and below the aortic arch. The peripheral chemoreceptors respond to decreases in PaO_2 and pH and to increases in $PaCO_2$. These changes also stimulate the respiratory center.

In a healthy person an increase in $PaCO_2$ or a decrease in pH causes an immediate increase in the respiratory rate. The $PaCO_2$ does not vary more than about 3 mm Hg if lung function is normal. Conditions such as COPD alter lung function and may result in chronically elevated $PaCO_2$ levels. In these instances the patient is relatively insensitive to further increases in $PaCO_2$ as a stimulus to breathe and may be maintaining ventilation largely because of a hypoxic drive from the peripheral chemoreceptors (see Chapter 29).

Mechanical Receptors. **Mechanical receptors** (juxtacapillary and irritant) are located in the lungs, upper airways, chest wall, and diaphragm. They are stimulated by a variety of physiologic factors, such as irritants, muscle stretching, and alveolar wall distortion. Signals from the stretch receptors aid in the control of respiration. As the lungs inflate, pulmonary stretch receptors activate the inspiratory center to inhibit further lung expansion. This is termed the *Hering-Breuer reflex,* and it prevents overdistention of the lungs. Impulses from the mechanical sensors are sent through the vagus nerve to the brain. Juxtacapillary (J) receptors are believed to cause the rapid respiration (tachypnea) seen in pulmonary edema. These receptors are stimulated by fluid entering the pulmonary interstitial space.

Respiratory Defense Mechanisms

Respiratory defense mechanisms are efficient in protecting the lungs from inhaled particles, microorganisms, and toxic gases. The defense mechanisms include filtration of air, the mucociliary clearance system, the cough reflex, reflex bronchoconstriction, and alveolar macrophages.

Filtration of Air. Nasal hairs filter inspired air. In addition, the abrupt changes in direction of airflow that occur as air moves through the nasopharynx and larynx increase air turbulence. This causes particles and bacteria to contact the mucosa lining these structures. Most large particles (greater than 5 µm) are less dangerous because they are removed in the nasopharynx or bronchi and do not reach the alveoli.

The velocity of airflow slows greatly after it passes the larynx, facilitating the deposition of smaller particles (1 to 5 µm). They settle out the way sand does in a river, a process termed *sedimentation.* Particles less than 1 µm in size are too small to settle in this manner and are deposited in the alveoli. An example of small particles that can build up is coal dust, which can lead to pneumoconiosis (see Chapter 28).

Mucociliary Clearance System. Below the larynx, the movement of mucus is accomplished by the mucociliary clearance system, commonly referred to as the *mucociliary escalator.* This term is used to indicate the relationship between the secretion of mucus and the ciliary activity. Mucus is continuously secreted at a rate of about 100 mL/day by goblet cells and submucosal glands. It forms a mucous blanket that contains the impacted particles and debris from distal lung areas (see Fig. 26-1). The small amount of mucus normally secreted is swallowed without being noticed. Secretory immunoglobulin A (IgA) in the mucus helps protect against bacteria and viruses.

Cilia cover the airways from the level of the trachea to the respiratory bronchioles (see Fig. 26-1). Each ciliated cell con-

tains approximately 200 cilia, which beat rhythmically about 1000 times per minute in the large airways, moving mucus toward the mouth. The ciliary beat is slower further down the tracheobronchial tree. As a consequence, particles that penetrate more deeply into the airways are removed less rapidly. Ciliary action is impaired by dehydration; smoking; inhalation of high oxygen concentrations; infection; and ingestion of drugs such as atropine, anesthetics, alcohol, or cocaine. Patients with COPD and cystic fibrosis have repeated lower respiratory tract infections. Cilia are often destroyed during these infections, resulting in impaired secretion clearance; a chronic productive cough; and chronic colonization by bacteria, which leads to frequent respiratory tract infections.

Cough Reflex. The cough is a protective reflex action that clears the airway by a high-pressure, high-velocity flow of air. It is a backup for mucociliary clearance, especially when this clearance mechanism is overwhelmed or ineffective. Coughing is only effective in removing secretions above the subsegmental level (large or main airways). Secretions below this level must be moved upward by the mucociliary mechanism before they can be removed by coughing.

Reflex Bronchoconstriction. *Reflex bronchoconstriction* is another defense mechanism. In response to the inhalation of large amounts of irritating substances (e.g., dusts, aerosols), the bronchi constrict in an effort to prevent entry of the irritants. A person with hyperreactive airways, such as a person with asthma, may experience bronchoconstriction after inhalation of triggers such as cold air, perfume, or other strong odors.

Alveolar Macrophages. Because ciliated cells are not found below the level of the respiratory bronchioles, the primary defense mechanism at the alveolar level is alveolar macrophages. *Alveolar macrophages* rapidly phagocytize inhaled foreign particles such as bacteria. The debris is moved to the level of the bronchioles for removal by the cilia or removed from the lungs by the lymphatic system. Particles (e.g., coal dust, silica) that cannot be adequately phagocytized tend to remain in the lungs for indefinite periods and can stimulate inflammatory responses (see Chapter 28). Because alveolar macrophage activity is impaired by cigarette smoke, the smoker who is employed in an occupation with heavy dust exposure (e.g., mining, foundries) is at an especially high risk for lung disease.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON RESPIRATORY SYSTEM

Age-related changes in the respiratory system can be divided into alterations in structure, defense mechanisms, and respiratory control (Table 26-4). Structural changes include calcification of the costal cartilages, which can interfere with chest expansion. The outward curvature of the spine is marked, especially with osteoporosis, and the lumbar curve flattens. Therefore the chest may appear barrel shaped, and the older person may need to use accessory muscles to breathe. Respiratory muscle strength progressively declines after age 50. Overall, the lungs in the older adult are harder to inflate.[5]

Many older adults lose subcutaneous fat, and bony prominences are pronounced. Within the lung, the number of functional alveoli decreases, and they become less elastic. Small airways in the lung bases close earlier in expiration. As a consequence, more inspired air is distributed to the lung apices and ventilation is less well matched to perfusion, lowering the PaO_2. Therefore older adults have less tolerance for exertion, and dyspnea can occur if their activity exceeds their normal exercise.[6]

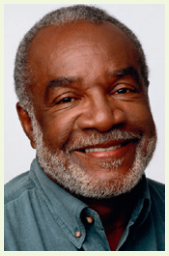
TABLE 26-4 GERONTOLOGIC ASSESSMENT DIFFERENCES

Respiratory System

Changes	Differences in Assessment Findings
Structures	
Chest wall stiffening Costal cartilage calcification ↓ Elastic recoil ↓ Chest wall compliance ↑ Anteroposterior diameter ↓ Functioning alveoli ↓ Respiratory muscle strength	Barrel chest appearance, kyphotic posture, ↓ chest wall movement, ↓ deep breathing; mucus thickened ↓ Vital capacity, ↑ residual volume, ↑ functional residual capacity Diminished breath sounds, particularly at lung bases; ↓ PaO_2 and SaO_2, normal pH and $PaCO_2$
Defense Mechanisms	
↓ Cell-mediated immunity ↓ Specific antibodies ↓ Cilia function ↓ Cough force ↓ Alveolar macrophage function ↓ Sensation in pharynx	↓ Cough effectiveness, ↓ secretion clearance ↑ Risk of upper respiratory aspiration, infection, influenza, pneumonia Respiratory infections may be more severe and last longer
Respiratory Control	
↓ Response to hypoxemia ↓ Response to hypercapnia	Greater ↓ in PaO_2 and ↑ in $PaCO_2$ before respiratory rate changes ↓ Ability to maintain acid-base balance Significant hypoxemia or hypercapnia may develop from relatively small incidents Retained secretions, excessive sedation, or positioning that impairs chest expansion may substantially alter PaO_2 or SpO_2 values

Respiratory defense mechanisms are less effective because of a decline in both cell-mediated and humoral immunity (ability to produce antibodies). The alveolar macrophages are less effective at phagocytosis. An older patient has a less forceful cough and fewer and less functional cilia. Mucous membranes tend to be drier. Retained mucus predisposes the older adult to respiratory tract infections. Formation of secretory IgA, an important defense mechanism, is diminished. Swallowing is slower because of transit time in the pharyngeal area, and there is reduced sensation in the pharynx. If the older adult patient has a superimposed neurologic condition, aspiration is likely.

Respiratory control is altered, resulting in a more gradual response to changes in blood oxygen or carbon dioxide level. The PaO_2 drops to a lower level and the $PaCO_2$ rises to a higher level before the respiratory rate changes.



The extent of these changes in people of the same age varies greatly. The older adult who has a significant smoking history, is obese, and is diagnosed with a chronic illness is at greatest risk of adverse outcomes.

ASSESSMENT OF RESPIRATORY SYSTEM

Determining a patient's needs related to the respiratory system requires an accurate health history and a thorough physical examination. A respiratory assessment can be done as part of a comprehensive physical examination or as a focused respiratory

CASE STUDY

Patient Introduction

Kevin Peterson/ Photodisc/Thinkstock

F.T. is a 70-year-old African American man who comes to the emergency department complaining of increased shortness of breath. He states that he started using his albuterol inhaler every 4 hours a few days ago, but it does not seem to be helping. He has been having trouble sleeping or doing any activity because of the shortness of breath.

Critical Thinking

As you read through this assessment chapter, think about F.T. with the following questions in mind:

1. What are the possible causes of F.T.'s shortness of breath?
2. What type of assessment would be most appropriate for F.T.: comprehensive, focused, or emergency?
3. What questions would you ask?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies might you expect to be ordered?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

examination. Use judgment in determining whether all or part of the history and physical examination will be completed based on the patient's problems and degree of respiratory distress. If respiratory distress is severe, only obtain pertinent information and defer a thorough assessment until the patient's condition stabilizes.

Subjective Data

Important Health Information

Past Health History. It is important to determine the frequency of upper respiratory problems (e.g., colds, sore throats, sinus problems, allergies) and whether seasonal changes have an effect on these problems. Question the patient with allergies about possible precipitating factors or triggers such as medications, pollen, smoke, mold, or pet exposure. Document characteristics and severity of the allergic reaction such as runny nose, wheezing, scratchy throat, or chest tightness. Inquire about a past history of lower respiratory problems, such as asthma, COPD, pneumonia, and tuberculosis (TB). Also determine the frequency of asthma exacerbations and triggers, if known. Because respiratory symptoms are often manifestations of problems that involve other body systems, it is important to ask about a history of additional health problems. For example, the patient with cardiac dysfunction may experience dyspnea (shortness of breath) as a consequence of heart failure. The patient with human immunodeficiency virus (HIV) infection may experience frequent respiratory tract infections because immune function is compromised.

Medications. Take a thorough medication history, including both prescription and over-the-counter medications. Ask about the reason for taking the medication, its name, the dose and frequency, length of time taken, its effect, and any side effects. Assess for overuse of short-term bronchodilators as a key indicator of symptom control, since this information will help guide management. Inquire about the use of an angiotensin-converting enzyme (ACE) inhibitor, since cough is a relatively common side effect of this class of drugs. Encourage the patient to bring her or his medication bottles to each visit with a health care provider.

If the patient is using oxygen to ease a breathing problem, document the fraction of inspired oxygen concentration (FIO_2), liter flow, method of administration, number of hours used per day, and effectiveness of the therapy. Assess safety practices, including the patient's mechanical and cognitive ability related to using oxygen.

Surgery or Other Treatments. Determine if the patient has been hospitalized for a respiratory problem. Note the dates, therapy (including surgery), and current status of the problem. Determine if the patient has ever been intubated because of a respiratory problem. Ask about the use and the response to respiratory treatments such as a nebulizer, humidifier, airway clearance modalities (see Chapter 29), high-frequency chest wall oscillation, postural drainage, and percussion.

Functional Health Patterns. Health history questions to ask a patient with a respiratory problem are presented in Table 26-5.

Health Perception–Health Management Pattern. Ask the patient if there has been a perceived change in health status within the last several days, months, or years. In COPD, lung function declines slowly over many years. The patient may not notice this decline because activity is altered to accommodate reduced exercise tolerance. If an upper respiratory tract infection is superimposed on a chronic problem, dyspnea and decreased exercise tolerance may occur very quickly. In asthma, symptoms may occur or worsen during exercise, if animals are present, or following a change in temperature.

Explore and document common signs of respiratory problems (e.g., cough, dyspnea). Also describe the course of the patient's illness, including when it began, the type of symptoms, and factors that alleviate or aggravate these symptoms. Because of the chronic nature of respiratory problems, the patient may relate a change in symptoms rather than the onset of new symptoms when describing the present illness. Carefully document any changes because they often suggest the cause of illness. For example, increased shortness of breath or increased purulence of sputum may suggest an acute exacerbation of COPD.

If a cough is present, evaluate its quality. For example, a loose-sounding cough indicates secretions; a dry, hacking cough indicates airway irritation or obstruction; a harsh, barky cough suggests upper airway obstruction from inhibited vocal cord movement related to subglottic edema. Assess whether the cough is strong enough to clear secretions, and note whether it is productive or nonproductive of secretions. Determine if a cough is acute or chronic (longer than 3 weeks in duration) or if it first began with an upper respiratory tract infection. The pattern and etiology of the cough are determined by asking questions such as the following: What has been the pattern of coughing? Has it been regular or paroxysmal (i.e., sudden, periodic onset), or related to a time of day, the weather, certain activities, talking, or deep breaths? Any change over time? Do you clear your throat a lot? What have you tried to alleviate the coughing? Did you try any prescription or over-the-counter drugs?

If the patient has a productive cough, evaluate the following characteristics of sputum: amount, color, consistency, and odor. Quantify the amount of sputum in teaspoons, tablespoons, or cups per day. Note any recent increases or decreases in the amount. The normal color is clear or slightly whitish. If a patient is a cigarette smoker, the sputum is usually clear to gray with occasional specks of brown. The patient with COPD may exhibit clear, whitish, or slightly yellow sputum, especially in the morning on rising. If the patient reports any change from base-

TABLE 26-5 HEALTH HISTORY

Respiratory System

Health Perception–Health Management
- Describe your daily activities. Have breathing problems changed activities that you could perform in the past several days?* Months?* Years?* Are your breathing problems better, worse, or about the same compared with 6 months ago?
- How do your breathing problems affect your self-care abilities?
- Have you ever smoked? Do you smoke now? If yes, how many cigarettes each day and for how long? Are you interested in stopping smoking? Are there aids we can tell you about that would assist your quitting? Would you be willing to come back for a visit so we can explore your quitting? If you stopped smoking, did you do so because of your health?* How did you stop?
- Have you ever smoked street drugs?*
- Have you had a Pneumovax vaccination? When was your last flu shot?
- What equipment helps you manage your respiratory problems? How often do you use it? Does it help? Cause problems?

Nutritional-Metabolic
- Have you recently lost weight because of difficulty eating secondary to a respiratory problem? How much? Voluntarily?
- Do any particular foods affect your sputum production or breathing?*

Elimination
- Does your respiratory problem make it difficult for you to get to the toilet?*
- Are you inactive because of dyspnea to the point that it causes constipation?*

Activity-Exercise
- Are you ever short of breath during exercise?* At rest?*
- Do you get too short of breath to do the things you want to do?*
- Is your home one story? Two stories? How many steps from the street to your door?
- Can you walk up a flight of steps without stopping?
- Are you able to maintain your typical activity pattern? If not, explain.
- What do you do when you get short of breath?

Sleep-Rest
- Do breathing problems cause you to awaken during the night?*
- Can you lie flat at night? If not, how many pillows do you use?
- Do you need to sleep upright in a chair?*
- Are you or your sleep partner aware of any snoring?
- Do you awaken in the morning feeling rested?
- Do you have a morning headache?*
- Do you fall asleep easily during the day?*

Cognitive-Perceptual
- Do you have any pain associated with breathing?* On a scale from 0 to 10, with 10 being the worst pain you can imagine, where would you rate your pain? Does it hurt more on inspiration?*
- Do you ever feel restless, irritable, or confused without a reason?*
- Do you have difficulty remembering things?*

Self-Perception–Self-Concept
- Describe how your respiratory problems have changed your life.
- If you use oxygen, do you ever go out without bringing it with you? When and why?

Role-Relationship
- Has your respiratory problem caused any difficulties in your work, family, or social relationships?*

Sexuality-Reproductive
- Has your respiratory problem caused a change in your sexual activity?*
- Do you want to discuss ways to decrease dyspnea during sexual activity?

Coping–Stress Tolerance
- How often do you leave your home?
- Would you want to join a support group? Pulmonary rehabilitation program?
- Does stress have an effect on your breathing?*
- What effect does your respiratory problem have on your emotions?

Value-Belief
- What do you believe causes your respiratory problems?
- Do you think the things you have been told to do for your respiratory problems really help? If not, why?

*If yes, describe.

line color, suspect pulmonary complications. Note any changes in consistency of sputum to thick, thin, or frothy and pink tinged. These changes may indicate dehydration, postnasal drip or sinus drainage, or possible pulmonary edema. Normally sputum should be odorless. A foul odor or exceptionally bad breath or taste in the mouth suggests an infectious process. Ask the patient if the sputum was produced along with a change in position (e.g., increased with lying down) or activity.

When assessing mucus, determine if the patient has a history of coughing up blood *(hemoptysis)*. Hemoptysis can range from a slight streaking of blood in the mucus to massive coughing up of blood, in which the patient loses 100 to 600 mL of blood in a 24-hour period. This situation is a medical emergency.

Frequently the patient cannot differentiate between hemoptysis and *hematemesis* (vomiting blood). Carefully question and then test the mucus for an acidic pH (which is present with hematemesis), since this will help differentiate the two. Hemoptysis can be found with a variety of conditions such as pneumonia, TB, lung cancer, and severe bronchiectasis.

Assess for a history of wheezing. *Wheezes* are musical sounds that can be audible. Wheezing indicates some degree of airway obstruction, such as asthma, foreign body aspiration, and emphysema. Assess for any history of family exposure to *Mycobacterium tuberculosis*.

GENETIC RISK ALERT
- Respiratory problems that have a strong genetic link include cystic fibrosis, COPD resulting from α_1-antitrypsin deficiency, and asthma.
- If people have a family history of these respiratory problems, they have a much greater risk of developing them.
- Although cigarette smoking is a major risk factor for COPD, only a minority of cigarette smokers develop symptomatic disease. The risk for COPD related to cigarette smoking is genetically related.
- Determine if there is a family history of any of these respiratory problems that may have genetic or familial tendencies.

Smoking is the most important risk factor for COPD and lung cancer. Discuss current and past smoking habits. Quantify smoking habits in *pack-years*. This is done by multiplying the number of packs smoked per day by the number of years smoked. For example, a person who smoked 1 pack per day for

15 years has a 15 pack-year history. In addition to asking about cigarette use, find out about the use of any tobacco products, including cigars, pipes, chewing tobacco, and smokeless tobacco products. Also find out about exposure to secondhand smoke. Determine if the patient has tried to quit using tobacco products, including using prescription, over-the-counter, and herbal remedies.

Assess if the patient received immunization for influenza (flu) and pneumococcal pneumonia (Pneumovax). Influenza vaccine should be administered yearly in the fall. Pneumovax is administered any time during the year. (The recommendations for use of Pneumovax are presented in Table 28-5.)

Ask where the patient has lived and traveled. Risk factors for TB include prior residence in Asia, Africa, the former Soviet Republic, Latin America, or any third-world country. Other TB risk factors include exposure to people with high rates of TB transmission such as the homeless, injection drug users, and people with HIV infection. Risk factors for fungal infections of the lung include living or traveling in the Southwest (coccidioidomycosis) and the Mississippi River Valley (histoplasmosis).

Ask the patient about the use of equipment to manage respiratory symptoms (e.g., home O_2 therapy equipment, inhalers, devices for sleep apnea). Question the patient about the type of equipment used, cleaning of the device, frequency of use, its effect, and any side effects. Have patients demonstrate the use of their inhalers. Many patients do not know how to use these devices correctly (see Chapter 29).

Nutritional-Metabolic Pattern. Weight loss is a symptom of many respiratory diseases. Determine if weight loss was intentional and, if not, if food intake is altered by anorexia (from medications), fatigue (from hypoxemia, increased work of breathing), or feeling full quickly (from lung hyperinflation). Anorexia, weight loss, and chronic malnutrition are common in patients with COPD, lung cancer, TB, and chronic severe infection (bronchiectasis). Also note fluid intake. Dehydration can cause mucus to thicken and obstruct the airway.

Excessive weight interferes with normal ventilation and may cause sleep apnea (see Chapter 8). Morbidly obese individuals may hypoventilate while awake or asleep, and weight loss can improve ABGs. Rapid weight gain from fluid retention may decrease pulmonary gas exchange.

Elimination Pattern. Healthy elimination habits depend on the ability to reach a toilet when necessary. Activity intolerance secondary to dyspnea could result in incontinence. Dyspnea can also be the cause of limited mobility, which can cause constipation. Question the patient with dyspnea about incontinence and constipation. People with a chronic cough, especially women, may be troubled with urinary incontinence during paroxysms of coughing.

Activity-Exercise Pattern. Determine if the patient's activity is limited by dyspnea at rest or during exercise. Also note whether the patient's residence (e.g., number of steps, levels) poses a problem that increases social isolation. Record and objectively measure the degree of the patient's dyspnea. For example, can the patient walk up one flight of stairs without stopping because of dyspnea? Is dyspnea that is associated with an activity better, worse, or about the same in the last few months? Determine if the patient has difficulty breathing in a certain position, or if relief of dyspnea can be obtained by assuming a different position (e.g., tripod position in COPD).

Discuss whether the patient is able to carry out activities of daily living without dyspnea or other respiratory symptoms. If unable, document the amount and type of care needed. Immobility and sedentary habits can be risk factors for hypoventilation leading to atelectasis or pneumonia.

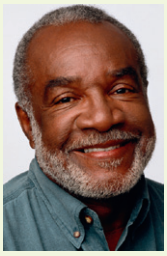
Sleep-Rest Pattern. Determine if the patient wakes up because of pulmonary problems. The patient with asthma or COPD may awaken at night with chest tightness, wheezing, or coughing. This suggests a need for adjunct therapy or other medication changes. The patient with cardiovascular disease (e.g., heart failure) may sleep with the head elevated on several pillows to avoid respiratory problems brought on by lying flat *(orthopnea).* Signs of sleep apnea include snoring, insomnia, abrupt awakenings, daytime drowsiness, and early morning headaches. Night sweats may be a manifestation of TB.

Cognitive-Perceptual Pattern. Because hypoxia can cause neurologic symptoms, ask the patient about apprehension, restlessness, irritability, and memory changes, which can indicate inadequate cerebral oxygenation (see Table 26-2). Hypoxemia interferes with the ability to learn and retain information. For this reason, teaching may be more effective if the caregiver is present during teaching sessions to provide reinforcement at a later date.

Assess the patient's cognitive ability to cooperate with treatment. Failure or inability to participate in needed therapy can result in exacerbation of respiratory problems.

Inquire about any discomfort or pain with breathing. Explore a complaint of chest pain carefully to rule out cardiac involvement. Problems such as pleurisy, fractured ribs, and costochondritis cause chest pain. Pleuritic pain is described as a sharp, localized, stabbing pain associated with movement or deep breathing. Fractured ribs cause localized sharp pain associated with breathing.

Self-Perception–Self-Concept Pattern. Dyspnea limits activity, impairs ability to fulfill normal roles, and often alters self-esteem. A patient may be reluctant to appear in public with a highly visible nasal cannula and O_2 equipment. Discuss with the patient his or her personal body image. A barrel chest, clubbed fingers, pursed-lip breathing, and frequent expectoration of sputum or throat clearing can be embarrassing and can lead to social isolation. Referral to a support group or pulmonary rehabilitation program may be beneficial in developing a support system and coping strategies.



Role-Relationship Pattern. Acute or chronic respiratory problems can seriously affect performance in work or other activities. Discuss the impact of medications, O_2 therapy, and special routines (e.g., pulmonary hygiene for cystic fibrosis) on the patient's family, job, and social life.

Document the nature of the patient's work and the frequency and intensity of exposure to fumes, toxins, asbestos, coal, fibers, or silica. Inquire whether symptoms are worse in specific situations (e.g., home versus work environments). Investigate any patient-specific allergens, such as dust or fumes, that could be present in the work environment. Hobbies such as woodworking (sawdust) or pottery (silica) and exposure to animals (allergies) may also cause respiratory problems. Because of hyperreactive airways, exposure to fumes, smoke, and other chemicals may trigger an attack in the patient with asthma.

Sexuality-Reproductive Pattern. Most patients can continue to have satisfactory sexual relationships despite marked physical limitations. In a tactful manner, determine whether breathing difficulties have caused alterations in sexual activity. If so, provide teaching about positions that decrease dyspnea during sexual activity and alternative strategies for sexual fulfillment.

CASE STUDY—cont'd

Subjective Data

Kevin Peterson/ Photodisc/Thinkstock

A focused subjective assessment of F.T. revealed the following information:

PMH: COPD, hypertension, and benign prostatic hyperplasia. No history of environmental allergies. Denies history of coronary artery disease or heart failure.

Medications: Metoprolol (Lopressor) 50 mg/day PO, finasteride (Proscar) 5 mg/day PO, Advair inhaler (fluticasone and salmeterol) 2 puffs bid, and albuterol inhaler 2 puffs q4hr PRN. Does not use O_2 at home.

Health Perception–Health Management: F.T. states that he usually manages his COPD well with just the Advair inhaler and occasional use of the albuterol inhaler as needed. However, he caught a cold from his granddaughter last week and has had increasing difficulty breathing, even with the use of albuterol.

Has a history of 30 pack-years of smoking, quitting 5 years ago. Had a Pneumovax vaccination 5 years ago and receives the flu vaccine on an annual basis.

Activity-Exercise: States that he can typically walk at least 2 blocks and up and down stairs without getting short of breath. However, at this point, he can't walk 100 feet without feeling short of breath, nor can he walk up one flight of stairs without stopping to catch his breath.

Sleep-Rest: Has been having difficulty sleeping with this most recent episode of shortness of breath. Typically uses just one pillow to sleep with but needed three pillows this week, and last night he slept upright in his recliner.

Cognitive-Perceptual: Denies any pain or confusion associated with shortness of breath. Feels slightly irritable because of lack of sleep.

Coping–Stress Tolerance: Denies any stress or emotional disturbance that could be having an impact on his breathing.

Many patients need to perform good pulmonary hygiene (bronchodilators, coughing and deep breathing) before intimacy. This is similar to what they would do before strenuous physical activity. They may need to use O_2 therapy equipment during intercourse.

Coping–Stress Tolerance Pattern. Dyspnea causes anxiety, and anxiety exacerbates dyspnea. The result is a vicious cycle—the patient avoids activities that cause dyspnea, becoming more deconditioned and more dyspneic. The outcome is often physical and social isolation. Assess how often the patient leaves home and interacts with others. Referral to a support group or pulmonary rehabilitation program may be beneficial.

The chronic nature of many respiratory problems such as COPD and asthma can cause prolonged stress. Inquire about the patient's coping strategies to manage this stress.

Value-Belief Pattern. Determine the patient's adherence to the management regimen. Explore reasons for lack of adherence, including conflict with cultural beliefs, financial constraints (e.g., costs of prescriptions), or failure to understand benefit. Including the patient and the caregiver in the planning of care can improve adherence.

Objective Data

Physical Examination. Vital signs, including temperature, pulse, respirations, blood pressure, and SpO_2 (oxygen saturation obtained by pulse oximetry), are important data to collect before examination of the respiratory system.

Nose. Inspect the nose for patency, inflammation, deformities, symmetry, and discharge. Check each naris for air patency with respiration while the other naris is briefly occluded. Tilt the patient's head backward and push the tip of the nose upward gently. With a nasal speculum and a good light, inspect the interior of the nose. The mucous membrane should be pink and moist, with no evidence of edema (bogginess), exudate, or bleeding.[7] Inspect the nasal septum for deviation, perforations, and bleeding. Some nasal deviation is normal in an adult. Inspect the turbinates for polyps, which are abnormal, fingerlike projections of swollen nasal mucosa. Polyps may result from long-term irritation of the mucosa (e.g., from allergies). Assess any discharge for color and consistency. Purulent and malodorous discharge could indicate the presence of a foreign body. Watery discharge could be secondary to allergies or from cerebrospinal fluid. Bloody discharge could be from trauma or dryness. Thick mucosal discharge could indicate infection.

Mouth and Pharynx. Using a good light source, inspect the interior of the mouth for color, lesions, masses, gum retraction, bleeding, and poor dentition. Inspect the tongue for symmetry and lesions. Observe the pharynx by pressing a tongue blade against the middle of the back of the tongue. If the oropharynx is tight, have the patient yawn, since this usually allows more structures to be visible. The pharynx should be smooth and moist, with no evidence of exudate, ulcerations, swelling, or postnasal drip. Note the color, symmetry, and any enlargement of the tonsils. Stimulate the gag reflex by placing a tongue blade along the side of the pharynx behind the tonsil. A normal response (gagging) indicates that cranial nerves IX (glossopharyngeal) and X (vagus) are intact and that the airway is protected.

Neck. Inspect the neck for symmetry and tender or swollen areas. Palpate the lymph nodes while the patient is sitting erect with the neck slightly flexed. Progression of palpation is from the nodes around the ears, to the nodes at the base of the skull, and then to those located under the angles of the mandible to the midline. The patient may have small, mobile, nontender nodes *(shotty nodes),* which are not a sign of a pathologic condition. Tender, hard, or fixed nodes indicate disease. Describe the location and characteristics of any palpable nodes.

Thorax and Lungs. Picture imaginary lines on the chest to help identify abnormalities (see Fig. 26-2). Describe abnormalities in terms of their location relative to these lines (e.g., 2 cm from the right midclavicular line).[8]

Chest examination is best performed in a well-lighted, warm room with measures taken to ensure the patient's privacy. Perform all physical assessment maneuvers (inspection, palpation, percussion, auscultation) on either the anterior or the posterior chest rather than moving from anterior to posterior or vice versa with each maneuver. It is best to begin on the posterior chest, particularly with female patients, since more information can be obtained without interference from the breast tissue. In addition, if the patient tires or you are interrupted, baseline data with the most information will have been obtained from examining the posterior of the chest.

Inspection. When inspecting the *anterior chest*, have the patient sit upright or with the head of the bed upright. The patient may need to lean forward for support on the bedside table to facilitate breathing. First, observe the patient's appearance and note any evidence of respiratory distress, such as tachypnea or use of accessory muscles. Next, determine the shape and symmetry of the chest. Chest movement should be

equal on both sides, and the AP diameter should be less than the side-to-side or transverse diameter by a ratio of 1:2. An increase in AP diameter (e.g., barrel chest) may be a normal aging change or result from lung hyperinflation. Observe for abnormalities in the sternum (e.g., *pectus carinatum* [a prominent protrusion of the sternum] and *pectus excavatum* [an indentation of the lower sternum above the xiphoid process]).

Next observe the respiratory rate, depth, and rhythm. The normal rate is 12 to 20 breaths/minute; in the older adult, it is 16 to 25 breaths/minute. Inspiration (I) should take half as long as expiration (E) (I:E ratio = 1:2). Observe for abnormal breathing patterns, such as Kussmaul (rapid, deep breathing), Cheyne-Stokes (abnormal respirations characterized by alternating periods of apnea and deep, rapid breathing), or Biot's (irregular breathing with apnea every four to five cycles) respirations.

Skin color provides clues to respiratory status. Cyanosis, a late sign of hypoxemia, is best observed in a dark-skinned patient in the conjunctivae, lips, and palms and under the tongue. Causes of cyanosis include hypoxemia or decreased cardiac output. Inspect the fingers for evidence of long-standing hypoxemia known as *clubbing* (an increase in the angle between the base of the nail and the fingernail to 180 degrees or more, usually accompanied by an increase in the depth, bulk, and sponginess of the end of the finger) (see eFig. 26-3 available on the website for this chapter).

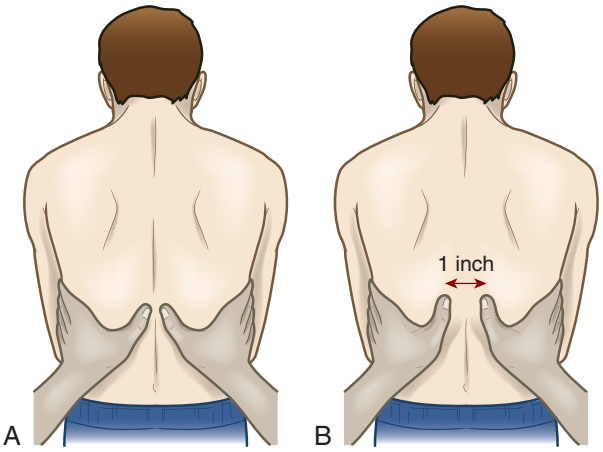
When inspecting the *posterior chest,* ask the patient to lean forward with arms folded. This position moves the scapulae away from the spine, exposing more of the area to be examined. The same sequence of observations that was done on the anterior part of the chest is performed on the posterior part. In addition, any spinal curvature is noted. Spinal curvatures that affect breathing include kyphosis, scoliosis, and kyphoscoliosis.

Palpation. Determine tracheal position by gently placing the index fingers on either side of the trachea just above the suprasternal notch and gently pressing backward. Normal tracheal position is midline; deviation to the left or right is abnormal. Tracheal deviation occurs away from the side of a tension pneumothorax or a neck mass, but toward the side of a pneumonectomy or lobar atelectasis.

Symmetry of chest expansion and extent of movement are determined at the level of the diaphragm. Place your hands over the lower anterior chest wall along the costal margin and move them inward until the thumbs meet at midline. Ask the patient to breathe deeply. Observe the movement of the thumbs away from each other. Normal expansion is 1 in (2.5 cm). Hand placement on the posterior side of the chest is at the level of the tenth rib. Move the thumbs until they meet over the spine (Fig. 26-6). Check expansion anteriorly or posteriorly, but it is not necessary to check both.

Normal chest movement is equal. Unequal expansion occurs when air entry is limited by conditions involving the lung (e.g., atelectasis, pneumothorax) or the chest wall (e.g., incisional pain). Equal but diminished expansion occurs in conditions that produce a hyperinflated or barrel chest or in neuromuscular diseases (e.g., amyotrophic lateral sclerosis, spinal cord lesions). Movement may be absent or unequal over a pleural effusion, an atelectasis, or a pneumothorax.

Fremitus is the vibration of the chest wall produced by vocalization. Tactile fremitus can be felt by placing the palmar surface of the hands with hyperextended fingers against the patient's chest. Ask the patient to repeat a phrase such as "ninety-nine" in a deeper, louder than normal voice. Move your hands from side to side at the same time from top to bottom on the patient's chest (Fig. 26-7). When performing percussion, palpate all areas of the chest and compare vibrations from similar areas. Tactile fremitus is most intense adjacent to the sternum and between the scapulae because these areas are closest to the major bronchi. Fremitus is less intense farther away from these areas.



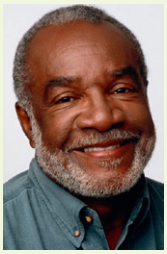


FIG. 26-6 Estimation of thoracic expansion. **A,** Exhalation. **B,** Maximal inhalation.

CASE STUDY—cont'd

Objective Data: Physical Examination

Kevin Peterson/ Photodisc/Thinkstock

Physical examination findings of F.T. are as follows: BP 170/90, apical pulse 110, respiratory rate 30, temp 37° C, O_2 saturation 87% on room air. Patient sitting on edge of bed with arms resting on bedside table. Slight use of accessory muscles in neck and shoulders noted. Chest expansion equal. Respirations regular but slightly labored with prolonged expiration. Skin color pale pink with no cyanosis. No clubbing noted. Trachea midline. Lungs auscultated for bibasilar crackles, scattered rhonchi, and expiratory wheezing. Moist, productive cough with yellow-tinged sputum.

As you continue to read this chapter, consider diagnostic studies you would anticipate being ordered for F.T.

Note an increase, decrease, or absence of fremitus. Increased fremitus occurs when the lung becomes filled with fluid or is denser. As the patient's voice moves through a dense tissue or fluid, you can feel that the vibration is increased. This is found in pneumonia, in lung tumors, with thick bronchial secretions, and above a pleural effusion (the lung is compressed upward). Fremitus is decreased if the hand is farther from the lung (e.g., pleural effusion) or the lung is hyperinflated (e.g., barrel chest). Absent fremitus may be noted with pneumothorax or atelectasis. The anterior of the chest is more difficult to palpate for fremitus because of the large muscles and breast tissue.

Percussion. Percussion is performed to assess the density or aeration of the lungs. Percussion sounds are described in Table 26-6. (The technique for percussion is described in Chapter 3.)

The anterior chest is usually percussed with the patient in a semi-sitting or supine position. Starting above the clavicles, percuss downward, interspace by interspace (see Fig. 26-7). The area over lung tissue should be resonant, with the exception of the area of cardiac dullness (Fig. 26-8). For percussion of the posterior chest, have the patient sit leaning forward with arms

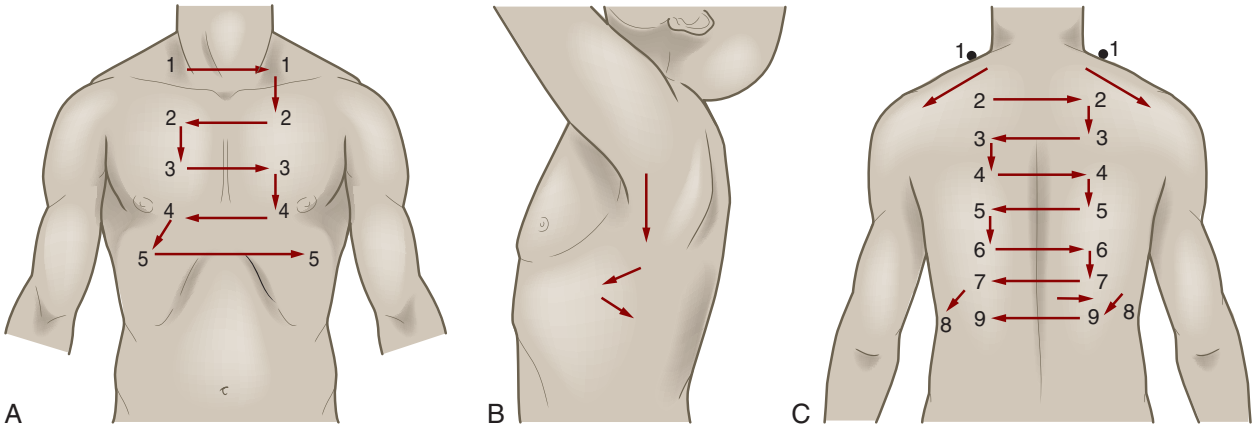

FIG. 26-7 Sequence for examination of the chest. **A,** Anterior sequence. **B,** Lateral sequence. **C,** Posterior sequence. For palpation, place the palms of the hands in the position designated as "1" on the right and left sides of the chest. Compare the intensity of vibrations. Continue for all positions in each sequence. For percussion, tap the chest at each designated position, moving downward from side to side. Compare percussion sounds at all positions. For auscultation, place the stethoscope at each position and listen to at least one complete inspiratory and expiratory cycle. Keep in mind that, with a female patient, the breast tissue will modify the completeness of the anterior examination.

TABLE 26-6 PERCUSSION SOUNDS

Sound	Description
Resonance	Low-pitched sound heard over normal lungs
Hyperresonance	Loud, lower-pitched sound than normal resonance heard over hyperinflated lungs, such as in chronic obstructive pulmonary disease and acute asthma
Tympany	Sound with drumlike, loud, empty quality heard over gas-filled stomach or intestine, or pneumothorax
Dull	Sound with medium-intensity pitch and duration heard over areas of "mixed" solid and lung tissue, such as over top area of liver, partially consolidated lung tissue (pneumonia), or fluid-filled pleural space
Flat	Soft, high-pitched sound of short duration heard over very dense tissue where air is not present, such as posterior chest below level of diaphragm

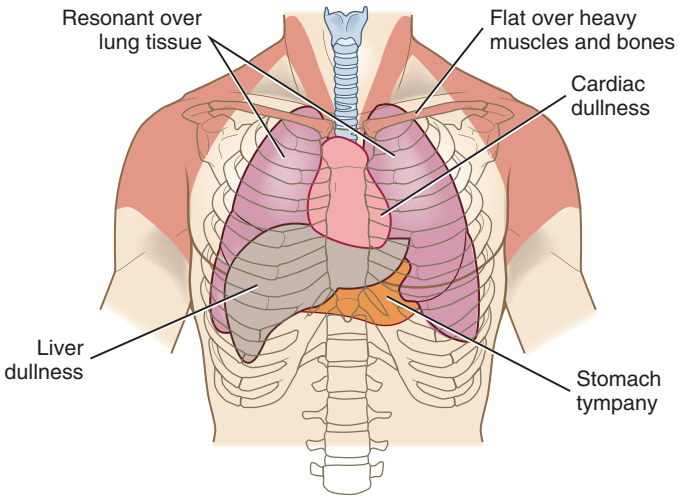

FIG. 26-8 Diagram of percussion areas and sounds in the anterior side of the chest.

folded. The posterior chest should be resonant over lung tissue to the level of the diaphragm (Fig. 26-9).

Auscultation. During chest auscultation, instruct the patient to breathe slowly and a little more deeply than normal through the mouth. Auscultation should proceed from the lung apices to the bases, comparing opposite areas of the chest, unless the patient is in respiratory distress or will tire easily; if so, start at the bases (see Fig. 26-7). Place the stethoscope over lung tissue, not over bony prominences. At each placement of the stethoscope, listen to at least one cycle of inspiration and expiration. Note the pitch (e.g., high, low), duration of sound, and presence of adventitious or abnormal sounds.[9] The location of normal auscultatory sounds is more easily understood by visualization of a lung model (Fig. 26-10).

The lung sounds are heard anteriorly from a line drawn perpendicular to the xiphoid process lateral to the midclavicular line. Palpate inferiorly (down) two ribs in the midaxillary line and around to the posterior chest. This gives you a fairly accurate and easy way to determine the lung fields to be auscultated. When documenting the location of the lung sounds, divide the anterior and posterior lung into thirds (upper, middle,

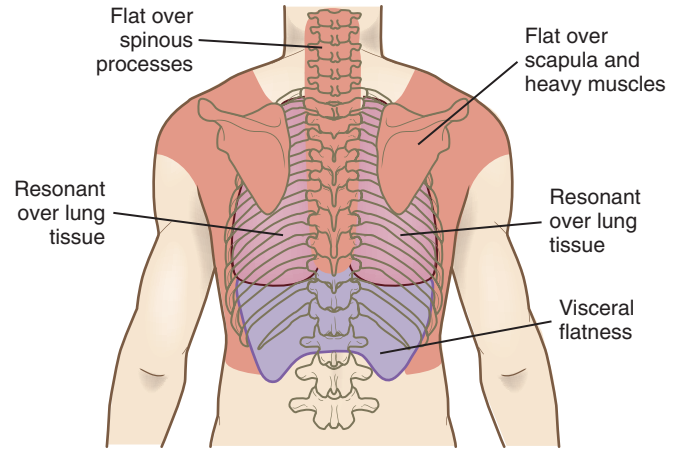

FIG. 26-9 Diagram of percussion areas and sounds in the posterior side of the chest. Percussion proceeds from the lung apices to the lung bases while comparing sounds in opposite areas of the chest.

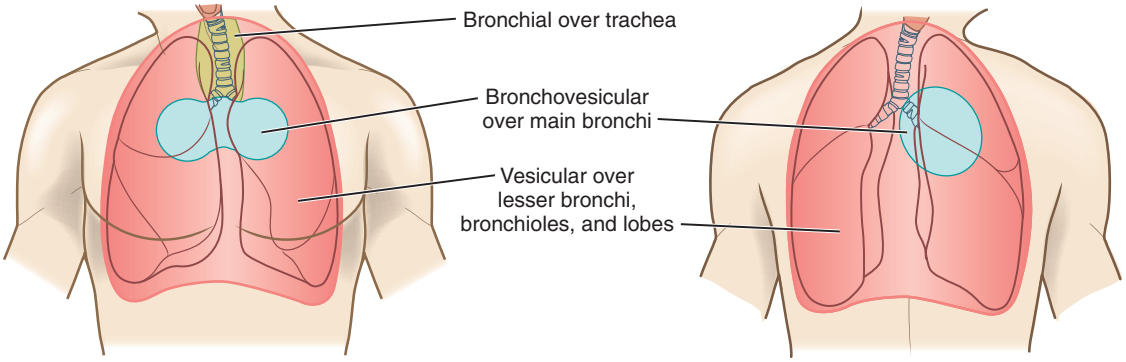

FIG. 26-10 Normal auscultatory sounds.

TABLE 26-7 NORMAL PHYSICAL ASSESSMENT OF THE RESPIRATORY SYSTEM

Nose	• Symmetric with no deformities • Nasal mucosa pink, moist with no edema, exudate, blood, or polyps • Nasal septum straight; nares patent bilaterally
Oral mucosa	• Light pink, moist, with no exudate or ulcerations
Pharynx	• Smooth, moist, and pink
Neck	• Trachea midline
Chest	• Anteroposterior to lateral diameter 1:2 • Respirations nonlabored at 14 breaths/min • Breath sounds vesicular without crackles, rhonchi, or wheezes • Excursion equal bilaterally with no increase in tactile fremitus

and lower) and note, for example, "crackles posterior right lower lung field." You are not expected to define which lobe of the lung has particular lung sounds.

The three normal breath sounds are vesicular, bronchovesicular, and bronchial. *Vesicular sounds* are relatively soft, low-pitched, gentle, rustling sounds. They are heard over all lung areas except the major bronchi. Vesicular sounds have a 3:1 ratio, with inspiration three times longer than expiration. *Bronchovesicular sounds* have a medium pitch and intensity and are heard anteriorly over the mainstem bronchi on either side of the sternum and posteriorly between the scapulae. Bronchovesicular sounds have a 1:1 ratio, with inspiration equal to expiration. *Bronchial sounds* are louder and higher pitched and resemble air blowing through a hollow pipe. Bronchial sounds have a 2:3 ratio with a gap between inspiration and expiration. This reflects the short pause between the respiratory cycles. To hear the likeness of bronchial breath sounds, place the stethoscope alongside the trachea in the neck.

The term *abnormal breath sounds* describes bronchial or bronchovesicular sounds heard in the peripheral lung fields. **Adventitious sounds** are extra breath sounds that are abnormal. Adventitious breath sounds include crackles, rhonchi, wheezes, and pleural friction rub (described in Table 26-7).

A variety of terms are used to describe breath sounds. The spoken voice can be auscultated over the thorax just as it can be palpated for fremitus. *Egophony* is positive (abnormal) when the person says "E" but it is heard as "A." *Bronchophony* is positive (abnormal) when a person repeats "ninety-nine" and the words are easily understood and are clear and loud. *Whispered pectoriloquy* is positive (abnormal) when the patient whispers "one-two-three" and the almost inaudible voice is transmitted clearly and distinctly. Conditions that increase lung density or a consolidated lung (e.g., pneumonia) have positive (abnormal) voice sounds.

A record of the normal physical assessment of the respiratory system is shown in Table 26-7. Assessment abnormalities of the thorax and lungs are presented in Table 26-8. Chest examination findings in common pulmonary problems are presented in Table 26-9. Age-related changes in the respiratory system and assessment findings are presented in Table 26-4.

A *focused assessment* is used to evaluate the status of previously identified respiratory problems and to monitor for signs of new problems (see Chapter 3, Table 3-6). A focused assessment of the respiratory system is presented in the box above.

FOCUSED ASSESSMENT

Respiratory System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Shortness of breath	Y	N
Wheezing	Y	N
Sputum production (color, quantity)	Y	N
Pain with breathing	Y	N
Cough	Y	N

Objective: Diagnostic

Check the following laboratory tests for critical values.

Arterial blood gases	✓
Chest x-ray	✓
Hct, Hgb	✓

Objective: Physical Examination

Observe

Respirations for rate, quality, and pattern	✓

Inspect

Skin and nails for integrity and color	✓
Neck for position of trachea	✓
Shape, symmetry, and movement of chest wall	✓

Palpate

Chest and back for masses	✓

Auscultate

Lung (breath) sounds	✓

Hct, Hematocrit; *Hgb,* hemoglobin.

TABLE 26-8 ASSESSMENT ABNORMALITIES

Respiratory System

Finding	Description	Possible Etiology and Significance*
Inspection		
Pursed-lip breathing	Exhalation through mouth with lips pursed together to slow exhalation.	COPD, asthma. Suggests ↑ breathlessness. Strategy taught to slow expiration, ↓ dyspnea.
Tripod position; inability to lie flat	Learning forward with arms and elbows supported on overbed table.	COPD, asthma in exacerbation, pulmonary edema. Indicates moderate to severe respiratory distress.
Accessory muscle use; intercostal retractions	Neck and shoulder muscles used to assist breathing; muscles between ribs pull in during inspiration.	COPD, asthma in exacerbation, secretion retention. Indicates severe respiratory distress, hypoxemia.
Splinting	Voluntary ↓ in tidal volume to ↓ pain on chest expansion.	Thoracic or abdominal incision, chest trauma, pleurisy.
↑ AP diameter	AP chest diameter equal to lateral; slope of ribs more horizontal (90 degrees) to spine.	COPD, asthma, cystic fibrosis, lung hyperinflation, advanced age.
Tachypnea	Rate >20 breaths/min; >25 breaths/min in older adults.	Fever, anxiety, hypoxemia, restrictive lung disease. Magnitude of ↑ above normal rate reflects increased work of breathing.
Kussmaul respirations	Regular, rapid, and deep respirations.	Metabolic acidosis. Increases CO_2 excretion.
Cyanosis	Bluish color of skin best seen in lips and on the palpebral conjunctiva (inside the lower eyelid).	Reflects 5-6 g of hemoglobin not bound with O_2. ↓ O_2 transfer in lungs, ↓ cardiac output. Nonspecific, unreliable indicator.
Finger clubbing	↑ Depth, bulk, sponginess of distal portion of finger (see eFig. 26-3 on the website for this chapter).	Chronic hypoxemia, cystic fibrosis, lung cancer, bronchiectasis.
Abdominal paradox	Inward (rather than normal outward) movement of abdomen during inspiration.	Inefficient and ineffective breathing pattern. Nonspecific indicator of severe respiratory distress.
Palpation		
Tracheal deviation	Leftward or rightward movement of trachea from normal midline position.	Nonspecific indicator of change in position of mediastinal structures. Medical emergency if caused by tension pneumothorax. Trachea deviates to the side opposite the collapsed lung.
Altered tactile fremitus	Increase or decrease in vibrations.	↑ In pneumonia, pulmonary edema. ↓ In pleural effusion, lung hyperinflation. Absent in pneumothorax, atelectasis.
Altered chest movement	Unequal or equal but diminished movement of two sides of chest with inspiration.	Unequal movement caused by atelectasis, pneumothorax, pleural effusion, splinting. Equal but diminished movement caused by barrel chest, restrictive disease, neuromuscular disease.
Percussion		
Hyperresonance	Loud, lower-pitched sound over areas that normally produce a resonant sound.	Lung hyperinflation (COPD), lung collapse (pneumothorax), air trapping (asthma).
Dullness	Medium-pitched sound over areas that normally produce a resonant sound.	↑ Density (pneumonia, large atelectasis), ↑ fluid in pleural space (pleural effusion).
Auscultation		
Fine crackles	Series of short-duration, discontinuous, high-pitched sounds heard just before the end of inspiration. Result of rapid equalization of gas pressure when collapsed alveoli or terminal bronchioles suddenly snap open. Similar sound to that made by rolling hair between fingers just behind ear.	Idiopathic pulmonary fibrosis, interstitial edema (early pulmonary edema), alveolar filling (pneumonia), loss of lung volume (atelectasis), early phase of heart failure.
Coarse crackles	Series of long-duration, discontinuous, low-pitched sounds caused by air passing through airway intermittently occluded by mucus, unstable bronchial wall, or fold of mucosa. Evident on inspiration and, at times, expiration. Similar sound to blowing through straw under water. Increase in bubbling quality with more fluid.	Heart failure, pulmonary edema, pneumonia with severe congestion, COPD.
Rhonchi	Continuous rumbling, snoring, or rattling sounds from obstruction of large airways with secretions. Most prominent on expiration. Change often evident after coughing or suctioning.	COPD, cystic fibrosis, pneumonia, bronchiectasis.
Wheezes	Continuous high-pitched squeaking or musical sound caused by rapid vibration of bronchial walls. First evident on expiration but possibly evident on inspiration as obstruction of airway increases. Possibly audible without stethoscope.	Bronchospasm (caused by asthma), airway obstruction (caused by foreign body, tumor), COPD.
Stridor	Continuous musical or crowing sound of constant pitch. Result of partial obstruction of larynx or trachea.	Croup, epiglottitis, vocal cord edema after extubation, foreign body.
Absent breath sounds	No sound evident over entire lung or area of lung.	Pleural effusion, mainstem bronchi obstruction, large atelectasis, pneumonectomy, lobectomy.

Continued

TABLE 26-8 ASSESSMENT ABNORMALITIES—cont'd

Respiratory System

Finding	Description	Possible Etiology and Significance*
Auscultation—cont'd		
Pleural friction rub	Creaking or grating sound from roughened, inflamed pleural surfaces rubbing together. Evident during inspiration, expiration, or both and no change with coughing. Usually uncomfortable, especially on deep inspiration.	Pleurisy, pneumonia, pulmonary infarct.
Bronchophony, whispered pectoriloquy	Spoken or whispered syllable more distinct than normal on auscultation.	Pneumonia.
Egophony	Spoken "E" similar to "A" on auscultation because of altered transmission of voice sounds.	Pneumonia, pleural effusion.

*Limited to common etiologic factors. (Further discussion of conditions listed may be found in Chapters 27 through 29.)

TABLE 26-9 CHEST EXAMINATION FINDINGS IN PULMONARY PROBLEMS

Problem	Inspection	Palpation	Percussion	Auscultation
Chronic obstructive pulmonary disease	Barrel chest, cyanosis, tripod position, use of accessory muscles	↓ Movement	Hyperresonant or dull if consolidation	Crackles, rhonchi, wheezes, distant breath sounds
Asthma				
In exacerbation	Prolonged expiration, tripod position, pursed lips	↓ Movement	Hyperresonance	Wheezes, ↓ breath sounds ominous sign (severely diminished air movement)
Not in exacerbation	Normal	Normal	Normal	Normal
Pneumonia	Tachypnea, use of accessory muscles, duskiness or cyanosis	↑ Fremitus over affected area	Dull over affected areas	*Early:* Bronchial sounds *Later:* Crackles, rhonchi, egophony, whispered pectoriloquy
Atelectasis	No change unless involves entire segment, lobe	If small, no change If large, ↓ movement, ↓ fremitus	Dull over affected area	Crackles (may disappear with deep breaths) Absent sounds if large
Pulmonary edema	Tachypnea, labored respirations, cyanosis	↓ Movement or normal movement	Dull or normal depending on amount of fluid	Fine or coarse crackles at bases moving upward as condition worsens
Pleural effusion	Tachypnea, use of accessory muscles	↑ Movement ↑ Fremitus above effusion Absent fremitus over effusion	Dull	Diminished or absent over effusion, egophony over effusion
Pulmonary fibrosis	Tachypnea	↓ Movement	Normal	Crackles or sounds like Velcro being pulled apart

DIAGNOSTIC STUDIES OF RESPIRATORY SYSTEM

Numerous diagnostic studies are available to assess the respiratory system. Table 26-10 identifies the most common studies, and select studies are described in more detail below.

Sputum Studies

Sputum samples can be obtained by expectoration, tracheal suction, or bronchoscopy (discussed below). When the patient is unable to expectorate spontaneously, sputum may also be collected by inhalation of an irritating aerosol, usually hypertonic saline. This is called sputum induction. The specimens may be examined for culture and sensitivity to identify an infecting organism (e.g., *Mycobacterium, Pneumocystis jiroveci*) or to confirm a diagnosis (e.g., malignant cells). Regardless of whether specimen tests are ordered, observe the sputum for color, blood, volume, and viscosity.

Skin Tests

Skin tests may be performed to test for allergic reactions (see Chapter 14) or exposure to TB bacilli or fungi. Skin tests involve the intradermal injection of an antigen. A positive result on a TB skin test indicates that the patient has been exposed to the antigen. It does not indicate that TB is currently present. A negative result indicates either no exposure or a depression of cell-mediated immunity such as occurs in HIV infection. Table 26-11 on p. 494 describes reactions that indicate a positive TB skin test.

Nursing responsibilities are similar for all skin tests. First, to prevent a false-negative reaction, be certain that the injection is intradermal and not subcutaneous. After the injection, circle the site(s) and instruct the patient not to remove the marks. When charting administration of the antigen, draw a diagram of the forearm and hand and label the injection sites. The diagram is especially helpful when more than one test is administered.

When reading test results, use a good light. If an induration is present, use a marking pen to indicate the periphery on all four sides of the induration. As the pen touches the raised area, make a mark. Then determine the diameter of the induration in millimeters. Reddened, flat areas are not measured.

Endoscopic Examinations Bronchoscopy. *Bronchoscopy* is a procedure in which the bronchi are visualized through a fiberoptic tube (Fig. 26-11). Bronchoscopy may be used for diagnos-

TABLE 26-10 DIAGNOSTIC STUDIES

Respiratory System

Study	Description and Purpose	Nursing Responsibility
Blood Studies		
Hemoglobin	Test reflects amount of hemoglobin available for combination with O_2. Venous blood is used. *Male:* 13.2-17.3 g/dL (132-173 g/L) *Female:* 11.7-16.0 g/dL (117-160 g/L)	Explain procedure and its purpose.
Hematocrit	Test reflects ratio of red blood cells to plasma. Increased hematocrit (polycythemia) found in chronic hypoxemia. Venous blood is used. *Male:* 39%-50% (0.39-0.50) *Female:* 35%-47% (0.35-0.47)	Explain procedure and its purpose.
Arterial blood gases (ABGs)	Arterial blood is obtained through puncture of radial or femoral artery or through arterial catheter. Performed to assess acid-base balance, ventilation status, need for O_2 therapy, change in O_2 therapy, or change in ventilator settings.* Continuous ABG monitoring is also possible via a sensor or electrode inserted into arterial catheter.	Indicate whether patient is using O_2 (percentage, L/min). Avoid change in O_2 therapy or interventions (e.g., suctioning, position change) for 20 min before obtaining sample. Assist with positioning (e.g., palm up, wrist slightly hyperextended if radial artery is used). Collect blood in heparinized syringe. To ensure accurate results, expel all air bubbles and place sample in ice, unless it will be analyzed in <1 min. Apply pressure to artery for at least 5 min after specimen is obtained to prevent hematoma at the arterial puncture site.
O_2 Monitoring		
Oximetry	Monitors arterial or venous O_2 saturation. Probe attaches to finger, toe, earlobe, bridge of the nose for SpO_2 monitoring (see eFig. 26-2) or is contained in a pulmonary artery catheter for SvO_2 monitoring. Oximetry is used for intermittent or continuous monitoring and exercise testing.	Apply probe. When interpreting SpO_2 and SvO_2 values, first assess patient status and presence of factors that can alter accuracy of pulse oximeter reading. For SpO_2 these include motion, low perfusion, cold extremities, bright lights, acrylic nails, dark skin color, carbon monoxide, and anemia. For SvO_2, these include change in O_2 delivery or O_2 consumption.
CO_2 Monitoring		
End-tidal CO_2 ($PETCO_2$) (capnography)	Assesses the level of CO_2 in exhaled air. Graphically displays partial pressure of CO_2. Expired gases are sampled from the patient's airway and are analyzed by a CO_2 sensor that uses infrared light to measure exhaled CO_2. The sensor may be attached to an adaptor on the endotracheal or tracheostomy tube. A nasal cannula with a sidestream capnometer can be used in patients without an artificial airway. Can be used as a diagnostic measure to detect lung disease and for monitoring patients. Normal difference between $PaCO_2$ and $PETCO_2$ is 2-5 mm Hg ($PaCO_2$: 35-45 mm Hg; $PETCO_2$: 37-50 mm Hg).	Teach patient and caregiver about the purpose of capnography monitoring, emphasizing the benefit of continuous monitoring. Make sure that sensor is properly attached. Record and document data per institution policy.
Sputum Studies		
Culture and sensitivity	Purpose is to diagnose bacterial infection, select antibiotic, and evaluate treatment. Sputum specimen is collected in a sterile container. Takes 48-72 hr for results.	Instruct patient on how to produce a good specimen (see Gram stain). If patient cannot produce specimen, bronchoscopy may be used (see Fig. 26-11).
Gram stain	Staining of sputum permits classification of bacteria into gram-negative and gram-positive types. Results guide therapy until culture and sensitivity results are obtained.	Instruct patient to expectorate sputum into container after coughing deeply. Obtain sputum (mucoidlike), not saliva. Obtain specimen in early morning after mouth care because secretions collect during night. If unsuccessful, try increasing oral fluid intake unless fluids are restricted. Collect sputum in sterile container (sputum trap) during suctioning or by aspirating secretions from the trachea. Send specimen to laboratory promptly.
Acid-fast smear and culture	Assesses sputum for acid-fast bacilli (e.g., *Mycobacterium tuberculosis*). A series of three early-morning specimens is used.	Instruct patient how to produce a good specimen (see Gram stain). Cover specimen and send to laboratory for analysis.
Cytology	Determines presence of abnormal cells that may indicate malignant condition. Single sputum specimen is collected in special container with fixative solution.	Instruct patient on how to produce a good specimen (see Gram stain). If patient cannot produce specimen, bronchoscopy may be used (see Fig. 26-11). Send specimen to laboratory promptly.

*For reference intervals, see Table 26-1.

Continued

TABLE 26-10 DIAGNOSTIC STUDIES—cont'd

Respiratory System

Study	Description and Purpose	Nursing Responsibility
Radiology		
Chest x-ray	Used to screen, diagnose, and evaluate changes in respiratory system. Most common views are anteroposterior (AP) and lateral.	Instruct patient to undress to waist, put on gown, and remove any metal between neck and waist.
Computed tomography (CT)	Performed for diagnosis of lesions difficult to assess (e.g., mediastinum, hilum, pleura) by conventional x-ray studies. Common types are helical or spiral CT (contrast medium is usually used) and high-resolution CT scan (contrast medium is not used). Spiral CT used to diagnose a pulmonary embolism.	Same as for chest x-ray. Contrast medium may be given IV. Evaluation of BUN and serum creatinine is done before contrast to assess renal function. Assess if patient is allergic to shellfish (iodine), since the contrast is iodine based. Be sure the patient is well hydrated before and after procedure (to excrete contrast). Warn patient that contrast injection may cause a feeling of being warm and flushed. Instruct the patient that he or she will need to lie still on a hard table and the scanner will revolve around the body with clicking noises.
Magnetic resonance imaging (MRI)	Used for diagnosis of lesions difficult to assess by CT scan (e.g., lung apex) and for distinguishing vascular from nonvascular structures.	Same as for chest x-ray and CT scan, except contrast medium is not iodine based. If closed MRI is used and patient has claustrophobia, provide with relaxation or other modes to cope. Patient must remove all metal (e.g., jewelry, watch) before test. Patients with pacemakers and implantable cardioverter-defibrillators may not be able to have MRI.
Ventilation-perfusion (V/Q) scan	Used to assess ventilation and perfusion of lungs. IV radioisotope given to assess perfusion. For the ventilation portion, the patient inhales a radioactive gas (xenon or krypton), which outlines the alveoli. Normal scans show homogeneous radioactivity. Diminished or absent radioactivity suggests lack of perfusion or airflow. Ventilation without perfusion suggests a pulmonary embolus.	Same as for chest x-ray. No precautions needed afterward because the gas and isotope transmit radioactivity for only a brief interval.
Pulmonary angiogram	Used to visualize pulmonary vasculature and locate obstruction or pathologic conditions (e.g., pulmonary embolus). Contrast medium is injected through a catheter threaded into pulmonary artery or right side of the heart. Series of x-rays are taken after contrast medium is injected into pulmonary artery. Chest CT is replacing angiography, since it is less invasive.	Same as for chest x-ray. (See CT scan for contrast media precautions.) Check pressure dressing site after procedure. Monitor blood pressure, pulse, and circulation distal to injection site. Report and record significant changes.
Positron emission tomography (PET) scan	Used to distinguish benign and malignant pulmonary nodules. Because malignant lung cells have an increased uptake of glucose, the PET scan, which uses an IV radioactive glucose preparation, can demonstrate increased uptake of glucose in malignant lung cells.	*Preprocedure:* Check the blood glucose levels as high levels may interfere with test. Food and fluids other than water may be restricted for 4-6 hr. *Postprocedure:* Encourage fluids to excrete radioactive substance.
Endoscopy		
Bronchoscopy (see Fig. 26-11)	Flexible fiberoptic scope is used for diagnosis, biopsy, specimen collection, or assessment of changes. It may also be done to suction mucous plugs, lavage the lungs, or remove foreign objects.	Instruct patient to be on NPO status for 6-12 hr before the test. Obtain signed permit. Give sedative if ordered. After procedure, keep patient NPO until gag reflex returns. Monitor for recovery from sedation. Blood-tinged mucus is not abnormal. If biopsy was done, monitor for hemorrhage and pneumothorax.

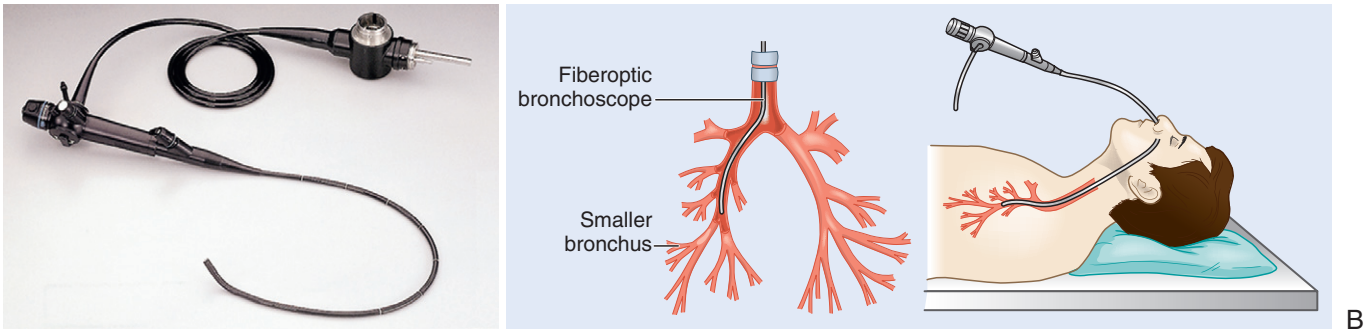

FIG. 26-11 Fiberoptic bronchoscope. **A,** The transbronchoscopic balloon-tipped catheter and the flexible fiberoptic bronchoscope. **B,** The catheter is introduced into a small airway and the balloon inflated with 1.5 to 2 mL of air to occlude the airway. Bronchoalveolar lavage is performed by injecting and withdrawing 30-mL aliquots of sterile saline solution, gently aspirating after each instillation. Specimens are sent to the laboratory for analysis.

TABLE 26-10 DIAGNOSTIC STUDIES—cont'd

Respiratory System

Study	Description and Purpose	Nursing Responsibility
Mediastinoscopy	Scope is inserted through a small incision in the suprasternal notch and advanced into the mediastinum to inspect and biopsy lymph nodes. Used to diagnose lung cancer, non-Hodgkin's lymphoma, granulomatous infections, and sarcoidosis.	Prepare patient for surgical intervention. Obtain signed informed consent. Performed in the operating room (OR) using a general anesthetic. Afterward, monitor as for bronchoscopy.
Lung Biopsy	Specimens may be obtained by transbronchial or percutaneous biopsy or via transthoracic needle aspiration (TTNA), video-assisted thoracoscopic surgery (VATS), or open lung biopsy. Transbronchial biopsy and VATS can be performed in the bronchoscopy suite. TTNA is done under CT guidance in radiology department. Open lung is performed in the OR. VATS can also be done in the OR. These tests are used to obtain specimens for laboratory analysis.	Same as bronchoscopy if procedure done with bronchoscope, and same as thoracotomy if open lung biopsy done. With TTNA, check breath sounds q4hr for 24 hr and report any respiratory distress. Check incision site for bleeding. A chest x-ray should be done after TTNA or transbronchial biopsy to check for pneumothorax. With VATS a chest tube may be in postprocedure until lung has reexpanded. Monitor breath sounds to follow chest reexpansion. Encourage deep breathing for lung reinflation. Obtain signed informed consent for all procedures.
Thoracentesis	Used to obtain specimen of pleural fluid for diagnosis, to remove pleural fluid, or to instill medication. Chest x-ray is always obtained after procedure to check for pneumothorax.	Explain procedure to patient and obtain signed informed consent before procedure, which is usually performed in the patient's room. Position patient upright with elbows on an overbed table and feet supported. Instruct the patient not to talk or cough, and assist during procedure. Observe for signs of hypoxia and pneumothorax, and verify breath sounds in all fields after procedure. Encourage deep breaths to expand lungs. Send labeled specimens to laboratory.
Pulmonary Function Tests	Used to evaluate lung function. Involves use of spirometer to assess air movement as patient performs prescribed respiratory maneuvers.†	Avoid scheduling immediately after mealtime. Avoid administration of inhaled bronchodilator 6 hr before procedure. Explain procedure to patient. Assess for respiratory distress before procedure and report. Provide rest after the procedure.
Exercise Testing	Used in diagnosis and in determining exercise capacity. A *complete test* involves walking on a treadmill while expired O_2 and CO_2, respiratory rate, heart rate, and heart rhythm are monitored. In a *modified test* (desaturation test) only SpO_2 is monitored.	Instruct patient to wear comfortable shoes. Encourage patient to walk as quickly as possible.
6-Min walk test	Used to measure functional capacity and response to treatment in patients with heart or lung disease. Pulse oximetry is usually monitored during the walk. The distance walked is measured and used to monitor progression of disease or improvement after rehabilitation.	The patient is instructed by a trained practitioner to walk as far as possible during 6 min, stopping when short of breath and continuing when able.

†For reference intervals, see Tables 26-12 and 26-13.

tic purposes to obtain biopsy specimens and assess results of treatment. Small amounts (30 mL) of sterile saline may be injected through the scope and withdrawn and examined for cells, a technique termed *bronchoalveolar lavage* (BAL). Bronchoscopy is also used for treatment, for example, to remove mucous plugs or foreign bodies. Laser therapy, electrocautery, cryotherapy, and stents may be placed through a bronchoscope to achieve patency of an airway that has been completely or partially obstructed by tumors.

Bronchoscopy can be performed in an outpatient procedure room, in a surgical suite, or at the bedside in the intensive care unit or on a medical-surgical unit, with the patient lying down or seated. After the nasopharynx and oropharynx are anesthetized with local anesthetic, the bronchoscope is coated with lidocaine (Xylocaine) and inserted, usually through the nose, and threaded down into the airways. Bronchoscopy can be done on mechanically ventilated patients through the endotracheal tube.

Lung Biopsy

Lung biopsy may be done (1) transbronchially, (2) percutaneously or via transthoracic needle aspiration (TTNA), (3) by video-assisted thoracic surgery (VATS), or (4) as an open lung biopsy. The purpose of a lung biopsy is to obtain tissue, cells, or secretions for evaluation. Transbronchial lung biopsy involves passing a forceps or needle through the bronchoscope for a specimen (Fig. 26-12). Specimens can be cultured or examined for malignant cells. A combination of transbronchial lung biopsy and BAL is used to differentiate infection and rejection in lung transplant recipients.

Percutaneous needle aspiration or TTNA involves inserting a needle through the chest wall, usually under computed tomography (CT) guidance. Because of the risk of a pneumothorax, a chest x-ray is ordered after TTNA.

In VATS a rigid scope with a lens is passed through a trocar placed into the pleura via one or two small incisions in the intercostal muscles. The physician views the lesions on a monitor

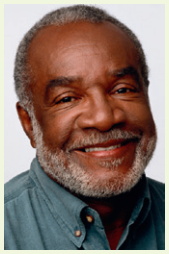

TABLE 26-11 INTERPRETING RESPONSES TO TUBERCULIN SKIN TESTING

Types of Responses	Consider Positive in the Following Groups
Positive Reactions	
≥5-mm induration	• HIV-infected people • People who had recent contact with a person with TB disease • People with fibrotic lesions on chest x-ray consistent with prior TB • Patients with organ transplants • People who are immunosuppressed (e.g., taking the equivalent of ≥15 mg/day of prednisone for ≥1 mo)
≥10-mm induration	• Recent immigrants (<5 yr) from high-prevalence countries • Injecting drug users • Residents and employees of high-risk congregate settings • Mycobacteriology laboratory personnel • People with clinical conditions (e.g., diabetes mellitus, end-stage kidney disease) that place them at high risk
≥15-mm induration	• All other people who are at low risk
False Reactions	**Possible Causes**
False-negative reactions (do not react even though infected)	• Anergy, immunosuppression • Recent TB infection (within 8-10 wk of exposure) • Overwhelming TB infection • Very old TB infection (many years) • Recent live virus vaccination (e.g., measles, chickenpox)
False-positive reactions (react even though not infected)	• Nontuberculous mycobacteria (e.g., *Mycobacterium avium-intracellulare* [MAI] or *Mycobacterium avium* complex [MAC]) • Previous BCG vaccine

CASE STUDY—cont'd

Objective Data: Diagnostic Studies

Kevin Peterson/ Photodisc/Thinkstock

The health care provider orders the following diagnostic studies for F.T.:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- ABGs
- Chest x-ray
- Sputum for culture and sensitivity

The ABGs demonstrate a compensated respiratory acidosis with hypoxemia. The WBC is 14,350/µL, and the chest x-ray shows lower lobe pneumonia. F.T. is admitted to the cardiopulmonary medical-surgical nursing unit.

directly via the lens, and biopsy specimens can be taken. A chest tube is kept in place until the lung expands. Lesions in the pleura or peripheral lung are biopsied via VATS. VATS is much less invasive than open lung biopsy and is the procedure of choice when appropriate.

Open lung biopsy is used when pulmonary disease cannot be diagnosed by other procedures. The patient is anesthetized, the chest is opened with a thoracotomy incision, and a biopsy specimen is obtained. Nursing care for the procedure is the same as after thoracotomy (see Chapter 28).

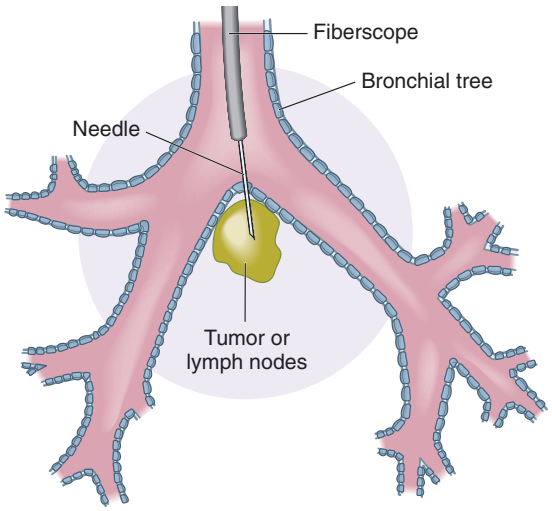

FIG. 26-12 Transbronchial biopsy needle penetrating the bronchial wall and entering a mass of subcarinal lymph nodes or tumor.

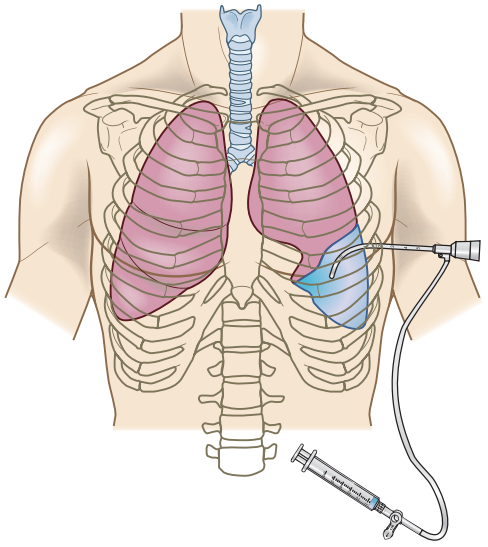

FIG. 26-13 Thoracentesis. A catheter is positioned in the pleural space to remove accumulated fluid.

Thoracentesis

Thoracentesis is the insertion of a large-bore needle through the chest wall into the pleural space to obtain specimens for diagnostic evaluation, remove pleural fluid, or instill medication into the pleural space (Fig. 26-13). The patient is positioned sitting upright with elbows on an overbed table and feet supported. The skin is cleansed and a local anesthetic (lidocaine) is instilled subcutaneously. A chest tube may be inserted to permit further drainage of fluid.

Pulmonary Function Tests

Pulmonary function tests (PFTs) measure lung volumes and airflow. The results of PFTs are used to diagnose pulmonary disease, monitor disease progression, evaluate disability, and assess response to bronchodilators. Airflow measurement is administered by trained personnel using a spirometer. The patient inserts a mouthpiece, takes as deep a breath as possible,

TABLE 26-12 LUNG VOLUMES AND CAPACITIES

Parameter	Definitions	Normal Values*
Volumes		
Tidal volume (V_T)	Volume of air inhaled and exhaled with each breath. Only a small proportion of total capacity of lungs.	0.5 L
Expiratory reserve volume (ERV)	Additional air that can be forcefully exhaled after normal exhalation is complete.	1.0 L
Residual volume (RV)	Amount of air remaining in lungs after forced expiration. Air available in lungs for gas exchange between breaths.	1.5 L
Inspiratory reserve volume (IRV)	Maximum volume of air that can be inhaled forcefully after normal inhalation.	3.0 L
Capacities		
Total lung capacity (TLC)	Maximum volume of air that lungs can contain (TLC = IRV + V_T + ERV + RV).	6.0 L
Functional residual capacity (FRC)	Volume of air remaining in lungs at end of normal exhalation (FRC = ERV + RV). Increase or decrease possible with lung disease.	2.5 L
Vital capacity (VC)	Maximum volume of air that can be exhaled after maximum inspiration (VC = IRV + V_T + ERV); higher VC for men (generally).	4.5 L
Inspiratory capacity (IC)	Maximum volume of air that can be inhaled after normal expiration (IC = V_T + IRV).	3.5 L

*Normal values vary with patient's height, weight, age, race, and gender.

TABLE 26-13 COMMON MEASURES OF PULMONARY FUNCTION AIRFLOW

Measure	Description	Normal Value*
Forced vital capacity (FVC)	Amount of air that can be quickly and forcefully exhaled after maximum inspiration.	>80% of predicted
Forced expiratory volume in first second of expiration (FEV_1)	Amount of air exhaled in first second of FVC. Grades severity of airway obstruction.	>80% of predicted
FEV_1/FVC ratio	Dividing value for FEV_1 by value for FVC. Useful in differentiating obstructive and restrictive pulmonary dysfunction.	Age <50: ≥75% of predicted Age ≥50: ≥70% of predicted
Forced midexpiratory flow rate ($FEF_{25\%-75\%}$)	Measurement of airflow rate in middle half of forced expiration; early indicator of disease of small airways.	Age <50: ≥75% of predicted Age ≥50: ≥70% of predicted
Maximal voluntary ventilation (MVV)	Deep breathing as rapidly as possible for specified period. Fairly nonspecific test that gives information about exercise capacity. Used in conjunction with exercise stress test.	About 170 L/min
Peak expiratory flow rate (PEFR)	Maximum airflow rate during forced expiration. Aids in monitoring bronchoconstriction in asthma. Can be measured with peak flow meter.	Up to 600 L/min

*Normal values vary with patient's height, age, race, and gender.

and exhales as hard, fast, and long as possible. Verbal coaching is given to ensure that the patient continues blowing out until exhalation is complete.

The computer calculates the patient's percentage of predicted values, that is, how well the performance compares with an average based on age, gender, race, and height. Normal values are approximately 80% to 120% of the predicted value.[10] Normal values for PFTs are shown in Tables 26-12 and 26-13 and in eFig. 26-4, available on the website for this chapter.

Spirometry may be ordered before and after the administration of a bronchodilator to determine the patient's response. This may help document reversibility of airway obstruction (e.g., asthma). A positive response to the bronchodilator is greater than 200 mL increase or greater than 12% increase between preadministration and postadministration values.

Home spirometry may be used to monitor lung function in people with asthma, cystic fibrosis, or COPD, as well as before and after lung transplantation or other thoracic surgeries.[11] A peak flow meter is the instrument used at home. It is a handheld device through which one blows forcefully and quickly after taking a deep breath. Spirometry changes at home can warn of early lung transplant rejection or infection. Data from a peak flow meter provide important feedback to patients with asthma so they can learn to modify activities and medications in response to changes in peak expiratory flow rates (see Chapter 29).

Pulmonary function parameters can also be used to determine the need for mechanical ventilation or the readiness to be weaned from ventilatory support (see Table 66-13).

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. To promote the release of surfactant, the nurse encourages the patient to
   - **a.** take deep breaths.
   - **b.** cough five times per hour to prevent alveolar collapse.
   - **c.** decrease fluid intake to reduce fluid accumulation in the alveoli.
   - **d.** sit with head of bed elevated to promote air movement through the pores of Kohn.
2. A patient with a respiratory condition asks "How does air get into my lungs?" The nurse bases her answer on her knowledge that air moves into the lungs because of
   - **a.** contraction of the accessory abdominal muscles.
   - **b.** increased carbon dioxide and decreased oxygen in the blood.
   - **c.** stimulation of the respiratory muscles by the chemoreceptors.
   - **d.** decrease in intrathoracic pressure relative to pressure at the airway.

3. The nurse can best determine adequate arterial oxygenation of the blood by assessing
   a. heart rate.
   b. hemoglobin level.
   c. arterial oxygen tension.
   d. arterial carbon dioxide tension.
4. When teaching a patient about the most important respiratory defense mechanism distal to the respiratory bronchioles, which topic would the nurse discuss?
   a. Alveolar macrophages
   b. Impaction of particles
   c. Reflex bronchoconstriction
   d. Mucociliary clearance mechanism
5. A student nurse asks the RN what can be measured by arterial blood gases (ABGs). The RN tells the student that the ABGs can measure *(select all that apply)*
   a. acid-base balance.
   b. oxygenation status.
   c. acidity of the blood.
   d. glucose bound to hemoglobin.
   e. bicarbonate (HCO_3^-) in arterial blood.
6. To detect early signs or symptoms of inadequate oxygenation, the nurse would examine the patient for
   a. dyspnea and hypotension.
   b. apprehension and restlessness.
   c. cyanosis and cool, clammy skin.
   d. increased urine output and diaphoresis.
7. During the respiratory assessment of the older adult, the nurse would expect to find *(select all that apply)*
   a. a vigorous cough.
   b. increased chest expansion.
   c. increased residual volume.
   d. increased breath sounds in the lung apices.
   e. increased anteroposterior (AP) chest diameter.
8. When assessing activity-exercise patterns related to respiratory health, the nurse inquires about
   a. dyspnea during rest or exercise.
   b. recent weight loss or weight gain.
   c. ability to sleep through the entire night.
   d. willingness to wear oxygen equipment in public.
9. When auscultating the chest of an older patient in respiratory distress, it is best to
   a. begin listening at the apices.
   b. begin listening at the lung bases.
   c. begin listening on the anterior chest.
   d. ask the patient to breathe through the nose with the mouth closed.
10. Which assessment finding of the respiratory system does the nurse interpret as abnormal?
    a. Inspiratory chest expansion of 1 in
    b. Percussion resonance over the lung bases
    c. Symmetric chest expansion and contraction
    d. Bronchial breath sounds in the lower lung fields
11. The nurse is preparing the patient for a diagnostic procedure to remove pleural fluid for analysis. The nurse would prepare the patient for which test?
    a. Thoracentesis
    b. Bronchoscopy
    c. Pulmonary angiography
    d. Sputum culture and sensitivity

1. a, 2. d, 3. c, 4. a, 5. a, b, c, e, 6. b, 7. c, e, 8. a, 9. b, 10. d, 11. a

LEARNING OUTCOMES

1. Describe the clinical manifestations and nursing and collaborative management of problems of the nose.
2. Discuss the clinical manifestations and nursing and collaborative management of problems of the paranasal sinuses.
3. Describe the clinical manifestations and nursing and collaborative management of problems of the pharynx and larynx.
4. Discuss the nursing management of the patient who requires a tracheostomy.
5. Identify the steps involved in performing tracheostomy care and suctioning an airway.
6. Describe the risk factors and warning symptoms associated with head and neck cancer.
7. Discuss the nursing management of the patient with a laryngectomy.
8. Explain the methods used in voice restoration for the patient with temporary or permanent loss of speech.

KEY TERMS

allergic rhinitis, p. 499
deviated septum, p. 497
epistaxis, p. 498
esophageal speech, p. 516
nasal polyps, p. 506
rhinoplasty, p. 498
sinusitis, p. 504
tracheostomy, p. 507

Disorders of the nose, sinuses, pharynx, and larynx are presented in this chapter. Nursing management of patients with a tracheostomy or total laryngectomy is also discussed.

PROBLEMS OF NOSE AND PARANASAL SINUSES

DEVIATED SEPTUM

Deviated septum is a deflection of the normally straight nasal septum. Although up to 80% of the adult population may have septums that are slightly off center, the diagnosis of deviated septum is generally reserved for those that are severely shifted.[1] Trauma to the nose, either at birth or later in life, is the most common cause of deviated septum.[2] Deviation from midline can interfere with airflow and sinus drainage through the narrowed passageway. Symptoms vary depending on the degree of deviation. Minor septal deviations may be asymptomatic. Common manifestations of septal deviation include obstruction to nasal breathing, nasal congestion, frequent sinus infections and nosebleeds *(epistaxis),* and facial pain.

Medical management of deviated septum is focused on symptom control of nasal inflammation and congestion (see Table 27-2). For recurrent or severe symptoms, a nasal septoplasty is performed to reconstruct and properly align the deviated septum.

NASAL FRACTURE

Nasal fracture is the most common facial fracture and the third most common fracture of any bone. Fracture of the nose occurs as a result of blunt trauma, such as occurs with fights, automobile accidents, falls, and sports injuries. Many cases of facial trauma can be prevented by using protective sports

Reviewed by Sharon A. Willadsen, RN, PhD, Nursing Instructor, Lakeshore Technical College, Cleveland, Wisconsin.

equipment and protecting against falls. Complications associated with nasal fractures include airway obstruction, epistaxis, meningeal tears causing cerebrospinal fluid (CSF) leakage, septal hematoma, and cosmetic deformity.

Nasal fractures can be classified as simple or complex. *Simple fractures* may be unilateral or bilateral and typically produce little or no displacement.[3] Powerful frontal blows can cause *complex fractures,* which may also involve subsequent damage to adjacent facial structures such as the teeth, eyes, or other facial bones. Orbital fractures may be seen with midfacial trauma.

Diagnosis of a nasal fracture is based on the health history and physical examination. Clinical manifestations suggestive of a nasal fracture include localized pain, crepitus on palpation, swelling, ecchymosis, cosmetic deformity, epistaxis, and difficulty breathing out of the nostrils. Although facial deformity with a nasal fracture is common, often epistaxis may be the only initial sign.

On inspection, assess the patient's ability to breathe through each side of the nose and note the presence of edema, bleeding, or hematoma. Ecchymosis may be under one or both eyes. Ecchymosis involving both eyes is often termed *raccoon eyes* and may suggest an orbital or basilar skull fracture (see Chapter 57). Inspect the nose internally for evidence of septal deviation, hemorrhage, or clear drainage. Clear, pink-tinged, or persistent drainage after control of epistaxis suggests a CSF leak. Perform a quick test at the bedside or send a specimen to the laboratory to determine if glucose is present; the presence of glucose indicates that the fluid is CSF.

Injury of sufficient force to fracture nasal bones results in considerable swelling of soft tissues. With extensive swelling, it may be necessary to wait to repair the fracture until the edema subsides, which may be 5 to 10 days.

Goals of nursing management are to maintain the airway, reduce edema and pain, prevent complications, and provide emotional support. The best way to maintain the airway is to keep the patient in an upright position. Apply ice to the face and nose in 10- to 20-minute intervals to help reduce edema and bleeding. Administer analgesia as ordered to control pain. Acetaminophen is preferred over nonsteroidal antiinflammatory drugs (NSAIDs) or acetylsalicylic acid (ASA; aspirin) for the first 48 hours to avoid prolonging clotting time and increasing the risk for bleeding. Nasal stuffiness may be relieved with nasal decongestants, saline nasal sprays, and a humidifier. Tell the patient to avoid hot showers and alcohol for the first 48 hours to prevent an increase in swelling. Encourage the patient to quit or decrease smoking to maximize tissue healing.

When a fracture is confirmed, the goals are to realign the fracture using closed or open reduction (septoplasty, rhinoplasty) and to ensure that a septal hematoma does not develop, since this increases the patient's risk for infection. In addition to reestablishing cosmetic appearance, these surgical procedures provide an adequate airway and function of the nose.

RHINOPLASTY

Rhinoplasty, the surgical reconstruction of the nose, is performed for cosmetic reasons or to improve airway function when trauma or developmental deformities result in nasal obstruction. When caring for rhinoplasty patients before surgery, assess the patient's expectations of the surgery. Any actual or perceived alteration in body image (e.g., a deformed or enlarged nose) can affect self-esteem and interactions with others. Computerized photographs can be used to show the patient's appearance after the surgery. These images often help patients decide whether to undergo rhinoplasty. Explain expected results of surgery frankly and truthfully to avoid disappointment.

Rhinoplasty is performed as an outpatient procedure using regional or general anesthesia. Sometimes nasal tissue is added or removed, and the nose may be lengthened or shortened. Plastic implants are sometimes used to reshape the nose. Incisions are typically inside the nose and are thus hidden. Sonic rhinoplasty incorporates the use of an ultrasonic device to gently aspirate bone, enabling a refined cosmetic result.[4]

After surgery, nasal packing may be inserted to apply pressure and prevent bleeding or septal hematoma formation. An external plastic splint protects and supports the new shape of the nose during the healing process. Nasal packing is usually removed the day after surgery, and the splint is left in place for approximately 1 week.

NURSING MANAGEMENT
NASAL SURGERY

Examples of nasal surgery include rhinoplasty, septoplasty, and nasal fracture reductions. Before surgery, instruct the patient not to take aspirin-containing drugs or NSAIDs for 2 weeks to reduce the risk of bleeding. Encourage preoperative smoking cessation to promote postoperative wound healing. Nursing interventions during the immediate postoperative period include maintenance of the airway; assessment of respiratory status; pain management; and observation of the surgical site for bleeding, infection, and edema. Teaching is important because the patient must be able to detect early and late complications at home. The patient typically experiences temporary edema and ecchymosis. Cold compresses and elevation of the head can help minimize swelling and discomfort. Teach activity restrictions aimed at preventing bleeding and injury (no nose blowing, swimming, heavy lifting, strenuous exercise).[5] Subtle swelling may be slow to resolve, delaying the achievement of a full cosmetic result for up to a year.

EPISTAXIS

Epistaxis (nosebleed) occurs in a bimodal distribution, with children 2 to 10 years of age and adults over age 50 most affected. Epistaxis can be caused by low humidity, allergies, upper respiratory tract infections, sinusitis, trauma, foreign bodies, hypertension, chemical irritants such as street drugs, overuse of decongestant nasal sprays, facial or nasal surgery, anatomic malformation, and tumors.[6] Any condition that prolongs bleeding time or alters platelet counts will predispose the patient to epistaxis. Bleeding time may also be prolonged if the patient takes aspirin, NSAIDs, warfarin, or other anticoagulant drugs.

Approximately 90% of nosebleeds occur in the anterior portion of the nasal cavity and are easily visualized. Posterior bleeding occurs more commonly with older adults secondary to other health problems. Anterior bleeding usually stops spontaneously or can be self-treated. Posterior bleeding may require medical treatment.

NURSING AND COLLABORATIVE MANAGEMENT
EPISTAXIS

Use simple first aid measures to control epistaxis: (1) keep the patient quiet; (2) place the patient in a sitting position, leaning slightly forward with head tilted forward; and (3) apply direct pressure by pinching the entire soft lower portion of the nose against the nasal septum for 10 to 15 minutes. If bleeding does not stop within 15 to 20 minutes, seek medical assistance.

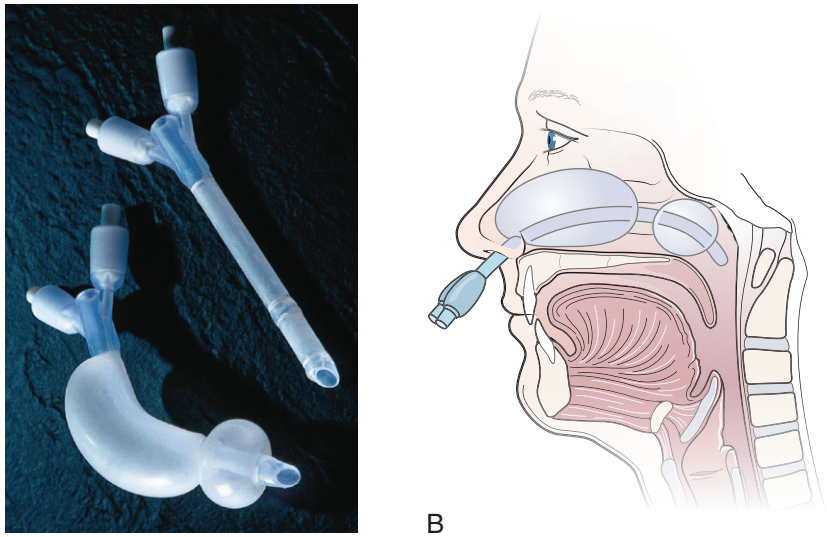
Medical management involves identifying the bleeding site and applying a vasoconstrictive agent, cauterization, or anterior packing. Pledgets (nasal tampon) impregnated with anesthetic solution (lidocaine) and/or vasoconstrictive agents such as cocaine or epinephrine are placed into the nasal cavity and left in place for 10 to 15 minutes. Silver nitrate may be used to chemically cauterize an identified bleeding point after epistaxis is controlled. Thermal cauterization is reserved for more severe bleeding and requires the use of local or general anesthesia.[7]

If bleeding does not stop, packing may be used. Packing with compressed sponges (e.g., Merocel) or epistaxis balloons (e.g., Rapid Rhino) is preferred over the use of traditional Vaseline ribbon gauze because of the ease of placement. Packing is inserted into the nares and advanced along the floor of the nasal cavity. The sponge expands with moisture to fill the nasal cavity and tamponade bleeding. The balloon is inflated with air to achieve the same pressure effect (Fig. 27-1). Alternatively, absorbable materials such as oxidized cellulose (surgical), gelatin foam (Gelfoam), or a gelatin-thrombin combination (Floseal) may be used as packing for anterior bleeds. In addition to providing pressure to stop bleeding, these materials increase clot formation and protect the nasal mucosa from further trauma.[7] A nasal sling (a folded 2 × 2-in gauze pad) may be taped under the nares to absorb drainage.

Nasal packing may impair respiratory status, especially in older adults. Closely monitor respiratory rate, heart rate and rhythm, oxygen saturation using pulse oximetry (SpO_2), and level of consciousness, and observe for signs of aspiration. Because of the risk of complications, all patients with posterior packing should be admitted to a monitored unit to permit closer observation.

Packing is painful because sufficient pressure must be applied to stop the bleeding. Nasal packing predisposes patients to infection from bacteria (e.g., *Staphylococcus aureus*) present in the nasal cavity. The patient should receive a mild opioid analgesic for pain (e.g., acetaminophen with codeine) and an antibiotic effective against staphylococci to protect against infection.

Nasal packing may be left in place for a few days. Before removal, medicate the patient for pain because this procedure is very uncomfortable. After removal, cleanse the nares gently and lubricate them with water-soluble jelly.



Teach the patient about home care before discharge. Instruct the patient to avoid vigorous nose blowing, engaging in strenuous activity, lifting, and straining for 4 to 6 weeks. Teach the patient to use saline nasal spray and/or a humidifier, to sneeze with the mouth open, and to avoid the use of aspirin-containing products or NSAIDs.

ALLERGIC RHINITIS

Allergic rhinitis is the reaction of the nasal mucosa to a specific allergen. Allergic rhinitis can be classified according to the causative allergen (seasonal or perennial) or the frequency of symptoms (episodic, intermittent, or persistent).[8] *Episodic* refers to symptoms related to sporadic exposure to allergens that are not typically encountered in the patient's normal environment, such as exposure to animal dander when visiting another person's home. *Intermittent* means that the symptoms are present less than 4 days a week or less than 4 weeks per year. *Persistent* means that the symptoms are present more than 4 days a week and for more than 4 weeks per year.

Seasonal rhinitis usually occurs in the spring and fall and is caused by allergy to pollens from trees, flowers, or grasses. The typical attack lasts for several weeks during times when pollen counts are high; then it disappears and recurs at the same time the following year. *Perennial rhinitis* occurs from exposure to environmental allergens, such as animal dander, dust mites, indoor molds, or cockroaches. Both seasonal and perennial rhinitis can be classified as episodic, intermittent, or persistent, depending on the duration and frequency of symptoms.

Sensitization to an allergen occurs with initial allergen exposure, which results in the production of antigen-specific immu-

A B

FIG. 27-1 **A,** Epistaxis balloon. The balloon is inflated after insertion. **B,** Epistaxis balloon in proper position in nares.

noglobulin E (IgE) (see Fig. 14-6). After exposure, mast cells and basophils release histamine, cytokines, prostaglandins, and leukotrienes, which cause the early symptoms of sneezing, itching, rhinorrhea, and congestion. Four to 8 hours after exposure, inflammatory cells infiltrate the nasal tissues, causing and maintaining the inflammatory response. Because symptoms of rhinitis resemble those of the common cold, the patient may believe the condition is a continuous or repeated cold.

Clinical Manifestations

Manifestations of allergic rhinitis are initially sneezing; watery, itchy eyes and nose; altered sense of smell; and thin, watery nasal discharge that can lead to a more sustained mucus production and nasal congestion. The nasal turbinates appear pale, boggy, and swollen. The turbinates may fill the air space and press against the nasal septum. The posterior ends of the turbinates can become so enlarged that they obstruct sinus aeration or drainage and result in sinusitis. With chronic exposure to allergens, the patient's responses include headache, congestion, pressure, nasal polyps, and postnasal drip as the most common cause of cough. The patient may complain of cough, hoarseness, and the recurrent need to clear the throat. Congestion may cause snoring.

NURSING AND COLLABORATIVE MANAGEMENT ALLERGIC RHINITIS

The most important step in managing allergic rhinitis is identifying and avoiding triggers of allergic reactions (Table 27-1). Instruct the patient to keep a diary of times when the allergic reaction occurs and the activities that precipitate the reaction. Patients are often more aware of intermittent exposure to an allergen such as pets than they are of a more persistent exposure to allergens such as dust mites, cockroaches, or mold. Identifying such triggers is the first step toward avoiding them.

The goal of medications is to reduce inflammation associated with allergic rhinitis, reduce nasal symptoms, minimize associated complications, and maximize quality of life. Appropriate oral medication options include H_1-antihistamines, corticosteroids, decongestants, and leukotriene receptor antagonists (LTRAs). Intranasal medications include antihistamines, anticholinergics, corticosteroids, cromolyn, and decongestants[9] (Table 27-2).

Second-generation antihistamines are preferred over first-generation antihistamines because of their nonsedating effects. Remind patients who are taking antihistamines to have adequate fluid intake to reduce adverse symptoms. Nasal corticosteroid sprays are used to decrease inflammation locally with little absorption in the systemic circulation. Therefore systemic side effects are rare. If symptoms are not relieved with monotherapy, a two-drug combination (such as an oral H_1-antihistamine and an intranasal corticosteroid) may be helpful. Immunotherapy (allergy shots) may be used when a specific, unavoidable allergen is identified and drugs are not tolerated or are ineffective in controlling symptoms. Immunotherapy involves controlled exposure to small amounts of the known allergen through frequent (at least weekly) injections with the goal of decreasing sensitivity. Sublingual or intranasal administration of allergen immunotherapy may be appropriate for selected patients. (Immunotherapy is discussed in Chapter 14.)

TABLE 27-1 PATIENT & CAREGIVER TEACHING GUIDE

Avoiding Allergens in Allergic Rhinitis

Include the following instructions when teaching a patient or caregiver about allergic rhinitis.

What to Avoid	Specific Approaches
House dust	• Focus on the bedroom. Remove carpeting. Limit furniture. • Put the pillows, mattress, and springs in airtight vinyl bags or containers. • Limit clothing in the bedroom to items used frequently. Place clothing in airtight, zipper-sealed vinyl clothes bags. • Install an air filter. Close the air conditioning vent into the room. Use blinds rather than draperies.
House dust mites	• Wash bedding in hot water (130° F [54° C]) weekly. • Wear a mask when vacuuming. Install a filter on the outlet port of the vacuum cleaner. • Avoid sleeping or lying on upholstered furniture. • Keep house temperature and conditions cool and dry.
Pet allergens	• Remove pets from interior of home. • Clean the living area thoroughly. • Do not expect instant relief. Symptoms usually do not improve significantly for 2 mo after pet removal.
Mold spores	• The three *D*s that promote growth of mold spores are darkness, dampness, and drafts. • Ventilate closed rooms and open doors. Consider adding windows to dark rooms. Consider keeping a small light on in closets. • Basement light with a timer that provides light several hours a day may decrease mold growth. • Avoid places where humidity is high (e.g., basements, clothes hampers, greenhouses, barns). Dehumidifiers are rarely helpful.
Pollens	• Stay inside with closed doors and windows during high-pollen season. • Install an air conditioner with a good air filter. Wash filters weekly during high-pollen season. • Put the car air conditioner on "recirculate" when driving. • Avoid having plants, especially in the bedroom.
Smoke	• Presence of a smoker will sabotage the best of all possible symptom reduction programs.

DRUG ALERT: Antihistamines

- First-generation antihistamines (e.g., chlorpheniramine [Chlor-Trimeton]) can cause drowsiness and sedation.
- Warn patients that operating machinery and driving may be dangerous because of the sedative effect.

DRUG ALERT: Pseudoephedrine (Sudafed)

- Large doses may produce tachycardia and palpitations, especially in patients with cardiac disease.
- Overdosage in those over 60 years of age may result in central nervous system depression, seizures, and hallucinations.

ACUTE VIRAL RHINITIS

Acute viral rhinitis (common cold or acute coryza) is an infection of the upper respiratory tract that can be caused by more than 200 different viruses. The majority of colds, which are caused by rhinoviruses, are mild and self-limiting. Other

TABLE 27-2 DRUG THERAPY

Rhinitis and Sinusitis

Drug	Mechanism of Action	Side Effects	Nursing Actions
Corticosteroids			
Nasal Spray	Inhibits inflammatory response of allergic rhinitis. At recommended dose, systemic side effects are unlikely because of low systemic absorption. Systemic effects may occur with higher than recommended doses.	Mild transient nasal burning and stinging, mucosal drying. In rare instances, localized fungal infection with *Candida albicans.*	• Instruct patient to use on regular basis and not PRN. • Instruct patient to clear nasal passages before use. • Reinforce that spray acts to decrease inflammation and it may take several days or weeks to achieve maximum effects. • Discontinue use if nasal infection develops.
beclomethasone (Beconase) budesonide (Rhinocort) ciclesonide (Omnaris) flunisolide (Nasalide) fluticasone (Flonase) fluticasone furoate (Veramyst) mometasone (Nasonex) triamcinolone (Nasacort)			
Mast Cell Stabilizer			
Nasal Spray	Suppresses release of histamine and other inflammatory mediators from mast cells.	Minimal side effects. Occasional burning or nasal irritation.	• Reinforce that spray prevents symptoms. • Begin 2 wk before pollen season starts and use throughout pollen season. • If isolated allergy, such as cat, use prophylactically (i.e., 10-15 min before exposure to allergen).
cromolyn spray (NasalCrom)			
Leukotriene Receptor Antagonists (LTRAs) and Inhibitors			
Antagonists	Suppress leukotriene activity, thereby inhibiting airway edema, bronchoconstriction, mucus production, and inflammation (see Fig. 12-2).	Generally well tolerated. May cause headaches, dizziness, rash, altered liver function tests, GI disturbances. *Zafirlukast and zileuton:* Monitor PT levels and theophylline levels if patient is taking warfarin or theophylline.	• Monitor liver function tests periodically while on therapy. Discontinue if elevated. • Administer on empty stomach. • Do not discontinue therapy without consulting health care professional. • Not to be used for acute attacks.
zafirlukast (Accolate) montelukast (Singulair)			
Inhibitors			
zileuton (Zyflo)			
Anticholinergic			
Nasal Spray	Blocks nasal cholinergic receptors, reducing nasal secretions in the common cold and nonallergic rhinitis.	Nasal dryness and irritation may occur. Does not cause systemic side effects.	• Need to prime pump with seven actuations before initial use • May reduce the need for other rhinitis medications.
ipratropium bromide (Atrovent)			
Antihistamines			
First-Generation Agents (Oral)	Bind with H_1 receptors on target cells, blocking histamine binding. Relieve acute symptoms of allergic response (itching, sneezing, rhinorrhea).	Cross blood-brain barrier, frequently causing sedation and somnolence. Can also cause paradoxical stimulation (restlessness, nervousness, insomnia). Anticholinergic side effects (e.g., palpitations, dry mouth, constipation, urinary hesitancy).	• Warn patient that operating machinery and driving may be dangerous because of sedative effect. • Teach patient to report palpitations, change in heart rate, change in bowel or bladder habits. • Instruct patient not to use alcohol with antihistamines because of additive depressant effect. • Rapid onset of action, no drug tolerance with prolonged use.
azatadine (Optimine) brompheniramine (Dimetane) chlorpheniramine (Chlor-Trimeton) clemastine (Tavist) dexchlorpheniramine (Polaramine) diphenhydramine (Benadryl) levocetirizine (Xyzal)			
Second-Generation Agents (Oral)	Same as above.	Limited affinity for brain H_1 receptors. Cause minimal sedation, few effects on psychomotor activities or bladder function.	• Teach patient to expect few, if any, side effects. • More expensive than classic antihistamines. • Rapid onset of action, no drug tolerance with prolonged use.
loratadine (Claritin) cetirizine (Zyrtec) fexofenadine (Allegra) desloratadine (Clarinex) levocetirizine (Xyzal)			
Second-Generation Agents (Intranasal)	Same as above.	Headache, bitter taste, somnolence, nasal irritation.	Longer use increases risk of rebound vasodilation, which can increase congestion.
azelastine (Astelin) olopatadine (Patanase)			

Continued

TABLE 27-2 DRUG THERAPY—cont'd

Rhinitis and Sinusitis

Drug	Mechanism of Action	Side Effects	Nursing Actions
Decongestants			
Oral			
pseudoephedrine (Sudafed)	Stimulates adrenergic receptors on blood vessels, promotes vasoconstriction, reduces nasal congestion.	CNS stimulation, causing insomnia, excitation, headache, irritability, increased blood and ocular pressure, dysuria, palpitations, tachycardia.	• Advise patient of adverse reactions. • Advise that some preparations are contraindicated for patients with cardiovascular disease, hypertension, diabetes, glaucoma, benign prostatic hyperplasia, hepatic and renal disease.
Topical (Nasal Spray)			
oxymetazoline (Dristan 12-Hour) phenylephrine (Neo-Synephrine)	Same as above.	Same as above, plus rebound nasal congestion.	• Teach patient that these drugs should not be used for >3 days or >3-4 times/day.
Combination Cold Medications			
Zutripro oral solution (hydrocodone, chlorpheniramine, and pseudoephedrine) Rezira oral solution (hydrocodone and pseudoephedrine)	Hydrocodone suppresses cough. Mechanism of action of chlorpheniramine and pseudoephedrine discussed above.	See individual drugs above.	• Avoid in patients with head injury or increased intracranial pressure. • Use with caution in patients with acute abdominal conditions.

PT, Prothrombin time.

viruses, such as coxsackieviruses and adenoviruses, can cause a more severe illness. Acute viral rhinitis is the most prevalent infectious disease, with the average adult contracting one to three colds per year.

The virus is spread by airborne droplet sprays emitted by the infected person while breathing, talking, sneezing, or coughing. Because the virus can survive on inanimate objects for up to 3 days, transmission can also occur by direct hand contact. Frequency of the infection increases in the winter months when people stay indoors and overcrowding is more common. Other factors that increase susceptibility include fatigue, physical and emotional stress, allergies that affect the nose and throat, and compromised immune status. Exercise can significantly reduce the number of upper respiratory tract infections.[10]

Symptoms of acute viral rhinitis typically begin 2 or 3 days after infection and may include runny nose, watery eyes, nasal congestion, sneezing, cough, sore throat, fever, headache, and fatigue. Cold symptoms may last 2 to 14 days, with typical recovery in 7 to 10 days.

NURSING AND COLLABORATIVE MANAGEMENT
ACUTE VIRAL RHINITIS

Interventions are directed toward relieving symptoms. Rest, fluids, proper diet, antipyretics, and analgesics are recommended. Warm salt water gargles, ice chips, throat lozenges, or throat sprays alleviate a sore throat. Petroleum jelly soothes a raw nose. Saline nasal spray reduces nasal congestion. Antihistamine and decongestant therapy reduces postnasal drip and significantly decreases severity of cough, nasal obstruction, and nasal discharge. Caution patients to use the intranasal decongestant sprays for no more than 3 days to prevent rebound congestion from occurring. Cough suppressants may be used.

COMPLEMENTARY & ALTERNATIVE THERAPIES

Echinacea

Scientific Evidence

- Echinacea may have some benefit in reducing the incidence and duration of the common cold.
- However, there is conflicting evidence on its use in prevention and treatment of upper respiratory tract infections.

Nursing Implications

- Echinacea is considered safe when used in recommended doses.
- Patients with asthma or allergies to plants in the daisy family (including ragweed, mums, marigolds, and daisies) are more likely to have allergic reactions.
- It may interfere with drugs that suppress the immune system and those that are metabolized by the liver.
- Caution is advised in patients with autoimmune disorders.

Complications of acute viral rhinitis include pharyngitis, sinusitis, otitis media, tonsillitis, and lung infections. Unless symptoms of complications are present, antibiotic therapy is not indicated. Antibiotics have no effect on viruses and, if taken injudiciously, may produce antibiotic-resistant bacteria. If symptoms remain for 10 to 14 days with no improvement, acute bacterial sinusitis may be present, and antibiotics will be prescribed.

Teach the patient to recognize the symptoms of secondary bacterial infection, such as a temperature higher than 100.4° F (38° C); tender, swollen glands; severe sinus or ear pain; or significantly worsening symptoms. Green, purulent nasal drainage during the later stages of a cold is not uncommon and is not considered indicative of bacterial infection. In the patient with pulmonary disease, signs of infection include a change in consistency, color, or volume of the sputum. Because infection

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Do Probiotics Prevent Upper Respiratory Tract Infections?

Clinical Question

In healthy patients (P) what is the effect of probiotics (I) versus placebo (C) in preventing acute upper respiratory tract infections (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Ten RCTs (n = 3451) including healthy children and adults up to age 40.
- Intervention was ingestion of any probiotic (single or mixture of strains, any dosage regimen or route of administration) for more than 7 days, compared with placebo or no treatment.
- Most common probiotics were lactic acid bacteria and bifidobacteria, often consumed in fermented foods (e.g., yogurt) or as dietary supplements.
- Probiotics were better than placebo in reducing the occurrence of acute URIs.
- The number of URIs requiring antibiotics was lower in patients using probiotics compared with those using placebo.

Conclusion

- Probiotics are effective in reducing the incidence of URIs.

Implications for Nursing Practice

- Encourage continued probiotic use to prevent acute URIs.
- Yogurt is an excellent food source for probiotics.
- Probiotics are also available as a dietary supplement.
- Advise patients with frequent URIs of potential benefit from probiotic ingestion.
- Probiotics are typically well tolerated, but can cause gastrointestinal (GI) side effects
- Counsel patients of minor probiotic side effects, including flatulence and increased GI irritability.

can progress rapidly, teach the patient with chronic respiratory disease to immediately report sputum changes, increased shortness of breath, and chest tightness. During the cold season, advise patients with a chronic illness or a compromised immune system to avoid crowded situations and other persons who have obvious cold symptoms. Frequent hand washing and avoiding hand-to-face contact help prevent direct spread.

INFLUENZA

Influenza (flu) is a highly contagious respiratory illness that causes significant morbidity and mortality. Millions of Americans (about 5% to 20% of U.S. population) contract influenza each year. The flu season begins in September and continues through April of each year, peaking anywhere from November to March. More than 200,000 people are hospitalized each year for flu-related complications.[11] Death rates vary from season to season. On average, influenza is responsible for 20,000 deaths annually. Vaccination of high-risk groups can prevent many of these deaths.

Etiology and Pathophysiology

Influenza viruses are classified into three serotypes (A, B, and C), but only A and B cause significant illness in humans. Influenza A is subtyped based on the presence of two surface proteins: hemagglutinin (H) and neuraminidase (N). The H antigens enable the virus to enter the cell, and the N antigens facilitate cell-to-cell transmission. Influenza A viruses are thus named according to their H and N type (e.g., H3N2).

Influenza A can infect a variety of animals as well as humans. More than 100 types of influenza A are found in birds (avian flu), pigs (swine flu), horses, seals, and dogs. The virus mutates to allow it to infect different species. When a new viral strain reaches humans, people do not have immunity, and the virus can spread quickly around the globe, causing a *pandemic.* The type A H1N1 influenza (swine flu) emerged in 2009 having never been seen in humans before. A worldwide pandemic resulted. Pandemics can also be triggered by the reemergence of a viral strain that has not circulated for many years. *Epidemics* are more localized outbreaks, usually occurring yearly, caused by variants of already circulating strains. Influenza A is the most common flu virus and also the most virulent.

Influenza B and C viruses are not divided into subtypes and only infect humans. Outbreaks of influenza B can also cause regional epidemics, but the disease it produces is generally milder than that caused by influenza A. Influenza C causes mild illness and does not cause epidemics or pandemics.

Influenza viruses have a remarkable ability to change over time. This accounts for widespread disease and the need for annual vaccination against new strains. Fewer cases of influenza result when a minor change in the virus occurs because most persons have partial immunity.

Influenza is transmitted from animals to humans by direct contact with infected animals or through exposure to water and surfaces contaminated with animal feces. Influenza is communicable between humans through droplet contact and inhalation of aerosolized particles. The virus has an incubation period of 1 to 4 days, with peak transmission risk starting at approximately 1 day before onset of symptoms and continuing for 5 to 7 days.

Clinical Manifestations

The onset of flu is typically abrupt, with systemic symptoms of chills, fever, anorexia, malaise, and generalized myalgia often accompanied by a headache, cough, rhinorrhea, and sore throat. Physical findings are usually minimal, with normal assessment on chest auscultation. Dyspnea and diffuse crackles are signs of pulmonary complications. In uncomplicated cases, symptoms subside within 7 days. Some patients, particularly older adults, experience weakness or lassitude that persists for weeks. Hyperactive airways and a chronic cough often occur during recovery.

The most common complication of influenza is pneumonia, which can be either primary influenza (viral) pneumonia or secondary bacterial pneumonia. The patient who develops secondary bacterial pneumonia usually experiences gradual improvement of influenza symptoms, then worsening cough and purulent sputum. Treatment with antibiotics is usually effective if started early.

Diagnostic Studies

Important diagnostic factors in influenza include the patient's health history, clinical findings, and other cases of influenza in the community. Although a diagnosis of flu is frequently based

on clinical findings, rapid flu tests can help in the diagnosis by detecting the virus in nasal secretions. Depending on the method, the test may be completed in the physician's office in less than 30 minutes or be sent to a laboratory, with results available the same day. The test can help differentiate influenza from other viral and bacterial infections with similar symptoms that may be serious and must be treated differently. Rapid flu tests are best used within the first 48 hours of the onset of symptoms to help diagnose influenza and determine whether antiviral drugs are a treatment option.[12] The main disadvantages of the rapid flu test are that it will miss some cases or occasionally be positive when a person does not actually have the flu.

Viral cultures are considered the "gold standard" for diagnosing influenza, but they can take up to 3 to 10 days for results. A viral culture has the advantage of identifying which virus (A, B, or another respiratory virus) and which strains of virus are present. These data are used in the formulation of the following season's flu vaccine.

NURSING AND COLLABORATIVE MANAGEMENT INFLUENZA

The most effective strategy for managing influenza is prevention. Two types of flu vaccines are available: inactivated and live attenuated (Table 27-3). The influenza vaccine may be changed on a yearly basis, depending on the virus strains identified by the Centers for Disease Control and Prevention as being most likely to cause illness in the upcoming flu season. The best time to receive the vaccine is in September (before flu exposure) because it takes 2 weeks for full protection to occur. Patients can receive it later if needed.

TABLE 27-3 TYPES OF INFLUENZA IMMUNIZATION

Trivalent Inactivated Influenza Vaccine (TIV)	Live Attenuated Influenza Vaccine (LSIV)
Given by injection	Given by nasal spray
Approved for use in people ≥6 mo of age	Approved for healthy people ages 2-49 yr
Can be used in people at increased risk: • People of any age with chronic medical conditions • Residents of nursing homes and long-term care facilities • People who are immunocompromised • Pregnant women	Should NOT be used in: • Children <2 yr or adults >50 yr • Pregnant women • People with known immunodeficiency • Children or adolescents receiving aspirin or other salicylates • People who have medical conditions that place them at increased risk for complications from influenza (chronic cardiovascular, pulmonary, or neurologic diseases; diabetes mellitus; renal or hepatic dysfunction; hemoglobinopathies) • Health care providers of high-risk patients because of risk of viral transmission from vaccine (should not care for high-risk patients for 7 days after vaccination)
Most common side effects are injection site reactions, such as pain, redness, and swelling	Most common side effects are runny nose and nasal congestion in all ages, fever in children ages 2-6 yr, and sore throat in adults

SAFETY ALERT

- Advocate for vaccination of all people older than 6 months of age but especially for those at high risk (e.g., health care workers, residents of long-term care facilities).
- Give high priority to groups, such as health care workers, that can transmit influenza to high-risk persons.

Vaccination of healthy people decreases the incidence and the risk of transmitting influenza to those who have less ability to cope with the effects of this illness. Despite obvious benefits, many persons are reluctant to be vaccinated. Current vaccines are highly purified, and reactions are extremely uncommon. Soreness at the injection site is usually the only side effect. Contraindications are history of Guillain-Barré syndrome within 6 weeks following a previous influenza vaccine and anaphylactic hypersensitivity to eggs.[13]

The primary nursing goals in influenza are relief of symptoms and prevention of secondary infection. Unless the patient with influenza is at high risk or complications develop, only supportive therapy is necessary. Rest, hydration, analgesics, and antipyretics can provide symptom relief. Older adults and those with a chronic illness may require hospitalization.

Two antiviral medications, zanamivir (Relenza) and oseltamivir (Tamiflu), are available to prevent and treat influenza A and B.[14] These drugs are neuraminidase inhibitors that prevent the virus from budding and spreading to other cells. These drugs shorten the duration of influenza symptoms and reduce the risk of complications. Treatment should be initiated as soon as possible in patients who are hospitalized with influenza, have severe or complicated illness, or are at high risk for complications. For maximum benefit in the treatment of influenza, therapy should begin within 2 days of the onset of symptoms, but it can be started later based on clinical judgment. Zanamivir is administered using an inhaler. Oseltamivir is available as an oral capsule.

SINUSITIS

Sinusitis affects one out of every seven adults in the United States. It develops when inflammation or hypertrophy (swelling) of the mucosa blocks the openings (ostia) in the sinuses through which mucus drains into the nose (Fig. 27-2). *Rhinosinusitis* is concurrent inflammation of the nasal mucosa. Obstruction of mucus drainage can also be caused by nasal polyps, foreign bodies, deviated septa, or tumors. The secretions

CULTURAL & ETHNIC HEALTH DISPARITIES

Immunizations in Hispanics

- Older Hispanics have lower influenza and pneumonia vaccination rates than non-Hispanic whites.
- Fifty-five percent of Hispanic older adults report receiving the "flu shot," compared with 67% of non-Hispanic older adults.
- Spanish-preferring Hispanic seniors are less likely to be immunized than English-preferring Hispanic seniors.
- Those living in newer immigration destinations are at greater risk for health disparities because of limited access to health care compared with persons in established Hispanic communities.
- Health care providers and policymakers need to target vulnerable subgroups of Hispanic seniors and identify areas of linguistic isolation to minimize these disparities.

Source: Haviland AM, Elliott MN, Hambarsoomian K, et al: Immunization disparities by Hispanic ethnicity and language preference, *Arch Intern Med* 171:158, 2011.

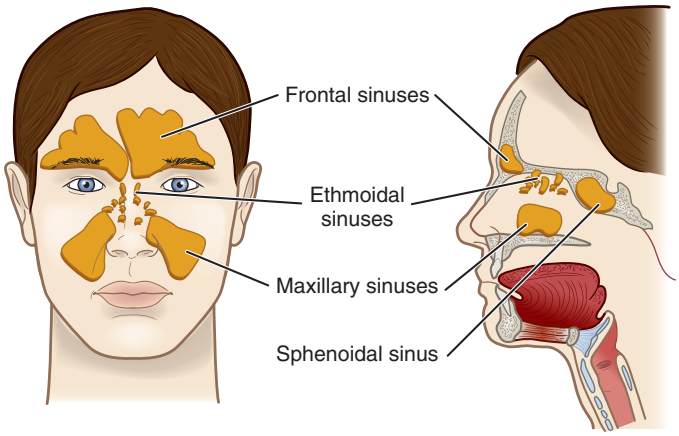

FIG. 27-2 Location of the sinuses.

that accumulate behind the blocked ostia provide a rich medium for growth of bacteria, viruses, and fungi, all of which may cause infection.

Viral sinusitis typically follows an upper respiratory tract infection in which the virus penetrates the mucous membrane and decreases ciliary function. Viral infections usually resolve without treatment in less than 14 days. If symptoms worsen after 3 to 5 days or persist for longer than 10 days, a secondary bacterial infection may be present. Only 5% to 10% of patients with viral sinusitis develop a bacterial infection requiring antibiotic therapy.[15] *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis* are the most common causes of bacterial sinusitis. Fungal sinusitis is uncommon, usually occurring in patients who are debilitated or immunocompromised.

Sinusitis can be classified as acute, subacute, or chronic. *Acute sinusitis* typically begins within 1 week of an upper respiratory tract infection and lasts less than 4 weeks. *Subacute sinusitis* is present when symptoms progress over 4 to 12 weeks. *Chronic sinusitis* (lasting longer than 12 weeks) is a persistent infection usually associated with allergies and nasal polyps. Chronic sinusitis generally results from repeated episodes of acute sinusitis that result in irreversible loss of the normal ciliated epithelium lining the sinus cavity.

COMPLEMENTARY & ALTERNATIVE THERAPIES

Zinc

Scientific Evidence

- When administered within 24 hr of onset of symptoms, zinc reduces the duration and severity of cold symptoms in healthy people.
- When zinc supplementation is taken for at least 5 mo, the incidence of colds is reduced.

Nursing Implications

- Zinc is regarded as relatively safe when taken at recommended doses.
- Zinc lozenges are more apt to cause adverse effects (bad taste, nausea) than syrup or tablets.
- Oral zinc should not be taken with foods that will reduce its absorption, such as caffeine and dairy products.

Source: Singh M, Das RR: Zinc for the common cold, *Cochrane Database Syst Rev* 16(2):CD001364, 2011.

Clinical Manifestations

Acute sinusitis causes significant pain over the affected sinus, purulent nasal drainage, nasal obstruction, congestion, fever, and malaise. The patient looks and feels sick. Assessment involves inspection of the nasal mucosa and palpation of the sinus points for pain. Findings that indicate acute sinusitis include hyperemic and edematous mucosa, discolored purulent nasal drainage, enlarged turbinates, and tenderness over the involved frontal and/or maxillary sinuses. Some patients have recurrent headaches that change in intensity with position changes or when secretions drain.

Chronic sinusitis is difficult to diagnose because symptoms are often nonspecific. The patient is rarely febrile. The patient may have facial or dental pain, nasal congestion, and increased drainage, but severe pain and purulent drainage are often absent. Some symptoms mimic those seen with allergies. X-rays or computed tomography (CT) scan of the sinuses may be done to confirm the diagnosis. CT scans may show the sinuses to be filled with fluid or a thickened mucous membrane. Nasal endoscopy with a flexible scope may be used to examine the sinuses, obtain drainage for culture, and restore normal drainage.

As many as 50% of patients with moderate to severe asthma have chronic sinusitis. The exact link between these diseases is unclear. Postnasal drip associated with sinusitis may trigger asthma by stimulating bronchoconstriction. Gastroesophageal reflux disease (GERD) and smoking may increase the risk of a person with asthma developing sinusitis. Appropriate treatment of sinusitis often causes a reduction in asthma symptoms.

NURSING AND COLLABORATIVE MANAGEMENT SINUSITIS

If allergies are the precipitating cause of sinusitis, instruct the patient about ways to reduce sinus inflammation and infection, including environmental control of allergens and appropriate drug therapy (see section on allergic rhinitis, earlier in this chapter).

Initial treatment for acute sinusitis focuses on symptom relief. Medications include oral or topical decongestants to promote drainage, nasal corticosteroids to decrease inflammation, analgesics to relieve pain, and saline nasal spray to relieve congestion. Instruct patients using topical decongestants to use the medication for no longer than 3 days to prevent rebound congestion caused by vasodilation. Saline irrigation of the nasal cavity can be used to rinse nasal passages, facilitate drainage, and decrease inflammation. Saline nasal spray is available over the counter as sterile physiologic saline solution in spray bottles. Alternatively, a saline solution can be prepared at home with ¼ tsp of salt dissolved in 8 oz of tap water. Patients may also add a pinch of baking soda to soften the effect of salt. Two to four puffs of nasal saline should be administered at least three times a day. The alternative, more aggressive method is lavage with a squeeze bottle, neti pot, or syringe while leaning over the sink with the mouth open.[16] Repeated full-syringe wash is recommended at least once a day to wash out the secretions if they cannot be effectively removed with saline spray alone. Alternatively, patients can use a Waterpik device on the lowest setting.

If symptoms worsen or persist for longer than 10 days, antibiotic therapy may be prescribed. Antibiotic therapy, consisting of amoxicillin as the first-line drug of choice, is continued for 10 to 14 days to prevent the formation of antibiotic-resistant

TABLE 27-4 PATIENT & CAREGIVER TEACHING GUIDE

Acute or Chronic Sinusitis

Include the following instructions when teaching the patient and caregiver about management of sinusitis.

1. Get plenty of rest to help body fight infection and promote recovery.
2. Keep well hydrated by drinking six to eight glasses of water to loosen secretions.
3. Take hot showers twice daily. Use a steam inhaler (15-min vaporization of boiled water), bedside humidifier, or nasal saline spray to promote secretion drainage.
4. Apply warm, damp towels around nose, cheeks, and eyes to ease facial pain.
5. Sleep with head elevated to help sinuses drain and reduce congestion.
6. Report a temperature of 100.4° F (38° C) or higher, which indicates infection.
7. Follow prescribed medication regimen:
   - Take analgesics to relieve pain.
   - Take decongestants/expectorants to relieve swelling.
   - Take antibiotics (as prescribed) for infection. Be sure to take entire prescription and report continued symptoms or a change in symptoms.
   - Administer nasal sprays correctly.
8. Perform large-volume nasal saline washes once or twice a day to wash sinuses.
9. Do not smoke, and avoid exposure to smoke. Smoke is an irritant and will worsen symptoms.
10. If allergies predispose to sinusitis, follow instructions regarding environmental control, drug therapy, and immunotherapy to reduce the inflammation and prevent sinus infection.

organisms. If symptoms do not resolve, the antibiotic should be changed to a broader spectrum cephalosporin antibiotic. With chronic sinusitis, mixed bacterial flora is often present and infections are difficult to eliminate. Broad-spectrum antibiotics may be used for 4 to 6 weeks. Patient and caregiver teaching for acute and chronic sinusitis is presented in Table 27-4.

Medical therapy may not relieve the symptoms of some patients with persistent or recurrent sinus complaints. They may require nasal endoscopic surgery to relieve blockage caused by hypertrophy or septal deviation. This is an outpatient procedure usually performed using local anesthesia. Propel, a self-expanding dissolvable implant, can be placed directly in the sinus during surgery to maintain postoperative patency and provide localized corticosteroid delivery directly to the sinus lining[17] (see Nursing Management: Nasal Surgery on p. 498).

OBSTRUCTION OF NOSE AND SINUSES

Nasal Polps

Nasal polyps are soft, painless, benign growths that form slowly in response to repeated inflammation of the sinus or nasal mucosa. Polyps, which appear as gray-blue, semitransparent projections in the naris, can exceed the size of a grape. The patient may be anxious, fearing they are malignant. Small polyps are typically asymptomatic. Clinical manifestations of larger polyps include nasal obstruction, nasal discharge (usually clear mucus), and speech distortion. Topical and systemic corticosteroids are the primary medical therapy used to shrink nasal polyps. Endoscopic or laser surgery can remove nasal polyps, but recurrence is common.

Foreign Bodies

A variety of foreign bodies may lodge in the upper respiratory tract. Inorganic foreign bodies such as buttons and beads may cause no symptoms and be incidentally discovered on routine examination. Organic foreign bodies such as wood, cotton, beans, peas, and paper produce a local inflammatory reaction and nasal discharge, which may become purulent and foul smelling if the object remains in the nasal cavity for an extended time. Foreign bodies can also cause pain, difficulty breathing, and nasal bleeding.

Foreign bodies should be removed from the nose through the route of entry. Sneezing or blowing the nose with the opposite nostril closed is often effective in removing foreign bodies. Avoid irrigating the nose or pushing the object backward, since either could cause aspiration and airway obstruction. If sneezing or blowing the nose does not remove the object, the patient should see a health care provider.

PROBLEMS OF PHARYNX

ACUTE PHARYNGITIS

Acute pharyngitis is an acute inflammation of the pharyngeal walls. It may include the tonsils, palate, and uvula. It can be caused by a viral, bacterial, or fungal infection. Viral pharyngitis accounts for approximately 90% of cases in adults. Bacterial pharyngitis ("strep throat") usually results from β-hemolytic streptococci and accounts for 10% of cases in adults. Fungal pharyngitis, such as candidiasis, can develop with prolonged use of antibiotics or inhaled corticosteroids. It can also occur in immunosuppressed patients, especially those with human immunodeficiency virus (HIV) infection. Other causes of pharyngitis include dry air, smoking, GERD, allergy and postnasal drip, chemicals, neoplasia, and endotracheal intubation.[18]

Clinical Manifestations

Symptoms of acute pharyngitis range in severity from complaints of a "scratchy throat" to pain so severe that swallowing is difficult. Both viral and strep infections appear as a red and edematous pharynx, with or without patchy exudates. Fever, anterior cervical lymph node enlargement, tonsillar exudates, and the absence of cough are highly suggestive of bacterial pharyngitis. However, appearance is not always diagnostic. When two or three of the above criteria are present, a rapid strep antigen test and/or a culture is done to establish the cause and direct appropriate management. White, irregular patches on the oropharynx suggest fungal infection with *Candida albicans*.

NURSING AND COLLABORATIVE MANAGEMENT ACUTE PHARYNGITIS

The goals of nursing management are infection control, symptom relief, and prevention of secondary complications. Penicillin is the drug of choice for bacterial pharyngitis. This antibiotic needs to be taken several times a day for a full 10 days to prevent rheumatic fever, a sequela to the infection. Other antibiotics (amoxicillin, azithromycin [Zithromax], cephalosporins) may also be used. Most people with strep infections are contagious until they have been on antibiotics for 24 to 48 hours.

Candida infections are treated with nystatin (Mycostatin), an antifungal antibiotic. Tell patients to swish the preparation in

their mouth as long as possible before swallowing it. Treatment should continue until symptoms are gone. Patients taking inhaled corticosteroids are at risk for infection with *Candida* organisms. Thoroughly rinsing the mouth out with water after using corticosteroids can prevent this infection.

Instruct patients to use ibuprofen or acetaminophen for pain relief. Encourage the patient with pharyngitis to increase fluid intake. To relieve the symptoms, instruct the patient to gargle with warm salt water (½ tsp of salt in 8 oz of water); drink warm or cold liquids; and suck on popsicles, hard candies, or throat lozenges. Cool, bland liquids and gelatin will not irritate the pharynx; citrus juices are often irritating. Encourage the patient to use a cool-mist vaporizer or humidifier.

PERITONSILLAR ABSCESS

Peritonsillar abscess is a complication of acute pharyngitis and is most often caused by β-hemolytic streptococci. The abscess causes pain, swelling, and (when severe) blockage of the throat, threatening airway patency. The patient also experiences a high fever, chills, leukocytosis, difficulty swallowing, and a muffled voice. IV antibiotic therapy is given along with needle aspiration or incision and drainage of the abscess. In some cases an emergency tonsillectomy is performed, or an elective tonsillectomy is scheduled after the infection has subsided.

PROBLEMS OF TRACHEA AND LARYNX

AIRWAY OBSTRUCTION

Acute airway obstruction is a medical emergency. Airway obstruction can be caused by aspiration of food or a foreign body, allergic reactions, edema and inflammation caused by infections or burns, peritonsillar or retropharyngeal abscesses, malignancy, laryngeal or tracheal stenosis, and trauma. Symptoms include choking, stridor, use of accessory muscles, suprasternal and intercostal retractions, flaring nostrils, wheezing, restlessness, tachycardia, cyanosis, and change in level of consciousness. Airway obstruction may be partial or complete. Prompt assessment and treatment are essential because partial obstruction may quickly progress to complete obstruction. Complete airway obstruction can result in permanent brain damage or death if not corrected within 3 to 5 minutes.

Interventions to reestablish a patent airway include the obstructed airway (Heimlich) maneuver (see Appendix A), cricothyroidotomy, endotracheal intubation, and tracheostomy. Unexplained or recurrent symptoms indicate the need for additional tests, such as a chest x-ray, laryngoscopy, and bronchoscopy.

TRACHEOSTOMY

A **tracheostomy** is a surgically created stoma (opening) in the trachea to establish an airway. It is used to (1) bypass an upper airway obstruction, (2) facilitate removal of secretions, or (3) permit long-term mechanical ventilation. Most patients who require mechanical ventilation are initially managed with an endotracheal tube, which can be quickly inserted in an emergency. (Care of the patient with an endotracheal tube is discussed in Chapter 66.)

Most *surgical tracheostomies* are performed in the operating room using general anesthesia. These are typically done elective on patients already intubated who require prolonged mechanical ventilation. When swelling, trauma, or upper airway obstruction prevents endotracheal intubation, an emergent surgical tracheostomy may be performed at the bedside.

A minimally invasive *percutaneous tracheostomy* can also be performed at the bedside using local anesthesia and sedation. A needle is placed into the trachea, followed by a guide wire. The opening is progressively dilated until it is large enough for insertion of a tracheostomy tube.

A tracheostomy provides a more secure airway, is less likely to be displaced, and allows more freedom of movement than an endotracheal tube. There is less risk of long-term damage to the vocal cords. Airway resistance and work of breathing are decreased, facilitating independent breathing.[19] Patient comfort may be increased because no tube is present in the mouth. The patient can eat with a tracheostomy because the tube enters lower in the airway (Fig. 27-3). Speaking is also permitted once the tracheostomy cuff can be deflated.

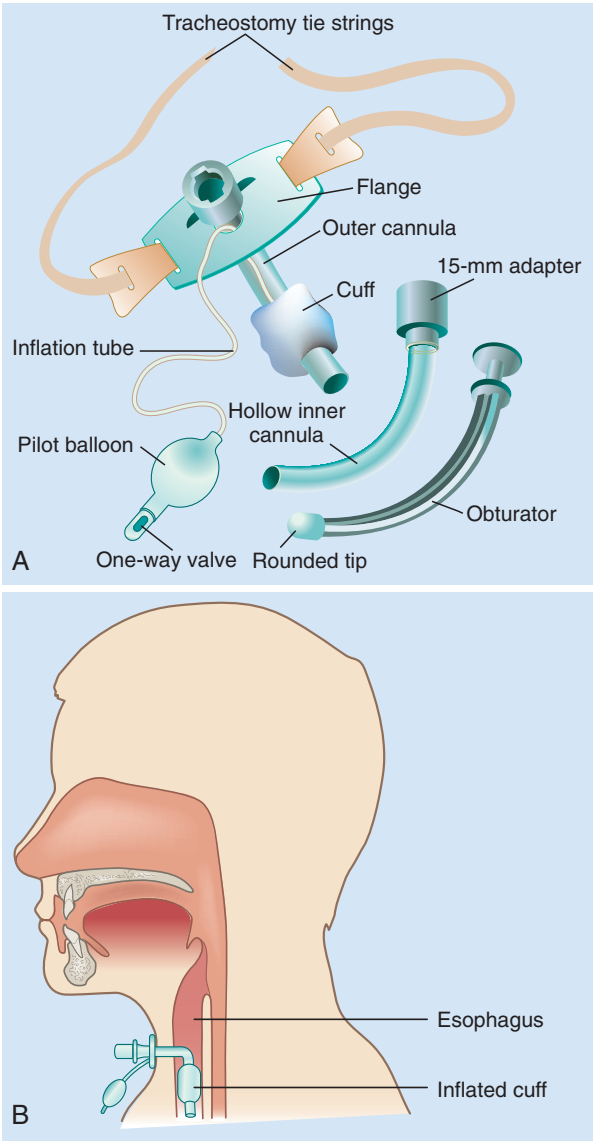

FIG. 27-3 Tracheostomy tube. **A,** Parts of a tracheostomy tube. **B,** Tracheostomy tube inserted in airway with inflated cuff. (See Table 27-5 and eNursing Care Plan 27-1 [on the website for this chapter] for related nursing management.)

NURSING MANAGEMENT TRACHEOSTOMY

PROVIDING TRACHEOSTOMY CARE

Before the tracheostomy procedure, explain to the patient and the caregiver the purpose of the procedure. Also inform them that the patient will not be able to speak while an inflated cuff is used.

A variety of tubes are available to meet individual patient needs (Table 27-5; see Fig. 27-3). All tracheostomy tubes contain a faceplate, or *flange,* which rests on the neck between the clavicles and outer cannula. In addition, all tubes have an *obturator,* which is used when inserting the tube (see Fig. 27-3, *A*). During insertion of the tube, place the obturator inside the outer cannula with its rounded tip protruding from the end of the tube to ease insertion. After insertion, immediately remove the obturator so air can flow through the tube. Keep the obturator in an easily accessible place at the bedside (e.g., taped to the wall) so that it can be used quickly in case of accidental decannulation.

TABLE 27-5 NURSING MANAGEMENT OF TRACHEOSTOMIES

Tube and Characteristics	Nursing Management
Tracheostomy tube with cuff and pilot balloon (see Fig. 27-3, *A* and *B*) When properly inflated, low-pressure, high-volume cuff distributes cuff pressure over large area, minimizing pressure on tracheal wall.	**Procedure for cuff inflation** • *Mechanically ventilated patient:* Inflate the cuff using *minimal occlusion volume (MOV) technique* by slowly injecting air into the cuff until no leak (sound) is heard at peak inspiratory pressure (end of ventilator inspiration) when a stethoscope is placed over the trachea. An alternative approach, termed *minimal leak technique* (MLT), involves inflating the cuff to minimal occlusion pressure and then withdrawing 0.1 mL of air. • *Spontaneously breathing patient:* Inflate cuff using MOV by slowly injecting air into the cuff until no sound is heard after deep breath or during inhalation with manual resuscitation bag. If using MLT, remove 0.1 mL of air while maintaining seal. MLT should not be used if there is risk of aspiration. • *Immediately after cuff inflation (both groups):* Verify pressure is within accepted range (≤20 mm Hg or ≤25 cm H_2O) with a manometer. Record cuff pressure and volume of air used for cuff inflation in chart. **Care of patients with an inflated cuff** • Monitor and record cuff pressure q8hr. Cuff pressure should be ≤20 mm Hg or ≤25 cm H_2O to allow adequate tracheal capillary perfusion. If needed, remove or add air to the pilot tubing using a syringe and stopcock. Afterward, verify cuff pressure is within accepted range with manometer. • Report inability to keep the cuff inflated or need to use progressively larger volumes of air to keep cuff inflated. Potential causes include tracheal dilation at the cuff site or a crack or slow leak in the housing of the one-way inflation valve. If the leak is due to tracheal dilation, the physician may intubate the patient with a larger tube. Cracks in the inflation valve may be temporarily managed by clamping the small-bore tubing with a hemostat. The tube should be changed within 24 hr.
Fenestrated tracheostomy tube (Shiley, Portex) with cuff, inner cannula, and decannulation plug (see Fig. 27-7, *A*) When nonfenestrated inner cannula is removed, cuff deflated, and decannulation plug inserted, air flows around tube, through fenestration in outer cannula, and up over vocal cords. Patient can then speak. A fenestrated inner cannula can be used to facilitate cleaning.	• Assess risk of aspiration before removing inner cannula. This is best accomplished by consulting with a speech therapist. An alternative but less reliable method is the use of colored liquid (e.g., Kool-Aid). Deflate cuff. Note coughing. Have patient swallow a small amount of colored liquid. Observe secretions for color after patient coughs or is suctioned. Severe coughing or cyanosis after drinking is also indicative of aspiration. If no aspiration is noted, a fenestrated tube may be used. • ***Never*** insert decannulation plug in tracheostomy tube until cuff is deflated and nonfenestrated inner cannula removed. Prior insertion will prevent patient from breathing (no air inflow). This may precipitate a respiratory arrest. • Assess for signs of respiratory distress when a fenestrated cannula is first used. If this occurs, remove the cap, insert a nonfenestrated inner cannula, and reinflate the cuff. • A nonfenestrated inner cannula must be used to suction patient to prevent tracheal damage from suction catheter passing through fenestrated openings. • Cuff management as described above.
Speaking tracheostomy tube (Portex, National) with cuff, two external tubings (see Fig. 27-7, *B*) Has two tubings, one leading to cuff and second to opening above the cuff. When port is connected to air source, air flows out of opening and up over the vocal cords, allowing speech with cuff inflated.	• Once tube is inserted, wait 2 days before use so that the stoma can close around the tube and prevent leaks. • When patient desires to speak, connect port to compressed air (or O_2). Be certain to identify correct tubing. If gas enters the cuff, it will overinflate and rupture, requiring an emergency tube change. Use lowest flow (typically 4-6 L/min) that results in speech. High flows dehydrate mucosa. • Cover port adapter. This will cause the air to flow upward. Instruct patient to speak in short sentences because voice becomes a whisper with long sentences. • Disconnect flow when patient does not want to speak to prevent mucosal dehydration. • Cuff management as described above.
Tracheostomy tube (Bivona Fome-Cuf) with foam-filled cuff Cuff is filled with plastic foam. Before insertion, cuff is deflated. After insertion, cuff is allowed to fill passively with air. Pilot tubing is not capped, and no cuff pressure monitoring is required.	• Before insertion, withdraw all air from the cuff using a 20-mL syringe. Cap pilot balloon tubing to prevent reentry of air. After tracheostomy is inserted, remove cap from pilot tubing, allowing cuff to passively reinflate. • Do not inject air into tubing or cap pilot balloon tubing while it is in patient. Air will flow in and out in response to pressure changes (head turning). Place tag on tubing to alert staff not to cap or inflate cuff. • Deflate cuff daily via pilot balloon to evaluate integrity of cuff. Also assess ability to easily deflate cuff. Difficulty deflating cuff indicates a need for tube change. If aspirate returns with air, cuff is no longer intact. • Tube can be used for up to 1 mo in patients on home mechanical ventilation. • Good choice for patients who require inflated cuff at home, since teaching about cuff pressure is simplified.

Some tracheostomy tubes also have an inner cannula, which can be removed for cleaning (see Fig. 27-3, *A*). The inner cannula can be disposable or nondisposable. If it is disposable, replace per manufacturer and institutional guidelines. If nondisposable, clean the inner cannula at least every 8 hours (Table 27-6). Cleaning removes mucus from the inside of the tube to prevent airway obstruction. If humidification is adequate, mucus may not accumulate and a tube without an inner cannula can be used. Suction the airway via the tracheostomy tube as needed (Fig. 27-4 and Table 27-6). Also, clean around the stoma at least every 8 hours and change the tracheostomy ties as needed (Fig. 27-5 and Table 27-7). A two-person technique, one to stabilize the tracheostomy and one to change the ties, is best to ensure that the tracheostomy does not become accidentally dislodged during the procedure. Place two fingers underneath the ties to ensure they are not too tight around the neck.[20]

Both cuffed and uncuffed tracheostomy tubes are available. A tracheostomy tube with an inflated cuff is used if the patient is at risk of aspiration or needs mechanical ventilation. Because an inflated cuff exerts pressure on the tracheal mucosa, it is important to inflate the cuff with the minimum volume of air required to obtain an airway seal. Cuff inflation pressure should not exceed 20 mm Hg or 25 cm H_2O because higher pressures may compress tracheal capillaries, limit blood flow, and predispose the patient to tracheal necrosis. The minimal leak technique (MLT) and the minimal occlusion volume (MOV) are two commonly used methods to inflate the tracheostomy cuff (see Table 27-5).

Routine cuff deflation is no longer recommended.[21] When the patient is not at risk for aspiration, the cuff may be deflated to allow the patient to talk and swallow more easily. Before deflation, have the patient cough up secretions, if possible, and suction the tracheostomy tube and then the mouth (see Table 27-6). This step is important to prevent secretions from being aspirated during deflation. The cuff is deflated during exhalation because the exhaled gas helps propel secretions into the mouth. Have the patient cough, and then suction the tube after cuff deflation. Assess the patient's ability to protect the airway from aspiration. Remain with the patient when the cuff is initially deflated. If needed, reinflate the cuff during inspiration.

Retention sutures may be placed in the tracheal cartilage when the tracheostomy is performed. Tape the free ends of the sutures to the skin in a place and manner that leaves them accessible in case the tube is dislodged. Take care not to dislodge the tracheostomy tube during the first 5 to 7 days when the stoma is not mature (healed). Because tube replacement is difficult, several precautions are required: (1) keep a replacement tube of equal or smaller size at the bedside, readily available for emergency reinsertion; (2) do not change tracheostomy tapes for at least 24 hours after the insertion procedure; and (3) a physician

TABLE 27-6 SUCTIONING A TRACHEOSTOMY TUBE

1. Assess the need for suctioning q2hr. Indications include coarse crackles or rhonchi over large airways, moist cough, increase in peak inspiratory pressure on mechanical ventilator, and restlessness or agitation if accompanied by decrease in SpO_2 or PaO_2. Do not suction routinely or if patient is able to clear secretions with cough.
2. If suctioning is indicated, explain procedure to patient.
3. Collect necessary sterile equipment: suction catheter (no larger than half the lumen of the tracheostomy tube), gloves, sterile water, cup, and drape. If a closed tracheal suction system is used, the catheter is enclosed in a plastic sleeve and reused (see Fig. 27-4). No additional equipment is needed.
4. Check suction source and regulator. Adjust suction pressure until the dial reads –120 to –150 mm Hg pressure with tubing occluded.
5. Assess SpO_2 and heart rate and rhythm to provide baseline for detecting change during suctioning.
6. Wash hands and put on goggles.
7. Use sterile technique to open package, fill cup with sterile water, put on sterile gloves, and connect catheter to suction tubing. Designate one hand as contaminated for (1) connecting and disconnecting the tubing at the suction catheter, (2) using the resuscitation bag, and (3) operating the suction control. Suction sterile water through the catheter to test the system.
8. Provide preoxygenation for a minimum of 30 seconds by (1) adjusting ventilator to deliver 100% O_2; (2) using a reservoir-equipped manual resuscitation bag (MRB) connected to 100% O_2; or (3) asking the patient to take 5-6 deep breaths while administering O_2. The method chosen depends on the patient's underlying disease and acuity of illness. The patient who has had a tracheostomy for an extended period and is not acutely ill may be able to tolerate suctioning without use of an MRB or the ventilator.
9. Gently insert catheter *without suction* to minimize the amount of O_2 removed from the lungs. Insert the catheter to the point where the patient coughs or resistance is met, or 0.5-1.0 cm beyond the length of the artificial airway. Withdraw the catheter 0.5-1.0 cm before applying suction to prevent trauma to the carina.
10. Apply suction intermittently, while withdrawing catheter in a rotating manner. If secretion volume is large, apply suction continuously. Suction should be applied for as short a time as possible to minimize decreases in arterial oxygenation levels.
11. *Limit suction time to 10 seconds.* Discontinue suctioning if heart rate decreases from baseline by 20 beats/min, increases from baseline by 40 beats/min, a dysrhythmia occurs, or SpO_2 decreases to less than 90%.
12. After each suction pass, oxygenate for at least 30 sec with 5-6 breaths by ventilator or MRB or deep breaths with O_2.
13. Rinse catheter with sterile water between suction passes.
14. Repeat procedure until airway is clear. Limit insertions of suction catheter to as few as needed. If airway is not clear after three suction passes, allow the patient to rest before additional suctioning.
15. Return O_2 concentration to prior setting.
16. Rinse catheter, and suction the oropharynx or use mouth suction.
17. Dispose of catheter by wrapping it around fingers of gloved hand and pulling glove over catheter. Discard equipment in proper waste container.
18. Auscultate to assess changes in lung sounds. Record time, amount, and character of secretions and response to suctioning.

FIG. 27-4 Suctioning tracheostomy with closed system suction catheter.

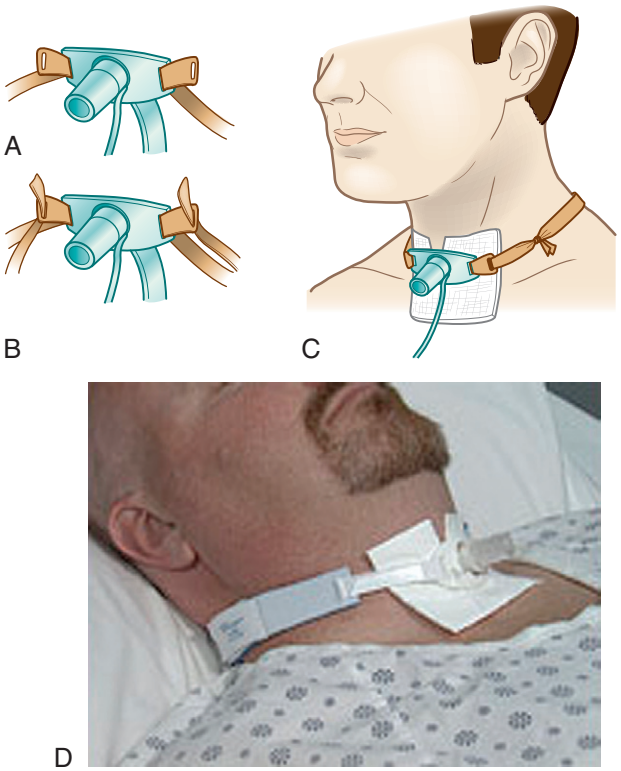

FIG. 27-5 Changing tracheostomy ties. **A,** A slit is cut about 1 in (2.5 cm) from the end. The slit end is put into the opening of the cannula. **B,** A loop is made with the other end of the tape. **C,** The tapes are tied together with a double knot on the side of the neck. **D,** A Velcro tracheostomy tube holder can be used instead of twill ties to make tracheostomy tube stabilization more secure.

performs the first tube change usually no sooner than 7 days after the tracheostomy.

If the tube is accidentally dislodged, immediately attempt to replace it. Grasp the retention sutures (if present) or use a hemostat to spread the opening to facilitate replacing the tube. Insert the obturator in the replacement tube, lubricated with saline poured over the tip, and insert the tube into the stoma at a 45-degree angle to the neck. Once the tube is inserted, remove the obturator immediately so that air can flow through the tube. Another method is to insert a suction catheter to allow passage of air and to serve as a guide for insertion. Thread the tracheostomy tube over the catheter and remove the suction catheter. If the tube cannot be replaced, assess the level of respiratory distress. Position the patient in the semi-Fowler's position to alleviate minor dyspnea until assistance arrives. Severe dyspnea may progress to respiratory arrest. If this situation occurs, cover the stoma with a sterile dressing, and ventilate the patient with bag-mask ventilation over the nose and mouth until help arrives. If a patient has had a total laryngectomy, there will be complete separation between the upper airway and the trachea. Ventilate this patient through the tracheostomy stoma.

Initially, tracheostomy patients should receive humidified air to compensate for the loss of the upper airway to warm and moisturize secretions. Humidification is essential to prevent retention of tenacious secretions and formation of mucous plugs. Change the tube approximately once a month after the first tube change. When a tracheostomy has been in place for several months, the healed tract will be well formed. Teach the patient to change the tube using a clean technique at home (Fig. 27-6). Monitor the patient for potential complications[22] (Table 27-8).

TABLE 27-7 TRACHEOSTOMY CARE

1. Explain procedure to patient.
2. Use tracheostomy care kit or collect necessary sterile equipment (e.g., suction catheter, gloves, water basin, drape, tracheostomy ties, tube brush or pipe cleaners, 4 × 4 gauze pads, sterile water or normal saline, and tracheostomy dressing [optional]). NOTE: Clean rather than sterile technique is used at home.
3. Position patient in semi-Fowler's position.
4. Assemble needed materials on bedside table next to patient.
5. Wash hands. Put on goggles and clean gloves.
6. Auscultate chest sounds. If rhonchi or coarse crackles are present, suction the patient if unable to cough up secretions (see Table 27-6). Remove soiled dressing and clean gloves.
7. Open sterile equipment, pour sterile H_2O or normal saline into two compartments of sterile container or two basins, and put on sterile gloves. NOTE: Hydrogen peroxide (3%) is no longer recommended unless an infection is present. If it is used, rinse the inner cannula and skin with sterile H_2O or normal saline afterward to prevent trauma to tissue.
8. Unlock and remove inner cannula, if present. Many tracheostomy tubes do not have inner cannulas. Care for these tubes includes all steps except for inner cannula care.
9. If disposable inner cannula is used, replace with new cannula. If a nondisposable cannula is used:
   - Immerse inner cannula in sterile solution and clean inside and outside of cannula using tube brush or pipe cleaners.
   - Rinse cannula in sterile solution. Remove from solution and shake to dry.
   - Insert inner cannula into outer cannula with the curved part downward, and lock in place.
10. Remove dried secretions from stoma using 4 × 4 gauze pad soaked in sterile water or saline. Gently pat area around the stoma dry. Be sure to clean under the tracheostomy faceplate, using cotton swabs to reach this area.
11. Maintain position of tracheal retention sutures (if present) by taping above and below the stoma.
12. Change tracheostomy ties. Use two-person change technique or secure new ties to flanges before removing the old ones. Tie tracheostomy ties securely with room for two fingers between ties and skin (see Fig. 27-5). To prevent accidental tube removal, secure the tracheostomy tube by gently applying pressure to the flange of the tube during the tie changes. *Do not change tracheostomy ties for 24 hr after the tracheostomy procedure.*
13. As an alternative, some patients prefer tracheostomy ties made of Velcro, which are easier to adjust.
14. If drainage is excessive, place dressing around tube (see Fig. 27-5). A tracheostomy dressing or unlined gauze should be used. Do not cut the gauze because threads may be inhaled or wrap around the tracheostomy tube. Change the dressing frequently. Wet dressings promote infection and stoma irritation.
15. Repeat care three times/day and as needed.

SWALLOWING DYSFUNCTION

The patient with a tracheostomy who cannot protect the airway from aspiration requires an inflated cuff. However, an inflated cuff may result in swallowing dysfunction by interfering with the normal function of muscles used to swallow. It is important to evaluate the patient's swallowing ability and risk for aspiration with the cuff deflated. If the patient is able to swallow without aspiration when the cuff is deflated, the cuff may be left deflated or a cuffless tube substituted. Clinical assessment of the patient's ability to swallow is done by a speech therapist, videofluoroscopy, or fiberoptic endoscopic evaluations.[23]

FIG. 27-6 Changing the tracheostomy tube at home. When a tracheostomy has been in place for several months, the tract will be well formed. The patient can be taught to change the tube using a clean technique at home.

TABLE 27-8 COMPLICATIONS OF TRACHEOSTOMY

Closely monitor patients with a tracheostomy for the following potential complications:

- Airway obstruction
- Air leak
- Altered body image
- Aspiration
- Bleeding
- Fistula formation
- Impaired cough
- Infection—wound or respiratory tract
- Subcutaneous emphysema
- Tracheal stenosis
- Tracheal necrosis
- Tube displacement

SPEECH WITH A TRACHEOSTOMY TUBE

A number of techniques promote speech in the patient with a tracheostomy. The spontaneously breathing patient may be able to talk by deflating the cuff, which allows exhaled air to flow upward over the vocal cords. This can be enhanced by the patient occluding the tube. However, this method is discouraged because bacteria from the fingers can lead to infection. Specialized tracheostomy tubes and speaking valves are available to facilitate speech. Advocating for the use of these devices will provide psychologic benefits and facilitate self-care for the patient with a tracheostomy.

A *fenestrated tube* has openings on the surface of the outer cannula that permit air from the lungs to flow over the vocal cords (see Fig. 27-7, *A*). A fenestrated tube allows the patient to breathe spontaneously through the larynx, speak, and cough up secretions while the tracheostomy tube remains in place. Air passes from the lungs through the openings in the tracheostomy into the upper airway and out the mouth and nose. Only patients who can swallow without risk of aspiration can use this tube. The inner cannula can be fenestrated or nonfenestrated. Use a nonfenestrated inner cannula when suctioning to decrease the risk of tracheal damage caused by the suction catheter going through the openings. The nonfenestrated inner cannula is also used whenever the patient needs to be mechanically ventilated.

Before using the fenestrated tube, determine the patient's ability to swallow without aspiration (see Table 27-5 and eNursing Care Plan 27-1, available on the website for this chapter). If there is no aspiration, (1) remove the inner cannula (if nonfenestrated), (2) deflate the cuff, and (3) place the decannulation cap in the tube (see Fig. 27-7, *A*). It is important to perform the steps in order because severe respiratory distress may result if the tube is capped before removing the inner cannula and deflating the cuff. When a fenestrated cannula is first used, frequently assess the patient for signs of respiratory distress. If the patient is not able to tolerate the procedure, remove the cap, insert a nonfenestrated inner cannula, and reinflate the cuff. A disadvantage of fenestrated tubes is the potential for development of tracheal polyps from tracheal tissue granulating into the fenestrated openings.

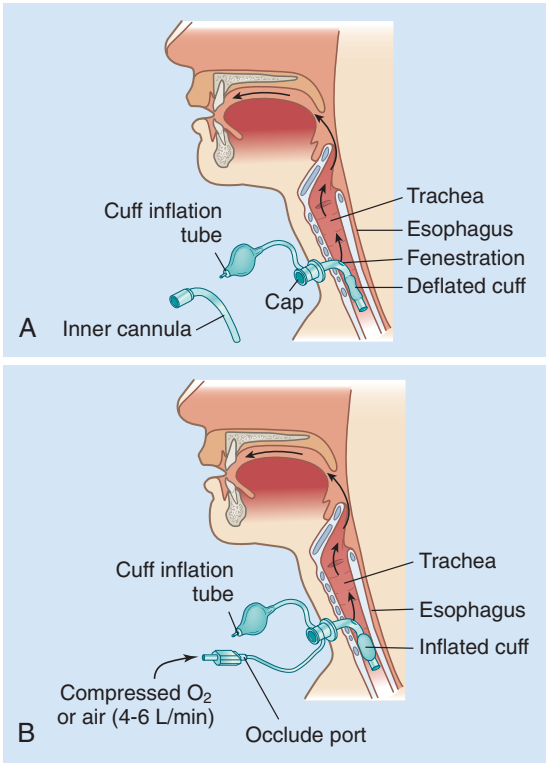

FIG. 27-7 Speaking tracheostomy tubes. **A,** Fenestrated tracheostomy tube with cuff deflated, inner cannula removed, and tracheostomy tube capped to allow air to pass over the vocal cords. **B,** Speaking tracheostomy tube. One tube is used for cuff inflation. The second tube is connected to a source of compressed air or O_2. When the port on the second tube is occluded, air flows up over the vocal cords, allowing speech with an inflated cuff. (See Table 27-5 and eNursing Care Plan 27-1 for related nursing management.)

A speaking tracheostomy tube has two pigtail tubings. One tubing connects to the cuff and is for cuff inflation, and the second connects to an opening just above the cuff (see Fig. 27-7, *B*). When the second tubing is connected to a low-flow (4 to 6 L/minute) air source, sufficient air moves up over the vocal cords to permit speech. This device allows a patient at risk for aspiration to speak with the tracheostomy cuff inflated. However, speech quality is typically poor, with the patient barely speaking above a whisper.

A variety of speaking valves are available that can be attached to the tracheostomy tube (Fig. 27-8). These valves contain a thin plastic diaphragm that opens on inspiration and closes on expiration. During inspiration, air flows in through the valve. During expiration, the valve prevents exhalation and air flows upward over the vocal cords and into the mouth, allowing normal speech patterns. When a speaking tracheostomy valve is used, a cuffless tube must be in place or the cuff needs to be deflated to allow exhalation. Before attaching a speaking valve, evaluate the patient's ability to tolerate cuff deflation without

FIG. 27-8 Passy-Muir speaking tracheostomy valve. The valve is placed over the hub of the tracheostomy tube after the cuff is deflated. Multiple options are available and can be used for ventilated and nonventilated patients. The one-way valve allows air to enter the lungs during inspiration and redirects air upward over the vocal cords into the mouth during expiration.

INFORMATICS IN PRACTICE

Communication Devices for Patient With Laryngectomy

- Assisting with communication will improve a patient's quality of life after a laryngectomy.
- Use an iPad or iPhone and download a text-to-speech application. These applications allow the patient to type in text, and then a computer voice says the text aloud.
- You can also teach the patient how to use a keyboard-based communication program. The patient types on a traditional keyboard and generates speech that is transmitted through hand-held speakers.

aspiration or respiratory distress. Once the speaking valve is in place, carefully assess the patient's ability to breathe. The patient may initially be able to tolerate only short periods of use until he or she becomes acclimated to exhaling through the mouth. Remove the valve immediately if the patient demonstrates any signs of respiratory distress.

If speaking devices are not used, provide the patient with a paper and pencil or Magic Slate. A communication board with pictures of common needs and an alphabet for spelling words is useful for patients who are weak or have difficulty writing.

DECANNULATION

When the patient can adequately exchange air and expectorate secretions, the tracheostomy tube can be removed. Close the stoma with tape strips and cover it with an occlusive dressing. The dressing must be changed if it gets soiled or wet. Instruct the patient to splint the stoma with the fingers when coughing, swallowing, or speaking. Epithelial tissue begins to form in 24 to 48 hours, and the opening closes within 4 or 5 days. Surgical intervention to close the tracheostomy is not required.

LARYNGEAL POLYPS

Laryngeal polyps develop on the vocal cords from vocal abuse (e.g., excessive talking, singing) or irritation (e.g., intubation, cigarette smoking). The most common symptom is hoarseness. Polyps are treated conservatively with voice rest and adequate hydration. Surgical removal may be indicated for large polyps, which may cause dysphagia, dyspnea, and stridor. Polyps are usually benign but may be removed because they can become malignant.

HEAD AND NECK CANCER

Most head and neck cancers arise from squamous cells that line the mucosal surfaces of the head and neck region. The cancer is identified according to the area of origin (e.g., paranasal sinuses, oral cavity, nasopharynx, oropharynx, larynx). (Cancer of the oral cavity is discussed in Chapter 42.)

An estimated 52,600 new cases of head and neck cancer are diagnosed each year in the United States. Eighty-five percent are caused by tobacco use. Excessive alcohol consumption is also a major risk factor. Head and neck cancer occurs most frequently in patients 50 to 60 years of age. Cancers in patients younger than 50 have been associated with human papillomavirus (HPV) infection. Other risk factors include sun exposure (oral cavity), radiation therapy to the head and neck, exposure to asbestos and other industrial carcinogens, and poor oral hygiene.[24] Men are affected twice as often as women.[25]

Most people have locally advanced disease at the time of diagnosis. Disability from the disease and the treatment is great because of the potential loss of voice, disfigurement, and social consequences.

Clinical Manifestations

Early signs and symptoms of head and neck cancer vary with the tumor location. Cancer of the oral cavity may initially be seen as a white or red patch in the mouth, an ulcer that does not heal, or a change in the fit of dentures. Hoarseness that lasts more than 2 weeks may be a symptom of early laryngeal cancer. Some patients experience what feels like a lump in the throat or a change in voice quality. Other clinical manifestations include a sore throat that does not get better with treatment, unilateral sore throat or otalgia (ear pain), swelling or lumps in the neck, and coughing up blood. Difficulties chewing, swallowing, moving the tongue or jaw, and breathing are typically late symp-

toms. Unintentional weight loss and pain are also late symptoms of head and neck cancer.

Diagnostic Studies

Early detection is key to patient survival. Thoroughly examine the oral cavity, including the area under the tongue and dentures, with a flashlight. Bimanually palpate the floor of the mouth, tongue, and lymph nodes in the neck. There may be thickening of the normally soft and pliable oral mucosa. *Leukoplakia* (white patch) or *erythroplakia* (red patch) may be seen and should be noted for later biopsy. Both leukoplakia and carcinoma in situ (localized to a defined area) may precede invasive carcinoma by many years.

If lesions are suspected, the upper airways may be examined using indirect laryngoscopy, which involves using a laryngeal mirror or a flexible nasopharyngoscope to visualize the larynx. The larynx and vocal cords are visually inspected for lesions and tissue mobility. A CT scan or magnetic resonance imaging (MRI) may be performed to detect local and regional spread. Neoplastic tissue is identifiable because it has a greater density or because it distorts, displaces, or destroys normal anatomic structures. The use of positron emission tomography (PET) scanning along with CT has been successful in diagnosing recurrent cases of head and neck cancer. Typically, multiple biopsy specimens are obtained to determine the extent of the disease.

Collaborative Care

Head and neck cancer is staged based on tumor size (T), number and location of involved nodes (N), and extent of metastasis (M). TNM staging classifies disease as stage I to stage IV. Choice of treatment is based on exact location of tumor, disease stage, patient age and general health, cosmetic and functional considerations (e.g., ability to talk, swallow, and chew), urgency of treatment, and patient choice. Treatment modalities include surgery, radiation therapy, chemotherapy, and targeted therapy. Stage I and II cancers are potentially curable with single-modality radiation therapy or larynx-sparing surgery. Radiation therapy is often preferred for patients with early laryngeal cancer because it offers the patient good results with voice preservation. Surgery can then be reserved for recurrence or poor response to radiation. Patients with advanced disease (stages III and IV) are treated with various combinations of surgery, radiation, chemotherapy, and targeted therapy. Radiation therapy can be delivered by either external-beam therapy or internal implants (brachytherapy). Brachytherapy is a concentrated and localized method of delivering radiation that involves placing a radioactive source into or near the tumor. The goal is to deliver high doses of radiation to the target area while limiting exposure of surrounding tissues. Thin, hollow, plastic needles are inserted into the tumor area, and radioactive iridium seeds are placed in the needles. The seeds emit continuous radiation. (Radiation therapy and brachytherapy are discussed in Chapter 16.)

Surgical treatment varies depending on tumor location and stage. A *cordectomy* (partial removal of one vocal cord) is used for a superficial tumor involving one cord (Fig. 27-9). If the tumor is deeper but does not involve the entire larynx, one of several partial laryngectomy procedures are available that preserve speech and swallowing functions. A *hemilaryngectomy* involves removal of one side of the larynx. A *supraglottic laryngectomy* involves removing structures above the true cords—the false vocal cords and epiglottis. A *supracricoid laryngectomy* involves removal of the entire supraglottis; the false and true vocal cords; and the thyroid cartilage, including the paraglottic and preepiglottic spaces. The patient is at high risk of aspiration after these procedures and requires a temporary tracheostomy. Although speech is preserved, the quality and ease of speech vary. Voice quality is breathy, hoarse, and rough.

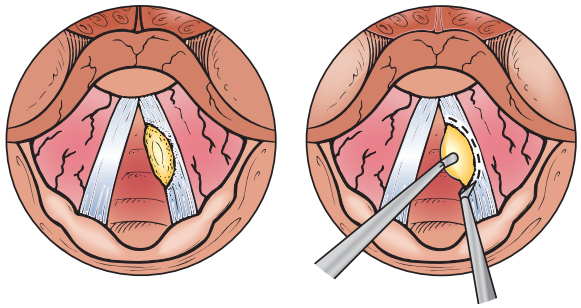

FIG. 27-9 Excision of laryngeal cancer. This cancer of the right vocal cord meets criteria for resection by transoral cordectomy. The cord is fully mobile, and the lesion can be fully exposed. It does not approach or cross the anterior commissure.

Advanced lesions are treated by a total laryngectomy, in which the entire larynx and preepiglottic region are removed and a permanent tracheostomy is performed. Airflow patterns before and after total laryngectomy are shown in Fig. 27-10. *Radical neck dissection* frequently accompanies total laryngectomy to decrease the risk of lymphatic spread. Depending on the extent of involvement, extensive dissection and reconstruction may be performed (Fig. 27-11). This procedure involves wide excision of the lymph nodes and their lymphatic channels. The following structures may also be removed or transected: sternocleidomastoid muscle and other closely associated muscles, internal jugular vein, mandible, submaxillary gland, part of the thyroid and parathyroid glands, and spinal accessory nerve.

A *modified neck dissection* is performed whenever possible as an alternative to a radical neck dissection. The dissection is modified by sparing as many structures as possible to limit disfigurement and functional loss. This usually involves dissection of the major cervical lymphatic vessels and lateral cervical space with preservation of nerves and vessels, including the sympathetic and vagus nerves, spinal accessory nerves, and internal jugular vein. Neck dissection with vocal cord cancer usually involves one side of the neck. However, if the lesion is midline, a bilateral neck dissection may be performed, with a modification on at least one side to minimize structural and functional deficits.

Some patients refuse surgical intervention for advanced lesions because of the extent of the procedure and the potential risk. In this situation, external radiation therapy is used as the sole treatment or in combination with chemotherapy. Your support and counseling are extremely important.

Chemotherapy is used in combination with radiation therapy for patients with stage III or IV cancers. A three-drug chemotherapeutic regimen using cisplatin (Platinol), docetaxel (Taxotere), and fluorouracil (5-FU) is used to treat locally advanced head and neck cancer.[26] Cetuximab (Erbitux), a targeted therapy, is also used in combination with radiation (first-line treatment) or as monotherapy for cancer that has metastasized after stan-

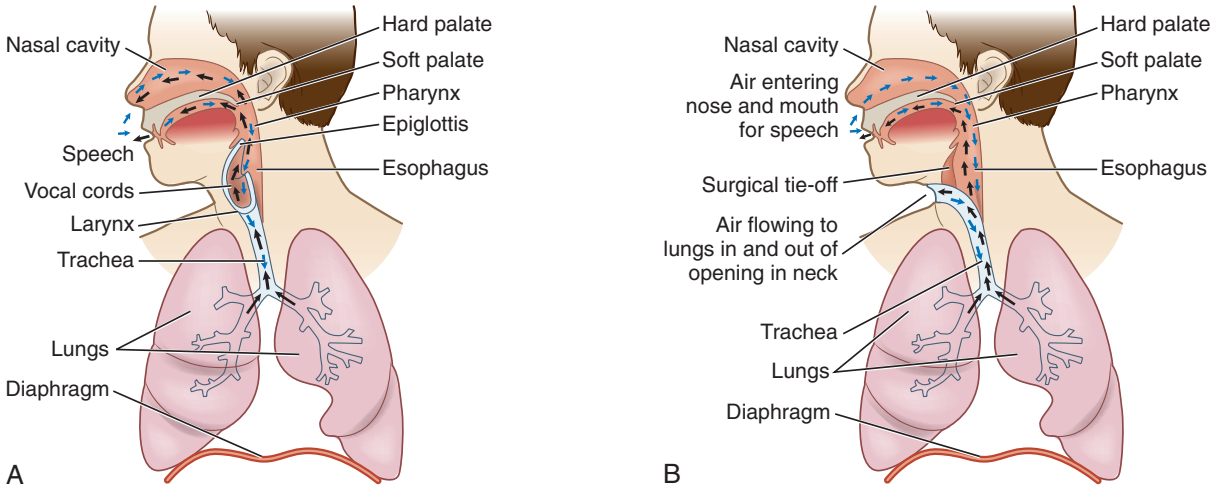

FIG. 27-10 **A,** Normal airflow in and out of the lungs. **B,** Airflow in and out of the lungs after total laryngectomy. Patients using esophageal speech trap air in the esophagus and release it to create sound.

FIG. 27-11 Reconstructive surgery involving skin grafts may be needed after a radical neck dissection.

dard chemotherapy. (Targeted therapy is discussed in Chapter 16 and Table 16-13.)

Isotretinoin (13-*cis*-retinoic acid) is currently under clinical evaluation for use as a chemopreventive agent. This drug is given daily for 1 year to prevent recurrence of head and neck cancer.[27]

Nutritional Therapy. As many as 50% of patients with head and neck cancer are malnourished even before treatment begins.[28] Treatment modalities increase the risk of malnutrition. After radical neck surgery the patient may be unable to take in nutrients orally because of swelling, the location of sutures, or difficulty with swallowing. Side effects from chemotherapy and radiation therapy can impair the patient's ability to maintain adequate nutrition. Painful oral mucositis frequently leads to breaks in treatment if the patient is relying solely on oral intake for nutrition.

A thorough nutritional assessment and prophylactic placement of a gastrostomy tube in high-risk patients are vital to maintaining adequate nutrition. Enteral nutrition may be started before initiation of treatment to obtain and maintain optimal nutritional status needed for tissue repair. (Enteral nutrition is described in Chapter 40.) Observe for tolerance of the feedings and adjust the amount, time, and formula if nausea, vomiting, diarrhea, or distention occurs. Instruct the patient and caregiver about the tube feedings.

Patients who are not candidates for or who refuse enteral feedings need to be monitored closely for weight loss. Antiemetics or analgesics may be given before meals to reduce nausea and mouth pain. Bland foods are easier for patients to tolerate. Patients can increase caloric intake by adding dry milk to foods during preparation, selecting foods high in calories, and using oral supplements. It is helpful to add sauces and gravies to food, which adds calories and moistens food so it is more easily swallowed. Elevate the head of the bed while the patient is eating.

Anticipate swallowing problems when the patient resumes eating after surgery. The type and degree of difficulty vary, depending on the procedure. Videofluoroscopic swallowing studies may be used to evaluate the safety of patient swallowing. When the patient can swallow, give small amounts of thickened liquids or pureed foods with the patient in high Fowler's position. Closely observe for choking. Suctioning may be necessary to prevent aspiration.

Avoid thin, watery fluids because they are difficult to swallow and increase the risk of aspiration. A better choice is nonpourable pureed foods, which are thicker and allow more control during swallowing. Using a commercially available thickening agent (Thick-It) to thicken liquids will enhance swallowing.

When a supraglottic laryngectomy is performed, the upper portion of the larynx is excised, including the epiglottis and false vocal cords. The patient can speak because the true vocal cords remain intact. However, the patient must learn a new technique, the *supraglottic swallow,* to compensate for removal of the epiglottis and minimize the risk of aspiration (Table 27-9). When learning this technique, the patient should start with carbonated beverages because the effervescence helps determine the liquid's position.

NURSING MANAGEMENT HEAD AND NECK CANCER

NURSING ASSESSMENT

Table 27-10 presents subjective and objective data to obtain from a person with head and neck cancer.

TABLE 27-9 PATIENT TEACHING GUIDE

Supraglottic Swallow

Include the following instructions when teaching a patient to perform a supraglottic swallow.

1. Its purpose is to voluntarily control the closure of the vocal cords before and after swallowing. It protects the trachea from aspiration.
2. To do the technique, take a deep breath and hold it tightly.*
3. Take a bite of food or sip of fluid in your mouth.
4. Swallow while holding your breath. Some food will enter airway and remain on top of closed vocal cords.
4. Cough immediately after swallow to remove food from top of vocal cords.
5. Swallow again.
6. Breathe after cough-swallow sequence to prevent aspiration of food collected on top of vocal cords.

*If patient aspirates with this technique, the super-supraglottic swallow may be useful. This involves having the patient perform the Valsalva maneuver to close the vocal cords while holding breath and during swallow.

TABLE 27-10 NURSING ASSESSMENT

Head and Neck Cancer

Subjective Data

Important Health Information

Past health history: Positive family history; prolonged tobacco use (cigarettes, pipes, cigars, chewing tobacco, smokeless tobacco); prolonged, heavy alcohol use; poor intake of fruits and vegetables

Medications: Prolonged use of over-the-counter medication for sore throat, decongestants

Functional Health Patterns

Health perception–health management: Does not participate in preventive health measures, long history of alcohol and tobacco use

Nutritional-metabolic: Mouth ulcer that does not heal, change in fit of dentures, change in appetite, weight loss, swallowing difficulty (e.g., sensation of lump in throat, pain with swallowing, aspiration when swallowing)

Activity-exercise: Fatigue with minimal exertion

Cognitive-perceptual: Sore throat, pain on swallowing, referred ear pain

Objective Data

Respiratory

Hoarseness, change in voice quality, chronic laryngitis, nasal voice, palpable neck mass and lymph nodes (tender, hard, fixed), tracheal deviation; dyspnea, stridor (late sign)

Gastrointestinal

White (leukoplakia) or red (erythroplakia) patches inside mouth, ulceration of mucosa, asymmetric tongue, exudate in mouth or pharynx, mass or thickening of mucosa

Possible Diagnostic Findings

Mass on direct or indirect laryngoscopy; tumor on soft tissue x-ray, computed tomography (CT) scan, or magnetic resonance imaging (MRI); positive biopsy

NURSING DIAGNOSES

Nursing diagnoses for the patient with head and neck cancer include, but are not limited to, the following:

- Ineffective airway clearance *related to* presence of artificial airway and excessive mucus
- Risk for aspiration *related to* presence of tracheostomy tube and impaired swallowing
- Anxiety *related to* lack of knowledge regarding surgical procedure and pain management
- Acute pain *related to* tissue injury from surgery
- Impaired verbal communication *related to* removal of vocal cords

Additional information on nursing diagnoses for the patient with head and neck cancer is presented in eNursing Care Plan 27-2 on the website for this chapter.

PLANNING

The overall goals are that the patient will have (1) a patent airway, (2) no spread of cancer, (3) no complications related to therapy, (4) adequate nutritional intake, (5) minimal to no pain, (6) the ability to communicate, and (7) an acceptable body image.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Development of head and neck cancer is closely related to personal habits, primarily tobacco use and excessive alcohol ingestion. Although tobacco use (including smokeless tobacco, also called "chewing tobacco" or "snuff") has been linked to most head and neck cancers, people who use both tobacco and alcohol are at greater risk than those who use just one.[24] Poor oral hygiene and HPV infection are also risk factors for head and neck cancer.

Include information about risk factors in health teaching. Encourage good oral hygiene. Teach patients about safe sex practices to prevent HPV infection (e.g., use condoms for every sex act, be in a monogamous relationship, and choose a partner who has had no or few previous partners). If cancer has been diagnosed, tobacco and alcohol cessation is still important. The likelihood of a cure, by any treatment modality, for a patient with head and neck cancer who continues to smoke and ingest alcoholic beverages is diminished. Additionally, risk of a second primary cancer is significantly increased. Give patients information about smoking cessation programs and techniques for success. If necessary, refer to an alcohol treatment program.

ACUTE INTERVENTION. Teach the patient and the caregiver about the type of therapy to be performed and care required. Help prepare them to deal with the psychologic impact of the diagnosis of cancer, alteration of physical appearance, possible need for enteral feedings, and potential for altered methods of communication because of the loss of a voice. The care plan should include assessment of the patient's support system. The patient may not have someone to provide assistance after discharge, may be unemployed, or may have a job that cannot be continued.

Radiation Therapy. Suggest interventions to reduce side effects of radiation therapy. Because the oral mucosa is frequently affected, patients should consult a dentist before starting radiation therapy. Dry mouth *(xerostomia),* the most frequent and annoying problem, typically begins within a few weeks of treatment. The patient's saliva decreases in volume and becomes thick. The change may be temporary or permanent. Pilocarpine hydrochloride (Salagen) is often effective in increasing saliva production and should be started before the initiation of radiation therapy. Amifostine (Ethyol) subcutaneous injection may also be ordered to decrease xerostomia. Patients can get symptom relief by increasing fluid intake, chewing sugarless gum or sugarless candy, using nonalcoholic mouth rinses (baking soda or glycerin solutions), and using artificial saliva. Over-the-counter mucous thinning agents (e.g., guaifenesin) two or three times daily and/or mucous solvents can be used to control thickening secretions. Instruct patients to always carry

a water bottle with them. Fluoride gels or treatments can help prevent dental deterioration caused by xerostomia. Acupuncture has also been found to improve discomfort related to xerostomia.[27]

Oral mucositis can cause irritation, ulceration, and pain. Empty fluoride gel trays, along with bite blocks, athletic mouth guards, or gauze pads, can be worn during radiation treatments to prevent radiation scatter to the tongue and cheek from metal work in the mouth that contributes to development of mucositis.[28] Instruct the patient on oral care basics, including the use of a soft toothbrush and regular flossing. Warm bland rinses such as salt and baking soda should be done four to six times daily. Sucking on ice chips can also help with the pain. Encourage patients to eat soft, bland foods. Patients should avoid commercial mouthwashes and hot, spicy, or acidic foods because they are irritating. If the problem is severe, a mixture of equal parts antacid, diphenhydramine (Benadryl), and topical lidocaine can be used. Instruct the patient to rinse the mouth with the mixture without swallowing it.

Fatigue is a common side effect of radiation therapy and usually begins a few weeks into therapy. Encourage patients to walk 15 to 30 minutes each day, since regular exercise can give them more energy. Instruct patients to do activities that are most important to them and to rest during periods of low energy. Identify support systems and encourage patients to ask for help.

Skin over the irradiated area often becomes reddened and sensitive to touch. Instruct patients to use only prescribed lotions and skin products while undergoing radiation therapy, and to not use any lotions within 2 hours before treatment. (Skin care for patients having radiation therapy is discussed in Chapter 16.)

Surgical Therapy. Preoperatively assess the patient's physical and psychosocial needs. Physical preparation is the same as for any major surgery, with an emphasis on oral hygiene. Explanations and emotional support are of special significance and should include postoperative measures relating to communication and feeding. Assess knowledge and understanding of the planned surgical procedure, and clarify information as needed. Include the caregiver in preoperative teaching.

Tailor teaching to the planned surgical procedure. For surgeries that involve a laryngectomy, include information about expected changes in speech. Establish a means of communication for the immediate postoperative period. Magic Slates, alphabet boards, writing materials, pictorial guides, or hand signals are useful methods for communicating. Programmable speech-generating devices allow use of recorded messages that are matched with a graphic representing each message. Integration of this technology into patient care enhances the patient's ability to communicate basic needs postoperatively.[29]

Immediately after surgery, focus your nursing care on airway management, wound care, nutrition, communication, and psychosocial issues related to body-image changes. Maintenance of a patent airway is essential. The inflammation in the surgical area may compress the trachea. A tracheostomy tube will be in place. Keep the patient in semi-Fowler's position to decrease edema and limit tension on the suture lines. The patient with a laryngectomy requires frequent suctioning via the tracheostomy tube. Secretions typically change in amount and consistency over time. The patient may initially have copious blood-tinged secretions that diminish and thicken. Normal saline bolus via the tracheostomy tube is not recommended to assist with removal of thickened secretions, since this causes hypoxia and damage to the epithelial cells. Maintain adequate fluid intake (IV, enteral, and oral when allowed) and humidification of inspired gases to keep secretions liquid and mucous membranes moist. Encourage deep breathing and coughing. Provide tracheostomy care as needed (see Table 27-7).

Monitor vital signs frequently because of the risk of hemorrhage and respiratory compromise. Pressure dressings, packing, or drainage tubes may be used for wound management, depending on the type of surgical procedure. If skin flaps are employed, dressings are typically not used. This allows better visualization of the incision and avoids excessive pressure on tissue (see Fig. 27-11). When a radical neck dissection is performed, the wound is suctioned with a portable system, such as a Hemovac. The drainage should be serosanguineous and gradually decrease in volume over 24 hours. Monitor patency of drainage tubes every 4 hours to ensure proper functioning. In addition, monitor the amount and character of drainage. If the tubing becomes obstructed, fluid will accumulate under the skin flap and predispose the patient to formation of hematomas or seromas, impair wound healing, and increase the risk for infection. After drainage tubes are removed, closely monitor the area to detect any swelling. If fluid continues to accumulate, aspiration may be necessary. Closely monitor incision sites for signs of infection.

The patient may have a nasogastric tube inserted during surgery to remove gastric contents via intermittent suction for the first 24 to 48 hours until peristalsis returns. Because the nasogastric tube lies close to internal incision lines, do not manipulate or move the tube. When bowel sounds return, enteral feedings may be started slowly and advanced to meet nutritional needs. Monitor daily weights and blood chemistries to evaluate the patient's nutritional status.

After a neck dissection, teach the patient to use the upper extremities to assist with support and movement of the head. After the immediate postoperative period the patient should begin an exercise program to maintain strength and movement in the affected shoulder and neck. This is especially important when the spinal accessory nerve and sternocleidomastoid muscles are removed or damaged. Without exercise, the patient will be left with a "frozen" shoulder and limited range of neck motion. The patient should continue this exercise program after discharge to prevent future functional disabilities.

Voice Rehabilitation. Preoperatively a speech therapist should meet with the patient having a total laryngectomy to discuss voice restoration options. The International Association of Laryngectomees, an association of laryngectomy patients, focuses on helping patients reestablish speech. Local groups, called "Lost Chord" or "New Voice" Clubs, often provide volunteers to visit the patient, preferably preoperatively. Three options are available to restore speech: esophageal speech, electrolarynx, and transesophageal puncture.

Esophageal speech involves swallowing air, trapping it in the esophagus, and releasing it to create sound. The air causes vibration of the pharyngoesophageal segment and sound (which initially is similar to a belch). With practice, many patients develop some speech skills, but few develop fluent speech.

An *electrolarynx* is a hand-held, battery-powered device that creates speech with the use of sound waves. The two most common types of electrolarynx devices are classified as neck and intraoral. The *neck type* is placed against the neck, under the chin (Fig. 27-12, *A*), or on the cheek. The patient moves the lips to articulate sound that is conducted into the oropharynx

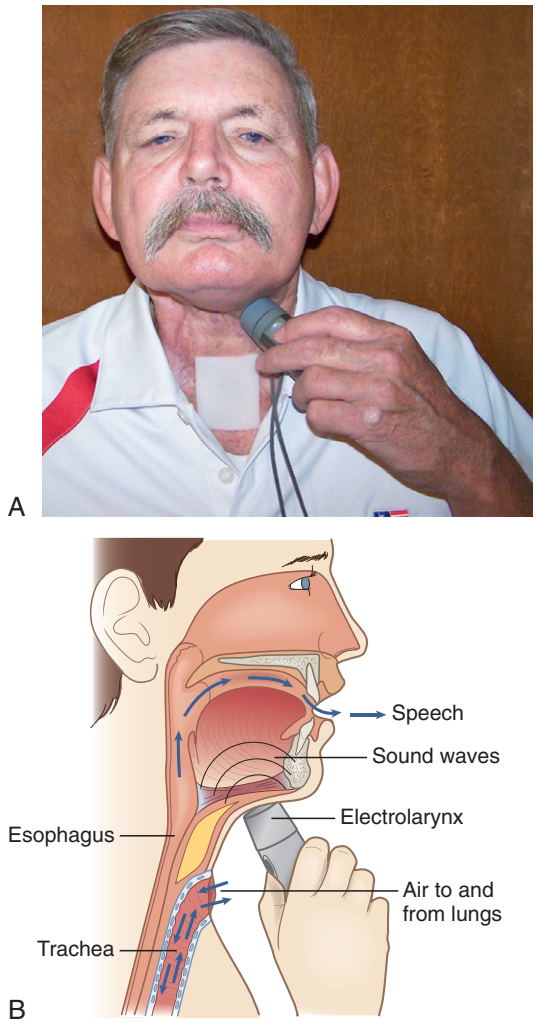

FIG. 27-12 Artificial larynx. **A,** Battery-powered electronic artificial larynx for patient who has had a total laryngectomy. **B,** The sound waves created by the electrolarynx allow the person to speak.

(Fig. 27-12, *B*). This option allows for speech immediately after surgery, is easy to learn, and requires little maintenance. Intraoral devices are used for patients who cannot achieve adequate sound conduction on the skin. The *intraoral electrolarynx* uses a plastic tube placed in the corner of the roof of the mouth to create vibrations. A hands-free device, using an electromyograph (EMG) transducer in the strap muscles of the neck, is also available.[30] With all devices, voice pitch is low and the sound is mechanical.

Transesophageal puncture, the most common voice rehabilitation method, offers the best speech quality with the highest patient satisfaction.[31] A transesophageal puncture creates a surgical fistula or tract between the esophagus and trachea. The puncture may be created at the same time as the total laryngectomy surgery or afterward if postoperative radiation is planned. A red rubber catheter is placed in the tracheoesophageal puncture as a stent. Several days later, the catheter is removed and a one-way valved prosthesis is placed in the tract. The valve prevents aspiration of food or saliva from the esophagus into the tracheostomy. To speak, the patient manually blocks the stoma with the finger. Air moves from the lungs, through the prosthesis, into the esophagus, and out the mouth. Speech is produced

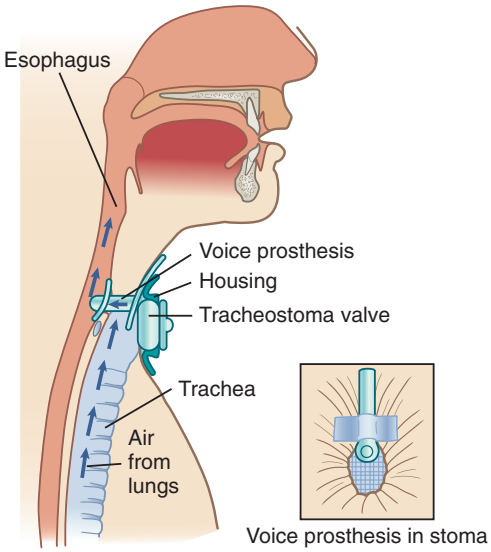

FIG. 27-13 Blom-Singer voice prosthesis and tracheostoma valve. With this prosthesis and valve, patients with a laryngectomy can speak normally. *Inset* shows laryngectomy stoma and voice prosthesis with tracheostoma valve removed.

by the air vibrating against the esophagus and is formed into words by moving the tongue and lips. The use of a hands-free external-airflow valve eliminates the need for finger occlusion of the stoma. The prosthesis must be cleaned regularly and replaced when it becomes blocked with mucus. The most commonly used voice prosthesis is the Blom-Singer prosthesis (Fig. 27-13).

Stoma Care. Before discharge, instruct the patient in the care of the laryngectomy stoma. The patient should wash the area around the stoma daily with a moist cloth. A nasal wash spray (e.g., Alkalol) can be used every 1 to 2 hours to keep the stoma moist and prevent crusting. Dried secretions can be removed with tweezers. If a laryngectomy tube is in place, the patient must remove the entire tube at least daily and clean it in the same manner as a tracheostomy tube. The inner cannula may need to be removed and cleaned more frequently. A scarf, a loose shirt, or a crocheted shield can be used to hide the stoma.

The patient should cover the stoma when coughing (because mucus may be expectorated) and during any activity (e.g., shaving, applying makeup) that might lead to inhalation of foreign materials. Because water can easily enter the stoma, the patient should wear a plastic collar when taking a shower. Swimming is contraindicated. Initially, humidification is administered via a tracheostomy mask. After discharge, the patient can use a bedside humidifier. The patient must also maintain a high oral fluid intake, especially in dry weather.

Inform the patient about the importance of wearing a Medic Alert bracelet or other identification that alerts emergency personnel of the neck breathing status. Because the patient no longer breathes through the nose, the ability to smell smoke and food is often lost. Advise the patient to install smoke and carbon monoxide detectors in the home. Encourage preparation of food that is colorful, attractive, and nutritious because taste may also be diminished secondary to the loss of smell and radiation therapy.

Depression. Depression is common in the patient who has had a radical neck dissection. The patient may not be able to speak because of the laryngectomy and cannot control saliva.

The neck and shoulders may be numb because of the transected nerves. The facial appearance may be significantly altered, with swelling, edema, and deformities. The patient must understand that many of the physical changes are reversible as the edema subsides and the tracheostomy tube is removed. Depression may also be related to concern about the prognosis. Allow the patient to talk about feelings and express emotions. Convey acceptance to help the patient regain an acceptable self-concept. Encourage participation in support groups. Information about available groups can be obtained through the local branch of the American Cancer Society. Sometimes a psychiatric referral is appropriate for the patient who is experiencing prolonged or severe depression.

Sexuality. Surgery and foreign attachments such as tracheostomy and gastrostomy tubes may dramatically affect body image. Xerostomia and fatigue can physically affect sexuality. Some patients feel less desirable. Assist the patient by allowing discussions regarding sexuality. Encourage the patient to discuss this problem with his or her partner. It may be difficult for the patient to talk about sexual problems because of the alteration in communication. Assist the patient in planning how to communicate with the sexual partner. Offer support and guidance to the sexual partner. Helping the patient see that sexuality involves much more than appearance may relieve some anxiety.

AMBULATORY AND HOME CARE. The patient is often discharged with a tracheostomy and a nasogastric or gastrostomy feeding tube. Some patients need home health care initially to evaluate the caregiver's or the patient's ability to perform self-care activities. The patient and the caregiver need to learn how to manage tubes and who to call if there are problems. Provide pictorial instructions for tracheostomy care, suctioning, stoma care, and enteral feeding as appropriate. The patient can resume exercise, recreation, and sexual activity when able. Most patients can return to work 1 to 2 months after surgery. However, many never return to full-time employment. The changes that follow a total laryngectomy can be upsetting. Loss of speech, loss of the ability to taste and smell, inability to produce audible sounds (including laughing and weeping), and the presence of a permanent tracheal stoma that produces undesirable mucus are often overwhelming to the patient. Although changes are discussed before surgery, the patient may not be prepared for the extent of these changes. If the patient has a significant other, this person's reaction to the patient's altered appearance is important. Acceptance by another person can promote an improved self-image. Encouraging the patient to participate in self-care is another important part of rehabilitation.

DELEGATION DECISIONS

Suctioning and Tracheostomy Care

Licensed practical nurses (LPNs) may do suctioning and give tracheostomy care to stable patients. In patients who have acute airway problems requiring an endotracheal or tracheostomy tube, these interventions should be done by the registered nurse (RN).

Role of Registered Nurse (RN)

- For unstable patients:
  - Assess for the need for suctioning.
  - Suction the endotracheal or tracheostomy tube.
  - Evaluate for adverse effects of suctioning such as dysrhythmias.
  - Evaluate whether patient status is improved after suctioning.
- Maintain appropriate cuff inflation pressure at 20-25 cm H_2O, or use minimal leak technique to maintain cuff pressure.
- Assess tracheostomy and any retention sutures for evidence of complications (e.g., infection).
- Replace the tracheostomy tube after accidental dislodgment.
- Ventilate the patient with a bag-valve-mask device after accidental tracheostomy dislodgment if needed.
- Assess swallowing ability and risk for aspiration.
- Develop plan to avoid aspiration in a patient with a tracheostomy.
- Teach patient and caregiver about home tracheostomy care.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- For stable patients:
  - Determine the need for suctioning.
  - Suction the tracheostomy.
  - Evaluate whether patient status is improved after suctioning.
- Provide tracheostomy care using sterile technique.

Role of Unlicensed Assistive Personnel (UAP)

- Provide oral care to patient with a tracheostomy.
- Suction patient's oropharynx (after being trained and evaluated in this procedure).
- Report increased need for oropharyngeal suctioning to the RN.

EVALUATION

Expected outcomes for the patient with head and neck cancer who is treated surgically are that the patient will

- Demonstrate effective coughing and secretion clearance
- Demonstrate the ability to swallow oral foods without aspiration
- Report satisfaction with pain relief
- Use written and nonverbal techniques to effectively communicate with others

Other outcomes for the patient with head and neck cancer who is treated surgically are addressed in eNursing Care Plans 27-1 and 27-2 on the website for this chapter.

CASE STUDY

Laryngeal Cancer

iStockphoto/Thinkstock

Patient Profile

M.R., a 60-year-old white man, was admitted for evaluation of mild pain on swallowing and a persistent sore throat over the past year. He has a history of type 2 diabetes mellitus.

Subjective Data

- States that his symptoms worsened in the past 2 mo
- Has used various cold remedies to relieve symptoms without relief
- Has lost weight because of decrease in appetite and difficulty swallowing
- Has smoked three packs of cigarettes a day for 40 yr
- Consumes 4-6 cans of beer a day

Objective Data

Laryngoscopy

- Subglottic mass

Physical Examination

- Enlarged cervical nodes

Computed Tomography Scan

- Subglottic lesion with lymph node involvement

Collaborative Care

- Percutaneous gastrostomy tube inserted preoperatively for enteral tube feeding
- Total laryngectomy with tracheostomy with inflated cuff
- Nasogastric tube postoperatively

Discussion Questions

1. What information in the assessment suggests that M.R. is at risk for cancer of the larynx?
2. ***Priority Decision:*** What are your priority teaching strategies for M.R. before and after laryngectomy?
3. Discuss methods used to restore speech after laryngectomy.
4. Is there anything in his history that may affect wound healing after surgery?
5. ***Priority Decision:*** While in the recovery room, M.R. develops shortness of breath. What are your priority nursing interventions?
6. What teaching is required to help this patient assume self-care after his surgery? What precautions should the patient take because of his stoma?
7. While on the medical-surgical unit, M.R. is tearful and is staring at the wall. What should you do?
8. ***Priority Decision:*** Based on the assessment data presented, what are your priority nursing diagnoses? Are there any collaborative problems?
9. ***Delegation Decision:*** What role can unlicensed assistive personnel (UAP) have in relation to the tracheostomy?
10. ***Evidence-Based Practice:*** How could you best meet M.R.'s communication needs during the first few postoperative days?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient was seen in the clinic for an episode of epistaxis, which was controlled by placement of anterior nasal packing. During discharge teaching, the nurse instructs the patient to
   a. use aspirin for pain relief.
   b. remove the packing later that day.
   c. skip the next dose of antihypertensive medication.
   d. avoid vigorous nose blowing and strenuous activity.
2. A patient with allergic rhinitis reports severe nasal congestion; sneezing; and watery, itchy eyes and nose at various times of the year. To teach the patient to control these symptoms, the nurse advises the patient to
   a. avoid all intranasal sprays and oral antihistamines.
   b. limit the usage of nasal decongestant spray to 10 days.
   c. use oral decongestants at bedtime to prevent symptoms during the night.
   d. keep a diary of when the allergic reaction occurs and what precipitates it.
3. A patient is seen at the clinic with fever, muscle aches, sore throat with yellowish exudate, and headache. The nurse anticipates that the collaborative management will include *(select all that apply)*
   a. antiviral agents to treat influenza.
   b. treatment with antibiotics starting ASAP.
   c. a throat culture or rapid strep antigen test.
   d. supportive care, including cool, bland liquids.
   e. comprehensive history to determine possible etiology.
4. The best method for determining the risk of aspiration in a patient with a tracheostomy is to
   a. consult a speech therapist for swallowing assessment.
   b. have the patient drink plain water and assess for coughing.
   c. assess for change of sputum color 48 hours after patient drinks small amount of blue dye.
   d. suction above the cuff after the patient eats or drinks to determine presence of food in trachea.
5. Which nursing action would be of highest priority when suctioning a patient with a tracheostomy?
   a. Auscultating lung sounds after suctioning is complete
   b. Providing a means of communication for the patient during the procedure
   c. Assessing the patient's oxygenation saturation before, during, and after suctioning
   d. Administering pain and/or antianxiety medication 30 minutes before suctioning
6. When planning health care teaching to prevent or detect early head and neck cancer, which people would be the priority to target *(select all that apply)?*
   a. 65-year-old man who has used chewing tobacco most of his life
   b. 45-year-old rancher who uses snuff to stay awake while driving his herds of cattle
   c. 78-year-old woman who has been drinking hard liquor since her husband died 15 years ago
   d. 21-year-old college student who drinks beer on weekends with his fraternity brothers
   e. 22-year-old woman who has been diagnosed with human papilloma virus (HPV) of the cervix

7. While in the recovery room, a patient with a total laryngectomy is suctioned and has bloody mucus with some clots. Which nursing interventions would apply?
   a. Notify the physician immediately.
   b. Place the patient in the prone position to facilitate drainage.
   c. Instill 3 mL of normal saline into the tracheostomy tube to loosen secretions.
   d. Continue your assessment of the patient, including O_2 saturation, respiratory rate, and breath sounds.

8. When using a prosthesis for transesophageal speech, the patient
   a. places a vibrating device in the mouth.
   b. blocks the stoma entrance with a finger.
   c. swallows air using a Valsalva maneuver.
   d. places a speaking valve next to the stoma.

1. d, 2. d, 3. c, d, e, 4. a, 5. c, 6. a, b, c, e, 7. d, 8. b

LEARNING OUTCOMES

1. Compare and contrast the clinical manifestations and collaborative and nursing management of patients with acute bronchitis and pertussis.
2. Differentiate among the types of pneumonia and their etiology, pathophysiology, clinical manifestations, and collaborative care.
3. Prioritize the nursing management of the patient with pneumonia.
4. Describe the pathogenesis, classification, clinical manifestations, complications, diagnostic abnormalities, and nursing and collaborative management of patients with tuberculosis.
5. Describe the causes, clinical manifestations, and collaborative management of patients with pulmonary fungal infections.
6. Explain the pathophysiology, clinical manifestations, and collaborative management of patients with lung abscesses.
7. Identify the causative factors, clinical manifestations, and nursing and collaborative management of patients with environmental lung diseases.
8. Describe the etiology, risk factors, pathophysiology, clinical manifestations, and nursing and collaborative management of lung cancer.
9. Compare and contrast the pathophysiology, clinical manifestations, and nursing and collaborative management of pneumothorax, fractured ribs, and flail chest.
10. Describe the purpose, function, and nursing responsibilities related to chest tubes and various drainage systems.
11. Explain the types of chest surgery and appropriate preoperative and postoperative care.
12. Describe the etiology, clinical manifestations, and nursing and collaborative management of patients with restrictive lung disorders such as pleural effusion, pleurisy, and atelectasis.
13. Describe the pathophysiology, clinical manifestations, and management of pulmonary embolism, pulmonary hypertension, and cor pulmonale.
14. Discuss the use of lung transplantation as a treatment for pulmonary disorders.

HEALTHY PEOPLE

Prevention of Respiratory Diseases

- Avoid cigarette smoking and exposure to environmental smoke.
- Wash hands frequently to prevent and avoid spreading infections.
- Avoid exposure to allergens, indoor pollutants, and ambient air pollutants.
- Get a pneumococcal vaccine and yearly flu vaccine as directed by health care provider.
- Wear proper protection when working in an occupation with prolonged exposure to dust, fumes, or gases.

A wide variety of problems affect the lower respiratory system. Lung diseases that are characterized primarily by an obstructive disorder, such as asthma, chronic obstructive pulmonary disease (COPD), and cystic fibrosis, are discussed in Chapter 29. This chapter discusses other lower respiratory tract diseases, including infectious, oncologic, traumatic, restrictive, and vascular disorders.

LOWER RESPIRATORY TRACT INFECTIONS

Lower respiratory tract infection is both a common and a serious occurrence. It is the third leading cause of death worldwide.[1] Pneumonia and influenza are the eighth leading cause of death in the United States, accounting for more than 56,000 deaths annually.[2]

ACUTE BRONCHITIS

Acute bronchitis is an inflammation of the bronchi in the lower respiratory tract. Up to 90% of acute bronchial infections are viral in origin. Cough, which is the most common symptom, lasts for up to 3 weeks. Clear, mucoid sputum is often present, although some patients produce purulent sputum. The presence of colored (e.g., green) sputum is not a reliable indicator of bacterial infection.[3] Associated symptoms include headache, fever, malaise, hoarseness, myalgias, dyspnea, and chest pain.

Assessment may reveal normal breath sounds or rhonchi, crackles, or wheezes, usually with expiration and exertion. Diagnosis is based on clinical assessment. Evidence of consolidation (e.g., fremitus, rales, egophony), which is suggestive of pneumonia, is absent with bronchitis. (*Consolidation* in the lungs occurs when fluid accumulates, causing the lung tissue to become stiff and unable to exchange gases.) Chest x-rays would be normal and are therefore not indicated unless pneumonia is suspected. (Chronic bronchitis is discussed in Chapter 29.)

Acute bronchitis is usually self-limiting, and treatment is supportive. Cough suppressants, β_2-agonist (bronchodilator) inhalers in patients with wheezing, and high-dose inhaled corticosteroids may be used.[3] Antibiotics generally are not prescribed unless the person has a prolonged infection associated with systemic symptoms. Explain to the patient that antibiotics are not effective in treating a viral infection and that they may cause side effects and antibiotic-resistant germs. Complementary and alternative therapies (e.g., echinacea, honey) may be useful for symptom relief. If the acute bronchitis is due to an influenza virus, treatment with antiviral drugs, either zanamivir (Relenza) or oseltamivir (Tamiflu), can be started. These drugs should be initiated within 48 hours of the onset of symptoms.

PERTUSSIS

Pertussis is a highly contagious infection of the respiratory tract caused by a gram-negative bacillus, *Bordetella pertussis*. Pertussis is characterized by uncontrollable, violent coughing. Despite improved childhood vaccination in the United States, the incidence of pertussis has been steadily increasing since the 1980s, with the largest increase noted in adults.[4] It is thought that immunity resulting from childhood vaccination with DPT (diphtheria, pertussis, tetanus) may wane over time, resulting in a milder infection that is still distressing and contagious. Therefore the Centers for Disease Control and Prevention (CDC) currently recommends that all adults age 18 years and older receive a one-time dose of Tdap (tetanus, diphtheria, and pertussis) vaccination.[4]

Clinical manifestations of pertussis occur in stages. The first (catarrhal) stage manifests as a mild upper respiratory tract infection (URI) with a low-grade or no fever, runny nose, watery eyes, and mild nonproductive cough. The second (paroxysmal) stage is characterized by paroxysms of cough. Inspiration after each cough produces the typical "whooping" sound as the patient tries to breathe in air against an obstructed glottis. Vomiting may also occur with the coughing. Like acute bronchitis, the coughing is more frequent at night. Unlike bronchitis, the cough with pertussis may last from 6 to 10 weeks.

Treatment is antibiotics, usually macrolides (erythromycin, azithromycin [Zithromax]), to minimize symptoms and prevent spread of the disease. Cough suppressants and antihistamines should not be used, since they are ineffective and may induce coughing episodes. Corticosteroids and bronchodilators are not useful in reducing symptoms.

PNEUMONIA

Pneumonia is an acute infection of the lung parenchyma. Until 1936, pneumonia was the leading cause of death in the United States. The discovery of sulfa drugs and penicillin was pivotal in the treatment of pneumonia. Since that time, remarkable progress has been made in the development of antibiotics to treat pneumonia. However, despite new antimicrobial agents, pneumonia is still associated with significant morbidity and mortality rates. Community-acquired pneumonia (CAP) is the sixth leading cause of death for people ages 65 years or older in the United States.[5]

Etiology

Normally, the airway distal to the larynx is protected from infection by various defense mechanisms. Mechanisms that create a mechanical barrier to microorganisms include air filtration, epiglottis closure over the trachea, cough reflex, mucociliary escalator mechanism, and reflex bronchoconstriction (see Chapter 26). Immune defense mechanisms include secretion of immunoglobulins A and G and alveolar macrophages.

Pneumonia is more likely to occur when the defense mechanisms become incompetent or are overwhelmed by the virulence or quantity of infectious agents. Decreased consciousness depresses the cough and epiglottal reflexes, which may allow aspiration of oropharyngeal contents into the lungs. Tracheal intubation interferes with the normal cough reflex and the mucociliary escalator mechanism. Air pollution, cigarette smoking, viral URIs, and normal changes that occur with aging can impair the mucociliary mechanism. Chronic diseases can

TABLE 28-1 RISK FACTORS FOR PNEUMONIA

- Abdominal or thoracic surgery
- Age >65 yr
- Air pollution
- Altered consciousness: alcoholism, head injury, seizures, anesthesia, drug overdose, stroke
- Bed rest and prolonged immobility
- Chronic diseases: chronic lung and liver disease, diabetes mellitus, heart disease, cancer, chronic kidney disease
- Debilitating illness
- Exposure to bats, birds, rabbits, farm animals
- Immunosuppressive disease and/or therapy (corticosteroids, cancer chemotherapy, human immunodeficiency virus [HIV] infection, immunosuppressive therapy after organ transplant)
- Inhalation or aspiration of noxious substances
- Intestinal and gastric feedings via nasogastric or nasointestinal tubes
- IV drug use
- Malnutrition
- Recent antibiotic therapy
- Resident of a long-term care facility
- Smoking
- Tracheal intubation (endotracheal intubation, tracheostomy)
- Upper respiratory tract infection

suppress the immune system's ability to inhibit bacterial growth. The risk factors for pneumonia are listed in Table 28-1.

Organisms that cause pneumonia reach the lung by three methods:

1. *Aspiration* of normal flora from the nasopharynx or oropharynx. Many of the organisms that cause pneumonia are normal inhabitants of the pharynx in healthy adults.
2. *Inhalation* of microbes present in the air. Examples include *Mycoplasma pneumoniae* and fungal pneumonias.
3. *Hematogenous spread* from a primary infection elsewhere in the body. An example is *Staphylococcus aureus.*

Types of Pneumonia

Bacteria, viruses, *Mycoplasma* organisms, fungi, parasites, and chemicals are all potential causes of pneumonia. Although pneumonia can be classified according to the causative organism, a clinically effective way is to classify it as *community-acquired* or *medical care–associated* pneumonia. Classifying pneumonia is important because of the differences in the likely causative organisms (Table 28-2) and the selection of appropriate antimicrobial therapy.

Community-Acquired Pneumonia. **Community-acquired pneumonia (CAP)** is an acute infection of the lung occurring in patients who have not been hospitalized or resided in a long-term care facility within 14 days of the onset of symptoms.[5] The decision to treat the patient at home or admit him or her to the hospital is based on several factors such as the patient's age, vital signs, mental status, and presence of co-morbid conditions. Clinicians can use tools such as the CURB-65 scale (Table 28-3) or the Pneumonia Patient Outcomes Research Team (PORT) Pneumonia Severity Index (PSI) to supplement clinical judgment. (The PSI calculator is available online at *http://pda.ahrq.gov/clinic/psi/psicalc.asp*). Empiric antibiotic therapy should be started as soon as possible. (*Empiric therapy* is the initiation of treatment before a definitive diagnosis. It is based on experience and knowledge of drugs known to be effective for the likely causative agent.)

TABLE 28-3 ASSESSING PNEUMONIA USING CURB-65

The CURB-65 scale may be used as a supplement to clinical judgment to determine the severity of pneumonia and if patients need to be hospitalized.

Identifying the Level of Risk

Patients receive 1 point for each of the following indicators:

- **C:** Confusion (compared to baseline)
- **U:** BUN >20 mg/dL
- **R:** Respiratory rate ≥30 breaths/min
- **B:** Systolic blood pressure <90 mm Hg or diastolic blood pressure ≤60 mm Hg
- **65:** ≥Age 65 yr

Scoring and Decision Making

Score	Decision
0	Treat at home
1-2	Consider hospital admission
3 or more	Hospital admission
4-5	Consider admission to intensive care unit

Source: Lim WS, van der Eerden MM, Laing R, et al: Defining community acquired pneumonia severity on presentation to hospital: an international derivation and validation study, *Thorax* 58(5):377, 2003.

Medical Care–Associated Pneumonia. **Medical care–associated pneumonia (MCAP)** encompasses three forms of pneumonia: hospital-associated pneumonia, ventilator-associated pneumonia, and health care–associated pneumonia.[6]

Hospital-associated pneumonia (HAP) is pneumonia that occurs 48 hours or longer after hospital admission and was not incubating at the time of hospitalization. *Ventilator-associated pneumonia* (VAP) refers to pneumonia that occurs more than 48 hours after endotracheal intubation. (VAP is discussed in Chapter 66.) *Health care–associated pneumonia* (HCAP) is a new-onset pneumonia in a patient who (1) was hospitalized in an acute care hospital for 2 days or longer within 90 days of the infection; (2) resided in a long-term care facility; (3) received IV antibiotic therapy, chemotherapy, or wound care within the past 30 days of the current infection; or (4) attended a hospital or hemodialysis clinic.[6]

These infections cause significant morbidity and increase the risk of death. HAP, VAP, and HCAP also increase health care costs with longer hospital stays and associated costs.

Once the diagnosis is made, empiric treatment of the pneumonia is initiated based on known risk factors, early versus late onset, and probable organism. Antibiotic therapy can be adjusted once the results of sputum cultures identify the exact pathogen.

A major problem in treating MCAP is multidrug-resistant (MDR) organisms. Antibiotic susceptibility tests can identify MDR organisms. The virulence of these organisms can severely limit the available and appropriate antimicrobial therapy. In addition, MDR organisms can increase the morbidity and mortality risks associated with pneumonia. (Chapter 15 discusses MDR organisms.)

Aspiration Pneumonia. *Aspiration pneumonia,* occurring as either CAP or MCAP, results from the abnormal entry of material from the mouth or stomach into the trachea and lungs. Conditions that increase the risk of aspiration include decreased level of consciousness (e.g., seizure, anesthesia, head injury, stroke, alcohol intake), difficulty swallowing, and nasogastric intubation with or without tube feeding. With loss of consciousness, the gag and cough reflexes are depressed, and aspiration is more likely to occur. Other high-risk groups are those who are seriously ill, have poor dentition, or are receiving acid-reducing medications.[7]

The aspirated material (food, water, vomitus, or oropharyngeal secretions) triggers an inflammatory response. The most common form of aspiration pneumonia is a primary bacterial infection. Typically, more than one organism is identified on sputum culture, including both aerobes and anaerobes, since they comprise the flora of the oropharynx. Until the cultures are completed, the choice of antibiotic therapy is based on an assessment of the severity of illness, where the infection was acquired (community versus medical care), and the probable causative organism. In contrast, aspiration of acidic gastric contents causes *chemical (noninfectious) pneumonitis,* which may not require antibiotic therapy. However, secondary bacterial infection can occur 48 to 72 hours later.

Opportunistic Pneumonia. Individuals at risk for opportunistic pneumonia include those with altered immune responses. This can include people with severe protein-calorie malnutrition or immunodeficiencies (e.g., human immunodeficiency virus [HIV] infection), and those receiving radiation therapy, chemotherapy, and any immunosuppressive therapy, including long-term corticosteroid therapy. In addition to the risk of bacterial and viral pneumonia, the immunocompromised person may develop an infection from microorganisms that do not normally cause disease, such as *Pneumocystis jiroveci* (formerly *carinii*) and cytomegalovirus (CMV).

P. jiroveci pneumonia (PCP) rarely occurs in the healthy individual but is the most common form of pneumonia in people with HIV disease. The onset is slow and subtle with symptoms of fever, tachypnea, tachycardia, dyspnea, nonproductive cough, and hypoxemia. The chest x-ray usually shows diffuse bilateral infiltrates. In widespread disease the lungs have massive consolidation. PCP can be life threatening, causing acute respiratory failure and death. Infection can also spread to other organs, including the liver, bone marrow, lymph nodes, spleen, and thyroid. Bacterial and viral pneumonias must first be ruled out because of the vague presentation of PCP. Treatment consists of a course of trimethoprim/sulfamethoxazole (Bactrim, Septra) either IV or orally depending on the severity of disease and the patient's response.

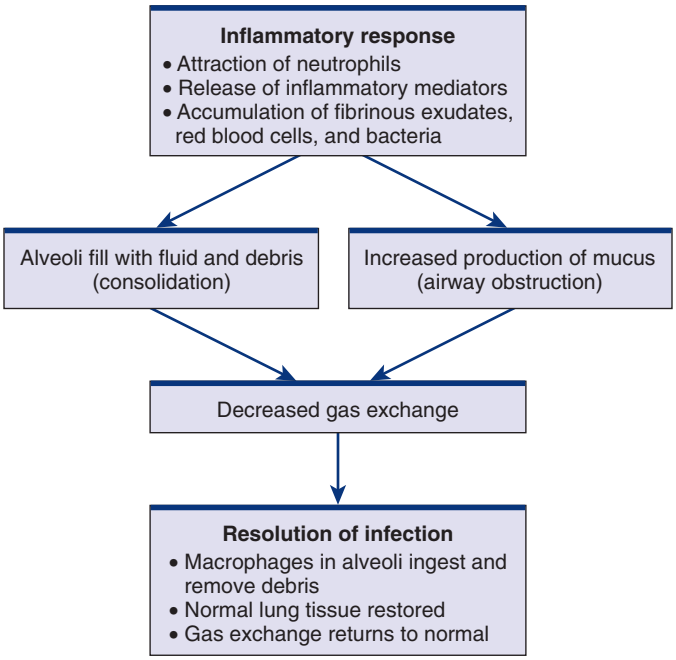

FIG. 28-1 Pathophysiologic course of pneumonia.

CMV, a herpes virus, can cause viral pneumonia. Most CMV infections are asymptomatic or mild, but severe disease can occur in people with an impaired immune response. CMV is the most common life-threatening infectious complication after hematopoietic stem cell transplantation.[8] Antiviral medications (e.g., ganciclovir [Cytovene], foscarnet [Foscavir], cidofovir [Vistide]) and high-dose immunoglobulin are used for treatment.

Pathophysiology

Specific pathophysiologic changes related to pneumonia vary according to the offending organism. Some viruses cause direct injury and cell death. The majority of organisms, however, trigger an inflammatory response in the lung (Fig. 28-1). A vascular reaction occurs, characterized by an increase in blood flow and vascular permeability. Neutrophils are activated to engulf and kill the offending organisms. The neutrophils, the offending organism, and fluid from surrounding blood vessels fill the alveoli and interrupt normal oxygen transportation, leading to clinical manifestations of hypoxia (e.g., tachypnea, dyspnea, tachycardia). Mucus production is also increased, which can obstruct airflow and further decrease gas exchange. Consolidation, a feature typical of bacterial pneumonia, occurs when the normally air-filled alveoli become filled with fluid and debris. Complete resolution and healing occur if there are no complications. Macrophages lyse and process the debris, normal lung tissue is restored, and gas exchange returns to normal.

Clinical Manifestations

The most common presenting symptoms of pneumonia are cough, fever, shaking chills, dyspnea, tachypnea, and pleuritic chest pain. The cough may or may not be productive. Sputum may appear green, yellow, or even rust colored (bloody). Viral pneumonia may initially be seen as influenza, with respiratory symptoms appearing and/or worsening 12 to 36 hours after

onset.[9] The older or debilitated patient may not have classic symptoms of pneumonia. Confusion or stupor (possibly related to hypoxia) may be the only finding. Hypothermia, rather than fever, may also be noted with the older patient. Nonspecific clinical manifestations include diaphoresis, anorexia, fatigue, myalgias, headache, and abdominal pain.

On physical examination, rhonchi and crackles may be auscultated over the affected region. If consolidation is present, bronchial breath sounds, egophony, and increased fremitus (vibration of the chest wall produced by vocalization) may be noted. Patients with pleural effusion may exhibit dullness to percussion over the affected area.

Complications

Complications develop more frequently in older individuals and those with underlying chronic diseases. Potential complications include the following:

- *Pleurisy* (inflammation of the pleura) is relatively common.
- *Pleural effusion* (fluid in the pleural space) can occur. In most cases, the effusion is sterile and is reabsorbed in 1 to 2 weeks. Occasionally, effusions require aspiration by thoracentesis.
- *Atelectasis* (collapsed, airless alveoli) of one or part of one lobe may occur. These areas usually clear with effective coughing and deep breathing.
- *Bacteremia* (bacterial infection in the blood) is more likely to occur in infections with *Streptococcus pneumoniae* and *Haemophilus influenzae.*
- *Lung abscess* is not a common complication of pneumonia. However, it may occur with pneumonia caused by *S. aureus* and gram-negative organisms.
- *Empyema*, the accumulation of purulent exudate in the pleural cavity, occurs in less than 5% of cases and requires antibiotic therapy and drainage of the exudate by a chest tube or open surgical drainage.
- *Pericarditis* results from spread of the infecting organism from infected pleura or via a hematogenous route to the pericardium.
- *Meningitis* can be caused by *S. pneumoniae*. The patient with pneumonia who is disoriented, confused, or drowsy may have a lumbar puncture to evaluate the possibility of meningitis.
- *Sepsis* can occur when bacteria within alveoli enter the bloodstream. Severe sepsis can lead to shock and multisystem organ dysfunction syndrome (MODS) (see Chapter 67).
- *Acute respiratory failure* is one of the leading causes of death in patients with severe pneumonia. Failure occurs when pneumonia damages the lungs' ability to exchange oxygen for carbon dioxide.
- *Pneumothorax* can occur when air collects in the pleura space, causing the lungs to collapse.

Pleurisy, pleural effusion, atelectasis, lung abscess, and pneumothorax are discussed later in this chapter.

Diagnostic Studies

The common diagnostic measures for pneumonia are presented in Table 28-4. History, physical examination, and chest x-ray often provide enough information to make management decisions without costly laboratory tests. Chest x-ray often shows a typical pattern characteristic of the infecting organism and is important in the diagnosis of pneumonia. X-ray can also show pleural effusions. A thoracentesis and/or bronchoscopy with washings may be used to obtain fluid samples for patients not responding to initial therapy.

TABLE 28-4 COLLABORATIVE CARE

Pneumonia

Diagnostic	Collaborative Therapy
• History and physical examination • Chest x-ray • Gram stain of sputum • Sputum culture and sensitivity test • Pulse oximetry or ABGs (if indicated) • Complete blood count, WBC differential, and routine blood chemistries (if indicated) • Blood cultures (if indicated)	• Appropriate antibiotic therapy (see Table 28-6) • Increased fluid intake (at least 3 L/day) • Limited activity and rest • Antipyretics • Analgesics • O_2 therapy (if indicated)

Ideally, a sputum specimen for culture and Gram stain to identify the organism is obtained before beginning antibiotic therapy. However, antibiotic administration should not be delayed if a specimen cannot be readily obtained. Delays in antibiotic therapy can increase morbidity and mortality risks. Blood cultures are done for patients who are seriously ill. Arterial blood gases (ABGs) may be obtained to assess for hypoxemia (partial pressure of oxygen in arterial blood [PaO_2] less than 80 mm Hg), hypercapnia (partial pressure of carbon dioxide in arterial blood [$PaCO_2$] greater than 45 mm Hg), and acidosis. Leukocytosis occurs in the majority of patients with bacterial pneumonia; the white blood cell (WBC) count is usually greater than 15,000/μL (15×10^9/L) with the presence of bands (immature neutrophils).

The use of biologic markers of infection to guide clinical decisions for treatment of pneumonia is under investigation. Serum levels of C-reactive protein (CRP) and procalcitonin have shown promise in providing information to guide the duration of antibiotic therapy.[10]

Collaborative Care

Pneumococcal vaccine is used to prevent *S. pneumoniae* (pneumococcus) pneumonia. Vaccination is recommended for individuals 65 years of age or older and younger patients who are at high risk. A one-time repeat vaccination in 5 years is recommended for those who received their initial vaccination when less than 65 years of age (Table 28-5).

Prompt treatment with the appropriate antibiotic almost always cures bacterial and mycoplasmal pneumonia. In uncomplicated cases the patient responds to drug therapy within 48 to 72 hours. Indications of improvement include decreased temperature, improved breathing, and reduced chest pain. Abnormal physical findings can last more than 7 days. A repeat chest x-ray is obtained in 6 to 8 weeks to assess for resolution.

In addition to antibiotic therapy, supportive measures are individualized to the patient's needs. These may include O_2 therapy to treat hypoxemia, analgesics to relieve chest pain, and antipyretics such as aspirin or acetaminophen for significantly elevated temperature. Although cough suppressants, mucolytics, bronchodilators, and corticosteroids are often prescribed as adjunctive therapy, there is insufficient evidence to support their use.[11]

Individualize rest and activity to the patient's tolerance. Benefits of mobility include improved diaphragm movement and

TABLE 28-5 PNEUMOVAX VACCINATION

Groups for Which Initial Vaccination Is Recommended

- People age ≥65 yr
- People ages 2-64 yr with long-term health problem (e.g., chronic cardiovascular disease, chronic pulmonary disease, sickle cell disease, diabetes mellitus, alcoholism, cirrhosis, leaks of cerebrospinal fluid, or cochlear implant)
- People ages 19-64 yr who smoke cigarettes or have asthma
- People ages 2-64 yr who have a disease or condition that lowers the body's resistance to infection (e.g., Hodgkin's disease, leukemia, lymphoma, kidney failure, multiple myeloma, HIV infection, nephrotic syndrome; those receiving immunosuppressive chemotherapy, radiation therapy, or long-term corticosteroids; asplenia; and after organ or bone marrow transplantation)
- People living in long-term care facilities

Groups for Which Revaccination Is Recommended

People age ≥65 yr	Patients who received vaccine ≥5 yr previously and were <65 yr at the time of vaccination
People ages 2-64 yr who have a disease or condition that lowers the body's resistance to infection (same as above for initial vaccination)	If ≥5 yr have elapsed since receipt of first dose

chest expansion, mobilization of secretions, and prevention of venous stasis.

Currently, no definitive treatment exists for the majority of viral pneumonias. Care is generally supportive. Antiviral therapy may be used to treat pneumonia caused by influenza (e.g., oseltamivir or zanamivir) and a few other select viruses (e.g., acyclovir [Zovirax] for herpes simplex virus).[12]

Drug Therapy. Once the pneumonia is classified, the health care provider bases empiric therapy on the likely infecting organism (see Table 28-2). Table 28-6 presents the drug therapy for bacterial CAP.

For HAP, VAP, and HCAP, empiric antibiotic therapy is based on whether the patient has risk factors for MDR organisms. The prevalence and resistance patterns of MDR pathogens vary among localities and institutions. Therefore the antibiotic regimen needs to be adapted to the local patterns of antibiotic resistance. Appropriate initial antibiotic therapy for HAP, VAP, and HCAP may also vary markedly. Multiple regimens exist, but all should include antibiotics that are effective against both resistant gram-negative and gram-positive organisms. Clinical improvement usually occurs in 3 to 5 days. Patients who deteriorate or fail to respond to therapy require aggressive evaluation to assess for noninfectious etiologies, complications, coexisting infectious processes, or pneumonia caused by a drug-resistant pathogen.

IV antibiotic therapy should be switched to oral therapy as soon as the patient is hemodynamically stable, is improving clinically, is able to ingest oral medication, and has a normally functioning gastrointestinal (GI) tract. Patients on oral therapy do not need to be observed in the hospital and can be discharged to home. Total treatment time for patients with CAP should be a minimum of 5 days, and the patient should be afebrile for 48 to 72 hours before stopping treatment. Longer treatment time may be needed if initial therapy was not active against the identified pathogen or complications occur.

Bacterial Community-Acquired Pneumonia

Patient Variable	Treatment Options
Outpatient	
Previously Healthy	
No recent antibiotic therapy in past 3 mo and no risk for drug-resistant *Staphylococcus pneumoniae* (DRSP)	Macrolide OR doxycycline
Co-morbidities (e.g., COPD; diabetes; chronic heart, liver, lung, or renal disease; malignancy; use of antibiotics in past 3 mo)	Respiratory fluoroquinolone OR β-Lactam plus macrolide (doxycycline may be substituted for macrolide)
Regions with ≥25% Macrolide-Resistant S. pneumoniae	Respiratory fluoroquinolone OR β-Lactam plus macrolide
Inpatient	
Medical Unit	Respiratory fluoroquinolone OR β-Lactam plus macrolide
ICU	β-Lactam plus either azithromycin or respiratory fluoroquinolone
Special Conditions	
• *Pseudomonas* infection	Antipneumococcal, antipseudomonal β-lactam plus either ciprofloxacin or levofloxacin OR Antipneumococcal, antipseudomonal β-lactam plus aminoglycoside and azithromycin OR Antipneumococcal, antipseudomonal β-lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone
• *Pseudomonas* infection but patient has penicillin allergy	Substitute aztreonam for the above β-lactam
• Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA)	Add vancomycin or linezolid (Zyvox)

Types of Antibiotics

Macrolides	erythromycin, azithromycin (Zithromax), clarithromycin (Biaxin)
Fluoroquinolones	moxifloxacin (Avelox, Vigamox), levofloxacin (Levaquin), gemifloxacin (Factive)
β-Lactams	High-dose amoxicillin, amoxicillin/clavulanate (Augmentin), cefpodoxime (Vantin), ceftriaxone (Rocephin), cefuroxime (Ceftin)
Antipneumococcal, antipseudomonal β-lactams	imipenem/cilastatin (Primaxin), meropenem (Merrem), cefepime (Maxipime), piperacillin/tazobactam (Zosyn)

Nutritional Therapy. Hydration is important in the supportive treatment of pneumonia to prevent dehydration and loosen secretions. Individualize and carefully monitor fluid intake if the patient has heart failure. If the patient cannot maintain adequate oral intake, IV administration of fluids and electrolytes may be necessary.

Weight loss often occurs in patients with pneumonia because of increased metabolic needs and difficulty eating due to shortness of breath and pleuritic pain. Small, frequent meals are easier for dyspneic patients to tolerate. Offer foods high in calories and nutrients.

NURSING MANAGEMENT PNEUMONIA

NURSING ASSESSMENT

Table 28-7 presents subjective and objective data to obtain from a patient with pneumonia.

NURSING DIAGNOSES

Nursing diagnoses for the patient with pneumonia may include, but are not limited to, the following:

- Impaired gas exchange *related to* fluid and exudate accumulation at the capillary-alveolar membrane
- Ineffective breathing pattern *related to* inflammation and pain
- Acute pain *related to* inflammation and ineffective pain management and/or comfort measures

Additional information on nursing diagnoses for the patient with pneumonia can be found in eNursing Care Plan 28-1 on the website for this chapter.

PLANNING

The overall goals are that the patient with pneumonia will have (1) clear breath sounds, (2) normal breathing patterns, (3) no signs of hypoxia, (4) normal chest x-ray, and (5) no complications related to pneumonia.

NURSING IMPLEMENTATION

HEALTH PROMOTION. To reduce the risk of pneumonia, teach individuals to practice good health habits, such as frequent hand washing, proper nutrition, adequate rest, regular exercise, and coughing or sneezing into the elbow rather than hands. Avoidance of cigarette smoke is one of the most important health-promoting behaviors. If possible, people should avoid exposure to people with URIs. If a URI occurs, it requires prompt attention with supportive measures (e.g., rest, fluids). If symptoms persist for longer than 7 days, the person should seek medical care. Encourage those at risk for pneumonia (e.g., the chronically ill, older adult) to obtain both influenza and pneumococcal vaccines (see Tables 27-3 and Table 28-5).

Identifying patients at risk (see Table 28-1) and taking measures to prevent pneumonia are priority interventions. Place the patient with altered consciousness in positions (e.g., side-lying, upright) that will prevent or minimize the risk of aspiration. Turn and reposition the patient at least every 2 hours to facilitate adequate lung expansion and to discourage pooling of secretions. Encourage and assist with ambulation and positioning in a chair. In the intensive care unit, strict adherence to all aspects of the ventilator bundle (see Table 68-8), a group of interventions aimed at reducing the risk of VAP, has been shown to significantly reduce VAP.[13]

TABLE 28-7 NURSING ASSESSMENT

Pneumonia

Subjective Data

Important Health Information

Past health history: Lung cancer, COPD, diabetes mellitus, chronic debilitating disease, malnutrition, altered consciousness, immunosuppression, exposure to chemical toxins, dust, or allergens

Medications: Antibiotics; corticosteroids, chemotherapy, or any other immunosuppressants

Surgery or other treatments: Recent abdominal or thoracic surgery, splenectomy, endotracheal intubation, or any surgery with general anesthesia; tube feedings

Functional Health Patterns

Health perception–health management: Cigarette smoking, alcoholism; recent upper respiratory tract infection, malaise

Nutritional-metabolic: Anorexia, nausea, vomiting; chills

Activity-exercise: Prolonged bed rest or immobility; fatigue, weakness; dyspnea, cough (productive or nonproductive); nasal congestion

Cognitive-perceptual: Pain with breathing, chest pain, sore throat, headache, abdominal pain, muscle aches

Objective Data

General

Fever, restlessness or lethargy; splinting of affected area

Respiratory

Tachypnea; pharyngitis; asymmetric chest movements or retraction; decreased excursion; nasal flaring; use of accessory muscles (neck, abdomen); grunting; crackles, friction rub on auscultation; dullness on percussion over consolidated areas, increased tactile fremitus on palpation; pink, rusty, purulent, green, yellow, or white sputum (amount may be scant to copious)

Cardiovascular

Tachycardia

Neurologic

Changes in mental status, ranging from confusion to delirium

Possible Diagnostic Findings

Leukocytosis; abnormal ABGs with ↓ or normal PaO_2, ↓ $PaCO_2$, and ↑ pH initially, and later ↓ PaO_2, ↑ $PaCO_2$, and ↓ pH; positive sputum on Gram stain and culture; patchy or diffuse infiltrates, abscesses, pleural effusion, or pneumothorax on chest x-ray*

*In the older dehydrated patient, chest x-ray may not be indicative of pneumonia until patient is rehydrated.

Patients who have orogastric or nasogastric tubes are at risk for aspiration pneumonia (see Chapter 40). Although the feeding tube is small, an interruption in the integrity of the lower esophageal sphincter can allow reflux of gastric contents. To prevent aspiration, elevate the head of the bed 30 to 45 degrees and monitor gastric residual volumes (see Table 40-12).

Elevate the patient's head-of-bed to at least 30 degrees and have patient sit up for all meals. The patient who has difficulty swallowing needs assistance in eating, drinking, and taking medication to prevent aspiration. Assess for a gag reflex before giving food or fluids in patients who have received local anesthesia to the throat. Patients with impaired mobility from any cause need assistance with turning and moving, as well as encouragement to breathe deeply at frequent intervals. Early mobilization, the use of an incentive spirometer, and twice-daily oral hygiene with chlorhexidine swabs have been shown to significantly reduce the incidence of pneumonia in postoperative

patients.[14] Treat pain to a comfort level that permits the patient to deep breathe, cough, and achieve optimum mobility.

Practice strict medical asepsis and adherence to infection control guidelines to reduce the incidence of health care–associated infections. Staff and visitors should wash their hands on entering and leaving the patient's room. Staff must wash or use sanitizing hand gel before and after providing care and on removing gloves. Respiratory devices, which can harbor microorganisms, have been associated with outbreaks of pneumonia. Use strict sterile aseptic technique when suctioning the patient's trachea, and use caution when handling ventilator circuits, tracheostomy tubing, and nebulizer circuits that can become contaminated from patient secretions. Avoid inappropriate use of antibiotics to prevent the development of drug-resistant organisms.

ACUTE INTERVENTION. Although many patients with pneumonia are treated on an outpatient basis, the nursing care plan for a patient with pneumonia (see eNursing Care Plan 28-1) applies to both these individuals and in-hospital patients. Essential nursing care for patients with pneumonia includes monitoring physical assessment parameters, providing treatment, and monitoring the patient's response to treatment. Along with physical assessment (including pulse oximetry monitoring), prompt collection of specimens and initiation of antibiotics are critical. Oxygen therapy, hydration, nutritional support, breathing exercises, early ambulation, and therapeutic positioning are part of nursing management. Collaboration with respiratory therapy for postural drainage and chest percussion is important.

AMBULATORY AND HOME CARE. Teach the patient about the importance of taking every dose of the prescribed antibiotic, any drug-drug and food-drug interactions for the prescribed antibiotic, and the need for adequate rest to continue recovery. Instruct the patient to drink plenty of liquids (at least 6 to 10 glasses/day, unless contraindicated) and to avoid alcohol and smoking. A cool mist humidifier or warm bath may help the patient breathe easier. Tell patients that it may be several weeks before their usual vigor and sense of well-being return. Explain that a follow-up chest x-ray will be done in 6 to 8 weeks to evaluate resolution of pneumonia. A prolonged period of convalescence may be necessary for the older adult or chronically ill patient.

Teaching should also include information about available influenza and pneumococcal vaccines. Patients can receive the pneumococcal vaccine and influenza vaccine at the same time in different arms.

EVALUATION

The expected outcomes are that the patient with pneumonia will

- Have effective respiratory rate, rhythm, and depth of respirations
- Lungs clear to auscultation

Additional outcomes for the patient with pneumonia are presented in eNursing Care Plan 28-1.

TUBERCULOSIS

Tuberculosis (TB) is an infectious disease caused by *Mycobacterium tuberculosis*. It usually involves the lungs, but any organ can be infected. TB is a primary cause of death worldwide from a potentially curable infectious disease. It is the leading cause of mortality in patients with HIV infection.[15] The incidence of TB worldwide declined until the mid-1980s when HIV disease emerged. The major factors contributing to the resurgence of TB were (1) high rates of TB among patients with HIV infection and (2) the emergence of MDR strains of *M. tuberculosis*. Worldwide, more than two billion people (one third of the population) are currently infected with TB. Although the prevalence of TB has increased in Europe, in the United States it has steadily declined since reaching a resurgence peak in 1992.[16,17]

TB occurs disproportionately in the poor, the underserved, and minorities. In the United States, people at risk include the homeless, residents of inner-city neighborhoods, foreign-born people, those living or working in institutions (long-term care facilities, prisons, shelters, hospitals), IV injecting drug users, people at poverty level, and those with poor access to health care. Immunosuppression from any etiology (e.g., HIV infection, malignancy, long-term corticosteroid use) increases the risk of active TB infection. The prevalence of TB in the United States is highest in those of Asian descent (see Cultural & Ethnic Health Disparities box).

Once a strain of *M. tuberculosis* develops resistance to two of the most potent first-line antituberculous drugs (e.g., isoniazid [INH], rifampin [Rifadin]), it is defined as *multidrug-resistant tuberculosis* (MDR-TB). Extensively drug-resistant TB (XDR-TB) occurs when the organism is also resistant to any of the fluoroquinolones plus any injectable antibiotic agent. Resistance results from several problems, including incorrect prescribing, lack of public health case management, and patient nonadherence to the prescribed regimen.[18]

CULTURAL & ETHNIC HEALTH DISPARITIES

Tuberculosis

- Of the reported tuberculosis (TB) cases in the United States, 82% occur in racial and ethnic minorities.
- Asians have the highest TB rate of any ethnic group in the United States. Native Hawaiian and other Pacific Islanders have the second-highest TB rate.
- African Americans have 40% of the TB cases in U.S.-born people.
- Of all the TB cases in the United States, 60% occur in foreign-born people. This rate is 11 times higher than in U.S.-born people.
- The percentage of foreign-born people with multidrug-resistant TB has increased from 25% in 1993 to 82% in 2010.
- Eleven U.S. states (California, Connecticut, Delaware, Iowa, Maine, Minnesota, Nebraska, New Hampshire, New York, North Dakota, and Utah) have ≥75% of their total cases of TB among foreign-born people.

Source: Centers for Disease Control and Prevention. Trends in tuberculosis—United States 2010, *Morbidity and Mortality Weekly Report* 60:11, 2011.

Etiology and Pathophysiology

M. tuberculosis is a gram-positive, acid-fast bacillus (AFB) that is usually spread from person to person via airborne droplets produced by breathing, talking, singing, sneezing, and coughing. A process of evaporation leaves small droplet nuclei, 1 to 5 μm in size, suspended in the air for minutes to hours. These droplet nuclei are then transmitted via inhalation to another person. TB is not highly infectious, and transmission usually requires close, frequent, or prolonged exposure. Brief exposure to a few tubercle bacilli rarely causes an infection. The disease cannot be spread by touching, sharing food utensils, kissing, or any other type of physical contact.

Factors that influence the likelihood of transmission include the (1) number of organisms expelled into the air, (2) concentration of organisms (small spaces with limited ventilation

TABLE 28-8 CLASSIFICATION OF TUBERCULOSIS (TB)

Class	Exposure or Infection	Description
0	No TB exposure	No TB exposure, not infected (no history of exposure, negative tuberculin skin test)
1	TB exposure, no infection	TB exposure, no evidence of infection (history of exposure, negative tuberculin skin test)
2	Latent TB infection, no disease	TB infection without disease (significant reaction to tuberculin skin test, negative bacteriologic studies, no x-ray findings compatible with TB, no clinical evidence of TB)
3	TB, clinically active	TB infection with clinically active disease (positive bacteriologic studies or both a significant reaction to tuberculin skin test and clinical or x-ray evidence of current disease)
4	TB, but not clinically active	No current disease (history of previous episode of TB or abnormal, stable x-ray findings in a person with a significant reaction to tuberculin skin test; negative bacteriologic studies if done; no clinical or x-ray evidence of current disease)
5	TB suspect	TB suspect (diagnosis pending); person should not be in this classification for >3 mo

would mean higher concentration), (3) length of time of exposure, and (4) immune system of the exposed person. Once inhaled, these small particles lodge in the bronchiole and alveolus. A local inflammatory reaction occurs, and the focus of infection is established. This is called the *Ghon focus,* which develops into a *granuloma,* the hallmark of TB. The formation of a granuloma is a defense mechanism aimed at walling off the infection and preventing further spread. Replication of the bacillus is inhibited and the infection is stopped.

Seventy percent of immunocompetent adults infected with TB are able to completely kill the mycobacteria. The rest of them contain the mycobacteria in a nonreplicating dormant state. Of these individuals, 5% to 10% go on to develop active TB infection when the bacteria begin to multiply months or years later. *M. tuberculosis* is aerophilic (oxygen loving) and thus has an affinity for the lungs. However, the infection can spread via the lymphatic system and find favorable environments for growth in other organs, including the kidneys, epiphyses of the bone, cerebral cortex, and adrenal glands.

Classification

Several systems can be used to classify TB. The American Thoracic Society classifies TB based on development of the disease (Table 28-8). TB can also be classified according to its (1) presentation (primary, latent, or reactivated) and (2) whether it is pulmonary or extrapulmonary.

Primary infection occurs when the bacteria are inhaled and initiate an inflammatory reaction. The majority of people mount effective immune responses to encapsulate these organisms for the rest of their lives, preventing primary infection from progressing to disease.

Latent TB infection (LTBI) occurs in a person who does not have active TB disease (Table 28-9). These individuals are asymptomatic and cannot transmit the TB bacteria to others. An estimated 10 million to 15 million Americans have LTBI; of these, 5% to 10% will develop active TB disease at some point. Therefore treatment of LTBI is important (discussed later in this chapter).

If the initial immune response is not adequate, the body cannot contain the organisms, the bacteria replicate, and *active TB disease* results. When active disease develops within the first 2 years of infection, it is termed *primary TB*. Postprimary TB, or *reactivation TB,* is defined as TB disease occurring 2 or more years after the initial infection. Individuals co-infected with HIV are at greatest risk for developing active TB. Immunosuppression, diabetes mellitus, poor nutrition, aging, pregnancy, stress, and chronic disease can also precipitate the reactivation of LTBI.[18] If the site of TB is pulmonary or laryngeal, the individual is considered infectious and can transmit the disease to others.

Clinical Manifestations

People with LTBI have a positive skin test but are asymptomatic (see Table 28-9). Symptoms of pulmonary TB usually do not develop until 2 to 3 weeks after infection or reactivation. The characteristic pulmonary manifestation is an initial dry cough that frequently becomes productive with mucoid or mucopurulent sputum. Active TB disease may initially manifest with constitutional symptoms such as fatigue, malaise, anorexia, unexplained weight loss, low-grade fevers, and night sweats. Dyspnea is a late symptom that may signify considerable pulmonary disease or a pleural effusion. Hemoptysis, which occurs in less than 10% of patients with TB, is also a late symptom.

Sometimes TB has a more acute, sudden presentation. The patient may have a high fever, chills, generalized flu-like symptoms, pleuritic pain, and a productive cough. Auscultation of

the lungs may be normal or reveal crackles, rhonchi, and/or bronchial breath sounds.

Immunosuppressed (e.g., HIV-infected) people and older adults are less likely to have fever and other signs of an infection. In patients with HIV, classic manifestations of TB such as fever, cough, and weight loss may be wrongly attributed to PCP or other HIV-associated opportunistic diseases. Clinical manifestations of respiratory problems in patients with HIV must be carefully investigated to determine the cause. A change in cognitive function may be the only initial presenting sign of TB in an older person.

The clinical manifestations of extrapulmonary TB depend on the organs infected. For example, renal TB can cause dysuria and hematuria. Bone and joint TB may cause severe pain. Headaches, vomiting, and lymphadenopathy may be present with TB meningitis.

Complications

Appropriately treated pulmonary TB typically heals without complications except for a scar and residual cavitation within the lung. Significant pulmonary damage, although rare, can occur in patients who are poorly treated or who do not respond to anti-TB treatment.

Miliary TB is the widespread dissemination of the mycobacterium. The bacteria are spread via the bloodstream to distant organs. The infection is characterized by a large amount of TB bacilli and may be fatal if left untreated. It can occur as a result of primary disease or reactivation of latent infection. Clinical manifestations of miliary TB slowly progress over a period of days, weeks, or even months. Symptoms vary depending on which organs are infected. Hepatomegaly, splenomegaly, and generalized lymphadenopathy may be present.

Pleural TB can result from either primary disease or reactivation of a latent infection. A pleural effusion is caused by bacteria in the pleural space, which trigger an inflammatory reaction and a pleural exudate of protein-rich fluid. Empyema is less common than effusion but may occur from large numbers of tubercular organisms in the pleural space.

Acute pneumonia may result when large amounts of tubercle bacilli are discharged from granulomas into the lung or lymph nodes. The clinical manifestations are similar to those of bacterial pneumonia.

Because TB can infect organs throughout the body, various acute and long-term complications can result. TB in the spine (Pott's disease) can lead to destruction of the intervertebral disc and adjacent vertebrae. Central nervous system TB can cause severe bacterial meningitis. Abdominal TB can lead to peritonitis, especially in HIV-positive patients. The kidneys, adrenal glands, lymph nodes, and urogenital tract may also be affected.

Diagnostic Studies

Tuberculin Skin Test. The tuberculin skin test (TST) (Mantoux test) using purified protein derivative (PPD) is the standard method to screen people for *M. tuberculosis*. The test is administered by injecting 0.1 mL of PPD intradermally on the dorsal surface of the forearm. The test is read by inspection and palpation 48 to 72 hours later for the presence or absence of induration. Induration (not redness) at the injection site means the person has been exposed to TB and has developed antibodies. (Antibody formation would occur 2 to 12 weeks after the initial exposure to the organisms.) The indurated area (if present) is measured and recorded in millimeters. Based on the size of the induration and the risk factors, an interpretation is made according to diagnostic standards for determining a positive test reaction.[15] (The procedure for performing the TST is described in Chapter 26.) Because the immunocompromised patient may have a decreased response to TST, smaller induration reactions (5 mm or larger) are considered positive. (See Table 26-11 for guidelines in interpreting responses to the TST.)

Some people who were previously infected with TB may have a waning immune response to the TST, resulting in a false negative result. However, the repeated TST may stimulate (boost) the body's ability to react to tuberculin in future tests. A positive reaction to a subsequent test could then be misinterpreted as a new infection, rather than the result of the boosted reaction to an old infection. To prevent misinterpretation in future testing, a two-step testing process is recommended for initial testing for health care workers (who get repeated testing) and for individuals who have a decreased response to allergens. A negative two-step TST ensures that any future positive results can be accurately interpreted as being caused by a new infection.[19]

Interferon-γ Release Assays. Interferon-γ (INF-γ) release assays (IGRAs) provide another screening tool for TB. These whole blood assays detect INF-γ released from T lymphocytes in response to mycobacterial antigens. Examples of IGRAs include QuantiFERON-TB test and the T-SPOT.TB test. Test results are available in a few hours.

IGRAs offer several advantages over the TST in that they require only one patient visit, are not subject to reader bias, have no booster phenomenon, and are not affected by prior bacillus Calmette-Guérin (BCG) vaccination.[15] The cost of an IGRA is substantially higher than the TST. Current guidelines suggest that both tests are viable options and that selection should be based on context and reasons for testing. Neither IGRAs nor TST can distinguish between LTBI and active TB infection. LTBI can only be diagnosed by excluding active TB.

Chest X-Ray. Although the findings on chest x-ray examination are important, it is not possible to make a diagnosis of TB solely on chest x-ray findings, since other diseases can mimic the appearance of TB. The chest x-ray may also appear normal in a patient with TB. Findings suggestive of TB include upper lobe infiltrates, cavitary infiltrates, and lymph node involvement.

Bacteriologic Studies. The diagnosis of TB requires the demonstration of tubercle bacilli bacteriologically. The initial testing involves a microscopic examination of stained sputum smears for AFB. Three consecutive sputum specimens collected on different days are obtained and sent for smear and culture. The culture to grow the organisms for confirmatory diagnosis can take up to 8 weeks. Treatment is warranted pending results for patients in whom clinical suspicion of TB is high. Samples for other suspected TB sites can be collected from gastric washings, cerebrospinal fluid (CSF), or fluid from an effusion or abscess.

Collaborative Care

Most patients with TB are treated on an outpatient basis (Table 28-10). Many people can continue to work and maintain their lifestyles with few changes. Patients with sputum smear–positive TB are generally considered infectious for the first 2 weeks after starting treatment. Advise these patients to restrict visitors and avoid travel on public transportation and trips to public places. Hospitalization may be needed for the severely ill or debilitated.

TABLE 28-10 COLLABORATIVE CARE

Pulmonary Tuberculosis

Diagnostic

- History and physical examination
- Tuberculin skin test (TST)
- QuantiFERON-TB test
- Chest x-ray
- Bacteriologic studies
- Sputum smear for acid-fast bacilli (AFB)
- Sputum culture

Collaborative Therapy

- Long-term treatment with antimicrobial drugs (see Tables 28-11 and 28-12)
- Follow-up bacteriologic studies and chest x-rays

TABLE 28-11 DRUG THERAPY

Tuberculosis (TB)

Drug	Side Effects*
isoniazid (INH)	Hepatitis, asymptomatic elevation of aminotransferases (ALT, AST) Monitor liver function tests monthly
rifampin (Rifadin)	Hepatitis, thrombocytopenia, orange discoloration of bodily fluids (sputum, urine, sweat, tears)
pyrazinamide (PZA)	Hepatitis, arthralgias, hyperuricemia
ethambutol (Myambutol)	Ocular toxicity (decreased red-green color discrimination) Monitor visual acuity and color discrimination regularly
rifabutin (Mycobutin)	Hepatitis, thrombocytopenia, neutropenia, orange discoloration of bodily fluids (sputum, urine, sweat, tears)
rifapentine (Priftin)	Similar to those of rifampin
streptomycin	Ototoxicity, neurotoxicity, nephrotoxicity
bedaquiline (Sirturo)	Dysrhythmias
aminoglycosides capreomycin (Capastat) kanamycin (Kantrex) amikacin (Amikin)	Ototoxicity, nephrotoxicity Used in selected cases for treatment of resistant strains
fluoroquinolones levofloxacin (Levaquin) moxifloxacin (Avelox, Vigamox)	GI disturbance, neurologic effects (dizziness, headache), rash Used in drug-resistant TB

*Only common side effects are listed.
ALT, Alanine transaminase; *AST,* aspartate aminotransferase.

The mainstay of TB treatment is drug therapy (Table 28-11). Promoting and monitoring adherence are critical for treatment to be successful.

Drug Therapy

Active TB Disease. Because of the growing prevalence of MDR-TB, it is important to manage the patient with active TB aggressively. Drug therapy is divided into two phases: initial and continuation (Table 28-12). In most circumstances the treatment regimen for patients with previously untreated TB consists of a 2-month initial phase with four-drug therapy (INH, rifampin, pyrazinamide [PZA], and ethambutol). If drug susceptibility test results indicate that the bacteria are susceptible to all drugs, ethambutol may be discontinued. If PZA cannot be included in the initial phase (because of liver disease, pregnancy, etc.), the remaining three drugs are used for the initial phase.

TABLE 28-12 DRUG THERAPY

Tuberculosis Disease Regimens

Initial Phase	Continuation Phase
Option 1 4-drug regimen consisting of INH, rifampin, pyrazinamide, ethambutol Given daily for 56 doses (8 wk) OR 5 days/wk DOT for 40 doses (8 wk)	INH, rifampin daily for 126 doses (18 wk) OR 5 days/wk DOT for 90 doses (18 wk)
Option 2 4-drug regimen consisting of INH, rifampin, pyrazinamide, ethambutol Given daily for 14 doses (2 wk), followed by twice weekly for 12 doses (6 wk) OR 5 days/wk DOT for 10 doses (2 wk), then twice weekly for 12 doses (6 wk)	INH, rifampin twice weekly for 36 doses (18 wk) OR once weekly for 18 doses (18 wk)
Option 3 4-drug regimen consisting of INH, rifampin, pyrazinamide, ethambutol Given 3 times weekly for 24 doses (8 wk)	INH, rifampin 3 times weekly for 54 doses (18 wk)
Option 4 3-drug regimen consisting of INH, rifampin, ethambutol Given daily for 56 doses (8 wk) OR 5 days/wk DOT for 40 doses (8 wk)	INH, rifampin daily for 217 doses (31 wk) OR 5 days/wk DOT for 155 doses (31 wk) OR twice weekly for 62 doses (31 wk)

DOT, Directly observed therapy; *INH,* isoniazid.

DRUG ALERT: Isoniazid (INH)

- Alcohol may increase hepatotoxicity of the drug. Instruct patient to avoid drinking alcohol during treatment.
- Monitor for signs of liver damage before and while taking drug.

Other drugs can be used if the patient develops a toxic reaction to the primary drugs. The newer rifamycins, rifabutin and rifapentine (Priftin), should be considered first line in special situations: rifabutin for patients receiving medications that have interactions with rifampin or who have an intolerance to rifampin, and rifapentine with INH in once-weekly dosing for selected patients. Treatment for drug-resistant TB is guided by sensitivity testing. MDR-TB therapy typically includes a fluoroquinolone and an injectable antibiotic (see Table 28-11). Bedaquiline (Sirturo), a relatively new drug, is used in combination with other drugs to treat MDR-TB. It works by inhibiting an enzyme needed for *M. tuberculosis* to replicate.

Directly observed therapy (DOT) involves providing the antituberculous drugs directly to patients and watching as they swallow the medications. It is the preferred strategy for all patients with TB to ensure adherence and is recommended for all patients at risk for nonadherence.[15] Nonadherence is a major factor in the emergence of multidrug resistance and treatment failures. Many individuals do not adhere to the treatment program in spite of understanding the disease process and the value of treatment. DOT is an expensive but essential public health measure. The risk for reactivation of TB and MDR-TB is increased in patients who do not complete the full course of therapy. In many areas the public health nurse administers DOT at a clinic site.

ETHICAL/LEGAL DILEMMAS

Patient Adherence

Situation

The health clinic for the homeless discovers that F.C., a 64-year-old African American man with tuberculosis (TB), has not been taking his prescribed medication. He tells you that it is hard for him to get to the clinic to obtain the medication, much less to keep on a schedule. You are concerned not only about this patient, but also about the risks for the other people at the shelter, in the park, and at the meal sites.

Ethical/Legal Points for Consideration

- Adherence is a complex issue involving a person's culture and values, perceived risk of disease, availability of resources, access to treatment, and perceived consequences of available choices.
- Advocacy for the patient and the community obliges you to involve other members of the health care team, such as social services, to assist in obtaining the necessary resources or support for the patient to complete a course of treatment.
- Legally the constitutionally granted right to control one's own body may be limited by the state and federal obligation to protect public health and safety. Most of these laws have provisions for the protection of constitutional rights such as right to counsel, the right to least restrictive alternative in terms of confinement setting, and the right to prompt judicial review.
- The federal government and many states have provisions for quarantine, detention, and treatment. With the threats of bioterrorism and the globalization of exposure to highly lethal infectious diseases, it seems unlikely that the government's power to detain will be removed.

Discussion Questions

1. What alternatives of care can be offered to F.C.?
2. Under what circumstances are health care providers justified in overriding a patient's autonomy or decision making?

When DOT is not used, fixed-dose combination drugs may enhance adherence. Combinations of INH and rifampin (Rifamate) and of INH, rifampin, and PZA (Rifater) are available to simplify therapy. The therapy for people with HIV follows the same therapy options outlined in Table 28-12. However, alternative regimens that include once-weekly INH plus rifapentine continuation dosing in any HIV-infected patient and twice-weekly INH plus rifampin or rifabutin should not be used if $CD4^+$ counts are less than 100/µL. Health care providers must also be alert for possible drug interactions between antiretrovirals (used to treat HIV) and rifamycins.

Teaching patients about the side effects of these drugs and when to seek prompt medical attention is critical. The major side effect of INH, rifampin, and PZA is nonviral hepatitis. Baseline liver function tests (LFTs) are done at the start of treatment. Monthly monitoring of LFTs is done if baseline tests are abnormal.

Latent Tuberculosis Infection. In people with LTBI, drug therapy helps prevent a TB infection from developing into active TB disease. Because a person with LTBI has fewer bacteria, treatment is much easier. Usually only one drug is needed. Drug therapy regimens for LTBI are presented in Table 28-13.

The standard treatment regimen for LTBI is 9 months of daily INH. It is an effective and inexpensive drug that the patient can take orally. The 9-month regimen is more effective, but adherence issues may make a 6-month regimen preferable. For HIV patients and those with fibrotic lesions on chest x-ray, INH is given for 9 months. An alternative 3-month regimen of INH and rifapentine may be used for otherwise healthy patients who are not presumed to be infected with drug-resistant bacilli. Four-month therapy with rifampin may be indicated if the patient is resistant to INH. Because of reports of severe liver injury and deaths, the CDC does not recommend the combination of rifampin and PZA for treatment of LTBI.

TABLE 28-13 DRUG THERAPY

Latent Tuberculosis Infection Regimens

Drugs	Duration	Interval	Minimum Doses
isoniazid	9 mo	Daily	270
		Twice weekly*	76
isoniazid	6 mo	Daily	180
		Twice weekly*	52
isoniazid and rifapentine	3 mo	Once weekly*	12
rifampin	4 mo	Daily	120

* Use directly observed therapy (DOT).

Vaccine. BCG vaccine is a live, attenuated strain of *Mycobacterium bovis*. The vaccine is given to infants in parts of the world with a high prevalence of TB. In the United States it is typically not recommended because of the low risk of infection, the vaccine's variable effectiveness against adult pulmonary TB, and potential interference with TB skin test reactivity. The BCG vaccination can result in a false-positive TST. IGRA results are not affected. The BCG vaccine should be considered only for select individuals who meet specific criteria (e.g., health care workers who are continually exposed to patients with MDR-TB and when infection control precautions are not successful).

NURSING MANAGEMENT TUBERCULOSIS

NURSING ASSESSMENT

Ask the patient about a previous history of TB, chronic illness, or any immunosuppressive medications. Obtain a social and occupational history to determine risk factors for transmission of TB. Assess the patient for productive cough, night sweats, afternoon temperature elevation, weight loss, pleuritic chest pain, and abnormal lung sounds. If the patient has a productive cough, early morning is the ideal time to collect sputum specimens for an AFB smear.

NURSING DIAGNOSES

Nursing diagnoses for the patient with TB may include, but are not limited to, the following:

- Ineffective breathing pattern *related to* decreased lung capacity
- Ineffective airway clearance *related to* increased secretions, fatigue, and decreased lung capacity
- Noncompliance *related to* lack of knowledge of disease process, lack of motivation, long-term nature of treatment, and lack of resources
- Ineffective self-health management *related to* lack of knowledge about the disease process and therapeutic regimen

PLANNING

The overall goals are that the patient with TB will (1) comply with the therapeutic regimen, (2) have no recurrence of disease, (3) have normal pulmonary function, and (4) take appropriate measures to prevent the spread of the disease.

NURSING IMPLEMENTATION

HEALTH PROMOTION. The ultimate goal is to eradicate TB worldwide. Screening programs in known risk groups are of value in detecting individuals with TB. Treatment of LTBI reduces the number of TB carriers in the community. The person with a positive TST should have a chest x-ray to assess for active TB disease. Individuals with a diagnosis of TB must be reported to the public health authorities for identification and assessment of contacts and risk to the community.

Programs to address the social determinants of TB are necessary to decrease transmission of TB.[20] Reducing HIV infection, poverty, overcrowded living conditions, malnutrition, smoking, and drug and alcohol abuse can help minimize TB infection rates. Improving access to health care and education is also important.

ACUTE INTERVENTION. Patients admitted to the emergency department or directly to the nursing unit with respiratory symptoms should be triaged for the possibility of TB. Those strongly suspected of having TB should (1) be placed on airborne isolation; (2) receive a medical workup, including chest x-ray, sputum smear, and culture; and (3) receive appropriate drug therapy. Airborne infection isolation is indicated for the patient with pulmonary or laryngeal TB until the patient is noninfectious (defined as effective drug therapy, clinical improvement, and three negative AFB smears). *Airborne infection isolation* refers to isolation of patients infected with organisms spread by the airborne route. It requires a single-occupancy room with negative pressure and airflow of 6 to 12 exchanges per hour.

High-efficiency particulate air (HEPA) masks are worn whenever entering the patient's room. These masks are highly effective at protecting from small particles 5 µm or less in diameter. Health care providers should be "fit tested" to ensure proper mask size. To be effective, the mask must be molded to fit tightly around the nose and mouth.

Teach patients to cover the nose and mouth with paper tissues every time they cough, sneeze, or produce sputum. The tissues should be thrown into a paper bag and disposed of with the trash, burned, or flushed down the toilet. Emphasize careful hand washing after handling sputum and soiled tissues. If patients need to be out of the negative-pressure room, they must wear a standard isolation mask to prevent exposure to others. Minimize prolonged visitation to other parts of the hospital.

Identify and screen close contacts of the person with TB. Anyone testing positive for TB infection will undergo further evaluation and needs to be treated for either LTBI or active TB disease.

AMBULATORY AND HOME CARE. Patients who respond clinically are discharged home (even with positive cultures) if their household contacts have already been exposed and the patient is not posing a risk to susceptible people. Negative cultures are needed to declare the patient not infectious. Monthly sputum collections for AFB are obtained until two consecutive specimens are culture negative.[15]

Teach the patient how to minimize exposure to close contacts and household members. Homes should be well ventilated, especially the areas where the infected person spends a lot of time. While still infectious, the patient should sleep alone, spend as much time as possible outdoors, and minimize time in congregate settings or on public transportation.

Teach the patient and caregiver about adherence with the prescribed regimen. This is important, since most treatment failures occur because the patient neglects to take the drug, discontinues it prematurely, or takes it irregularly. Strategies to improve adherence to drug therapy include teaching and counseling, reminder systems, incentives or rewards, contracts, and DOT.

Notification of the public health department is required. The public health nurse is responsible for follow-up on household contacts and assessment of the patient for adherence. If adherence is an issue, the public health agency may be responsible for DOT. Most individuals can be considered adequately treated when the therapy regimen has been completed and there is evidence of negative cultures, clinical improvement, and improvement on chest x-ray.

Because about 5% of individuals experience relapses, teach the patient to recognize the symptoms that indicate recurrence of TB. If these symptoms occur, the patient should seek immediate medical attention. Instruct the patient about certain factors that could reactivate TB, such as immunosuppressive therapy, malignancy, and prolonged debilitating illness. If the patient experiences any of these events, the health care provider must be told so that reactivation of TB can be closely monitored. In some situations it is necessary to put the patient on anti-TB therapy. Because smoking is associated with poor outcomes in TB, patients should be encouraged to quit. Provide patients with teaching and resources to help them stop smoking.

EVALUATION

The expected outcomes are that the patient with TB will have

- Complete resolution of the disease
- Normal pulmonary function
- Absence of any complications
- No transmission of TB

ATYPICAL MYCOBACTERIA

There are more than 30 varieties of acid-fast mycobacteria that do not cause TB but can cause pulmonary disease, lymphadenitis, skin or soft tissue disease, or disseminated disease. Pulmonary disease is indistinguishable from TB clinically and radiologically but can be differentiated by bacteriologic culture. Atypical mycobacteria are not airborne and thus are not transmitted by droplets.

Mycobacterium avium complex (MAC), found in aerosols generated from baths, hot spas, and swimming pools, is the most common cause of atypical mycobacteria pulmonary infection. Only a small number of people exposed to the organism actually develop MAC lung disease. People who are immunosuppressed (e.g., HIV/AIDS) or have chronic pulmonary disease are most susceptible. Treatment is similar to that for TB.

PULMONARY FUNGAL INFECTIONS

Pulmonary fungal pneumonia is an infectious process in the lungs caused by endemic (native and common) or opportunis-

TABLE 28-14 FUNGAL INFECTIONS OF THE LUNG

Infection	Organism
Endemic Fungal Infections	
Histoplasmosis	*Histoplasma capsulatum*
Coccidioidomycosis	*Coccidioides immitis*
Blastomycosis	*Blastomyces dermatitidis*
Opportunistic Fungal Infections	
Candidiasis	*Candida albicans*
Aspergillosis	*Aspergillus niger* or *Aspergillus fumigatus*
Cryptococcosis	*Cryptococcus neoformans*

tic fungi (Table 28-14). *Endemic* fungal pathogens cause infection in healthy people and in immunocompromised people in certain geographic locations in the United States. For example, *Coccidioides*, which cause coccidioidomycosis, is a fungus found in the soil of dry, low rainfall areas. It is endemic in many areas of the southwestern United States. *Opportunistic* fungal infections occur in immunocompromised patients (e.g., those being treated with corticosteroids, chemotherapy, and immunosuppressive drugs) and in patients with HIV and cystic fibrosis. These infections can be very serious.

Fungal infections are acquired by inhalation of spores. These infections are not transmitted from person to person, and the patient does not have to be placed in isolation. The clinical manifestations are similar to those of bacterial pneumonia. Skin testing, serology, and biopsy methods assist in identifying the infecting organism.

Amphotericin B remains the standard therapy for treating serious systemic fungal infections. It must be given IV to achieve adequate blood and tissue levels because the GI tract does not absorb it well. Less serious infections can be treated with oral antifungals such as ketoconazole (Nizoral), fluconazole (Diflucan), voriconazole (Vfend), and itraconazole (Sporanox). Effectiveness of therapy can be monitored with fungal serology titers.[21]

LUNG ABSCESS

Etiology and Pathophysiology

A **lung abscess** is caused by necrosis of lung tissue typically resulting from bacteria aspirated from the GI tract or from the oral cavity in patients with periodontal disease. Because oral secretions can contain large amounts of bacteria, even small amounts *(microaspiration)* can cause infection. The abscess usually develops slowly, beginning with an enlarging area of infection that becomes necrotic and eventually forms a cavity filled with purulent material. Lung abscesses can also result from IV drug use, malignancy, pulmonary emboli, TB, and various parasitic and fungal diseases. Abscesses usually contain more than one type of microbe, most commonly reflecting the anaerobic flora of the mouth.

The area of the lung most often affected is the posterior segment of the right upper lobe. The abscess may erode into the bronchial system, causing the production of foul-smelling or sour-tasting sputum. It may grow toward the pleura and cause pleuritic pain. Multiple small abscesses, sometimes referred to as necrotizing pneumonia, can occur within the lung.

Clinical Manifestations and Complications

Clinical manifestations usually occur slowly over a period of weeks to months, especially if anaerobic organisms are the primary cause. Symptoms of abscess caused by aerobic bacteria develop more acutely and resemble bacterial pneumonia. The most common manifestation is cough-producing purulent sputum (often dark brown) that is foul smelling and foul tasting. Hemoptysis is common, especially when an abscess ruptures into a bronchus. Other common manifestations are fever, chills, prostration, night sweats, pleuritic pain, dyspnea, anorexia, and weight loss.

Physical examination of the lungs indicates dullness to percussion and decreased breath sounds on auscultation over the involved segment of lung. Bronchial breath sounds may be transmitted to the periphery if the communicating bronchus becomes patent and the segment begins to drain. Crackles may also be present in the later stages as the abscess drains.

Complications include chronic pulmonary abscess, bronchopleural fistula, bronchiectasis, and empyema from perforation of the abscess into the pleural cavity. The infection can also spread via the bloodstream, resulting in a brain abscess.

Diagnostic Studies

A chest x-ray is often the only test needed. The presence of a solitary cavitary lesion with an air-fluid level and local infiltrate can confirm the diagnosis. Computed tomography (CT) scanning may be helpful if the cavitation is not clear on chest x-ray. As long as there is drainage via the bronchus, sputum will contain the microorganisms that are present in the abscess. However, expectorated sputum samples are contaminated with oral flora, making it difficult to determine the offending organisms. Bronchoscopy may be used (1) to avoid oropharyngeal contamination, (2) to collect a specimen if drainage is delayed, or (3) to investigate if there is a possibility of an underlying malignancy. Pleural fluid and blood cultures may be useful to identify the offending organisms. Although nonspecific, an elevated neutrophil count from a complete blood count (CBC) indicates an infectious process.

NURSING AND COLLABORATIVE MANAGEMENT LUNG ABSCESS

Monitor the patient's vital signs, level of consciousness, and respiratory status for any signs of hypoxia. Note any cyanosis or clubbing of the fingers. Administer oxygen as needed. Broad-spectrum antibiotic coverage is necessary because of mixed bacteria in an abscess. IV antibiotic therapy should be started as soon as possible. Clindamycin is first-line therapy. Parenteral antibiotics are switched to oral antibiotics once the patient shows clinical and x-ray evidence of improvement.

Because of the need for prolonged antibiotic therapy, the patient must be aware of the importance of continuing the medication for the prescribed period. Sometimes the patient is asked to return periodically during the course of antibiotic therapy for repeat cultures and sensitivity tests to ensure that the infecting organism is not becoming resistant to the antibiotic. When antibiotic therapy is completed, the patient is reevaluated.

Teach the patient how to cough effectively (see Table 29-23). Chest physiotherapy and postural drainage are not recommended because they may cause spillage of infection into other

bronchi, extending the infection. Rest, good nutrition, and adequate fluid intake are supportive measures to facilitate recovery. If dentition is poor and dental hygiene is not adequate, encourage the patient to obtain dental care. Consider collaboration with the social worker to evaluate available options for dental care if the patient has limited resources.

Percutaneous drainage of the abscess may be necessary if the patient does not adequately respond to antibiotic treatment. A CT- or ultrasound-guided catheter is placed to drain the abscess. Surgery is rarely indicated but occasionally necessary when reinfection of a large cavitary lesion occurs or to establish a diagnosis when there is evidence of an underlying problem such as a neoplasm. The usual procedure in such cases is a lobectomy. A pneumonectomy may be necessary for multiple abscesses.

ENVIRONMENTAL LUNG DISEASES

Environmental or occupational lung diseases result from inhaled dust or chemicals. The extent of lung damage is influenced by the toxicity of the inhaled substance, amount and duration of exposure, and individual susceptibility. Environmentally induced lung disease includes pneumoconiosis, chemical pneumonitis, hypersensitivity pneumonitis, and asthma. (Asthma is discussed in Chapter 29.)

Pneumoconiosis is a general term for a group of lung diseases caused by inhalation and retention of mineral or metal dust particles. The literal meaning of *pneumoconiosis* is "dust in the lungs." These diseases are classified according to the origin of the dust (e.g., silicosis, asbestosis, berylliosis). Black lung is caused by inhalation of large amounts of coal dust, an occupational hazard for underground coal miners. The inhaled substance is ingested by macrophages, which releases substances that cause cell injury and death. Fibrosis occurs as a result of tissue repair. Repeated exposure eventually results in diffuse *pulmonary fibrosis* (excess connective tissue). Fibrosis is the result of tissue repair after inflammation. Pneumoconiosis and other environmental lung diseases are presented in eTable 28-1 available on the website for this chapter.

Chemical pneumonitis results from exposures to toxic chemical fumes. Acutely, there is diffuse lung injury characterized as pulmonary edema. Chronically, the clinical picture is that of *bronchiolitis obliterans* (obstruction of the bronchioles due to inflammation and fibrosis), which is usually associated with a normal chest x-ray or one that shows hyperinflation. An example is silo filler's disease.

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, is a form of parenchymal lung disease seen when an individual inhales antigens to which he or she is allergic. Examples include bird fancier's lung and farmer's lung.

Lung cancer, either squamous cell carcinoma or adenocarcinoma, is the most frequent cancer associated with asbestos exposure. People with more exposure are at a greater risk of disease. There is a minimum lapse of 15 to 19 years between first exposure and development of lung cancer. Mesotheliomas, both pleural and peritoneal, are also associated with asbestos exposure.

Clinical Manifestations

Symptoms of many environmental lung diseases may not occur until at least 10 to 15 years after the initial exposure to the inhaled irritant. Clinical manifestations common to all pneumoconioses include dyspnea, cough, wheezing, and weight loss. Pulmonary function studies often show reduced vital capacity. A chest x-ray often reveals lung involvement specific to the primary problem. CT scans have been useful in detecting early lung involvement.

Cor pulmonale (described later in this chapter) is a late complication, especially in conditions characterized by diffuse pulmonary fibrosis. COPD is the most common complication of environmental lung disease. Other associated disorders include lung cancer, mesothelioma, and TB. Manifestations of these complications are often the reason the patient seeks health care.

Manifestations of acute hypersensitivity pneumonitis occur 4 to 6 hours after exposure and include chills, fever, cough, shortness of breath, and malaise. Symptoms of chronic hypersensitivity pneumonitis include cough, anorexia, and weight loss. Acute pulmonary edema may occur after exposure to chemical fumes.

Collaborative Care

The best approach to management of environmental lung diseases is to try to prevent or decrease environmental and occupational exposure. Teach the public about the risk and the appropriate protective equipment. Using well-designed, effective ventilation systems and wearing masks are appropriate for some occupations and household activities. Inhalation of smoke by nonsmoking workers has led to regulations requiring a smoke-free workplace. Periodic inspections and monitoring of workplaces by agencies such as the Occupational Safety and Health Administration (OSHA) and the National Institute for Occupational Safety and Health (NIOSH) reinforce the employers' obligations to provide a safe work environment. NIOSH is responsible for workplace safety and health regulations in the United States *(www.cdc.gov/niosh/homepage.html)*.

Early diagnosis is essential to halting the disease process. Strategies are directed toward preventing disease progression and improving or controlling respiratory symptoms. Discontinuation of exposure to the offending inhalant and smoking cessation may or may not be effective in stopping disease progression. Strategies to improve respiratory status include O_2 therapy, inhaled bronchodilators, percussion therapy, and pulmonary rehabilitation. Patients should also be immunized against pneumococcal pneumonia and influenza.

LUNG CANCER

Lung cancer is the leading cause of cancer-related deaths in the United States. Lung cancer accounts for 28% of all cancer deaths, more than those caused by breast, prostate, and colon cancer combined. An estimated 225,000 new cases of lung cancer are diagnosed and 160,000 deaths occur each year in the United States. Although lung cancer is associated with a high mortality and low cure rate, advances in medical treatment are improving the response to treatment.[22]

Etiology

Smoking is responsible for 80% to 90% of all lung cancers. Tobacco smoke contains 60 carcinogens in addition to substances (carbon monoxide, nicotine) that interfere with normal cell development. Exposure to tobacco smoke causes changes in the bronchial epithelium, which usually returns to normal when smoking is discontinued. The risk of lung cancer gradually

CULTURAL & ETHNIC HEALTH DISPARITIES

Lung Cancer

African Americans
- Have the highest incidence of lung cancer
- Are more likely to die from lung cancer than any other ethnic group
- Have a higher rate of lung cancer among men than in other ethnic groups

Whites
- Have the second-highest death rate from lung cancer
- Have a higher rate of lung cancer among women than in other ethnic groups

Asian/Pacific Islanders and Hispanics
- Have the lowest rates of lung cancer in both men and women

Other
- Regional variations among ethnic groups may be due to smoking prevalence, exposure to cancer-causing substances, and other factors.
- Cigarette consumption has decreased dramatically in developed countries such as the United States and Canada.
- Cigarette smoking is increasing in developing countries (e.g., nations in Africa, Asia, Latin America).

Source: Centers for Disease Control and Prevention: Racial/ethnic disparities and geographic differences in lung cancer incidence—38 states and the District of Columbia, 1998-2006. Retrieved from *www.cdc.gov/mmwr/PDF/wk/mm5944.pdf*.

decreases with smoking cessation, reaching that of nonsmokers within 10 to 15 years of quitting.

Assessment of the risk of lung cancer is now divided into three categories: (1) smokers, people who are currently smoking; (2) nonsmokers, people who formerly smoked; and (3) never smokers. The Memorial Sloan-Kettering Cancer Center has developed a tool that calculates risk for developing lung cancer for smokers and former smokers who quit 20 years ago or less (*www.mskcc.org/cancer-care/adult/lung/prediction-tools*).

The risk of developing lung cancer is directly related to total exposure to tobacco smoke, measured by total number of cigarettes smoked in a lifetime, age of smoking onset, depth of inhalation, tar and nicotine content, and the use of unfiltered cigarettes. Sidestream smoke (smoke from burning cigarettes, cigars) contains the same carcinogens found in mainstream smoke (smoke inhaled and exhaled by the smoker). This exposure to secondhand smoke creates a health risk to nonsmoking adults and children.

Other common causes of lung cancer include high levels of pollution, radiation (especially radon exposure), and asbestos.[22] Heavy or prolonged exposure to industrial agents such as ionizing radiation, coal dust, nickel, uranium, chromium, formaldehyde, and arsenic can also increase the risk of lung cancer, especially in smokers.

Marked variations exist in a person's propensity to develop lung cancer. Although genetic factors are not yet well understood, mutations in the epidermal growth factor receptor gene *(EGFR)* may be linked to familial lung cancer.[22] It is also theorized that people have different genetic carcinogen-metabolizing pathways. This may explain why some smokers develop lung cancer and others do not.

Differences in lung cancer incidence, risk factors, and survival exist between men and women (see Gender Differences box above). Genetic, hormonal, and molecular influences may contribute to these differences. Female smokers have a higher relative risk of developing lung cancer than male smokers.

GENDER DIFFERENCES

Lung Cancer

Men	Women
• More men than women are diagnosed with lung cancer. • More men than women die from lung cancer. • Male smokers are 10 times more likely to develop lung cancer than nonsmokers. • Men with lung cancer have a worse prognosis than women. • Lung cancer incidence and deaths are decreasing in men.	• Lung cancer incidence and deaths are increasing in women. • Women develop lung cancer after fewer years of smoking than men do. • Women develop lung cancer at a younger age than men. • Women are more likely to develop small cell carcinoma than men. • Nonsmoking women are at greater risk of developing lung cancer than men. • Women with lung cancer live, on the average, 12 months longer than men.

FIG. 28-2 Lung cancer (peripheral adenocarcinoma). The tumor shows prominent black pigmentation, suggestive of having evolved in an anthracotic scar.

Pathophysiology

Most primary lung tumors are believed to arise from mutated epithelial cells. The development of mutations, which are caused by carcinogens, are also influenced by various genetic factors.[23] Once started, continued tumor development is promoted by epidermal growth factor. These cells grow slowly, taking 8 to 10 years for a tumor to reach 1 cm in size, the smallest lesion detectable on an x-ray. Lung cancers occur primarily in the segmental bronchi or beyond and have a preference for the upper lobes of the lungs (Figs. 28-2 and 28-3).

Primary lung cancers are categorized into two broad subtypes (Table 28-15): non–small cell lung cancer (NSCLC) (80%) and small cell lung cancer (SCLC) (20%).[22] Lung cancers metastasize primarily by direct extension and via the blood and lymph system. The common sites for metastasis are the liver, brain, bones, lymph nodes, and adrenal glands.

Paraneoplastic Syndrome. *Paraneoplastic syndrome* is caused by humoral factors (hormones, cytokines) excreted by tumor cells or by an immune response against the tumor.

TABLE 28-15 TYPES OF PRIMARY LUNG CANCER

Type	Growth Rate	Characteristics	Response to Therapy
Non–Small Cell Lung Cancer (NSCLC)			
Squamous cell carcinoma	Slow	Accounts for 20%-30% of lung cancers. More common in men. Centrally located, producing early symptoms of nonproductive cough and hemoptysis. Does not have a strong tendency to metastasize.	Surgical resection may be attempted. Adjuvant chemotherapy and radiation. Depending on the staging, life expectancy is better than for small cell lung cancer.
Adenocarcinoma	Moderate	Accounts for 30%-40% of lung cancers. Most common lung cancer in people who have not smoked; more common in women. Peripherally located. Often has no clinical manifestations until widespread metastasis is present.	Surgical resection may be attempted depending on the staging. Does not respond well to chemotherapy.
Large cell (undifferentiated) carcinoma	Rapid	Accounts for 10% of lung cancers. Composed of large cells that are anaplastic and often arise in the bronchi. Is highly metastatic via lymphatics and blood.	Surgery is not usually attempted because of high rate of metastases. Tumor may be radiosensitive but often recurs.
Small Cell Lung Cancer (SCLC)			
Small cell carcinoma	Very rapid	Accounts for about 20% of lung cancers. Most malignant form of lung cancer. Spreads early via lymphatics and bloodstream; frequent metastasis to brain. Associated with endocrine disturbances.	Chemotherapy mainstay of treatment but overall poor prognosis. Radiation is used as adjuvant therapy and palliative measure.

FIG. 28-3 Lung carcinoma. The gray-white tumor tissue is infiltrating the lung. Histologically this tumor is identified as a squamous cell carcinoma.

Sometimes the symptoms of paraneoplastic syndrome manifest even before the diagnosis of a malignancy.

Examples of paraneoplastic syndrome include hypercalcemia, syndrome of inappropriate antidiuretic hormone (SIADH), adrenal hypersecretion, hematologic disorders, and neurologic syndromes. SCLCs are most often associated with the paraneoplastic syndrome. These conditions may stabilize with treatment of the underlying neoplasm.[24] (These effects are discussed in the section on metabolic emergencies in Chapter 16 on pp. 277-278.)

Clinical Manifestations

The clinical manifestations of lung cancer are usually nonspecific and appear late in the disease process. Symptoms may be masked by a chronic cough attributed to smoking or smoking-related lung disease. Manifestations depend on the type of primary lung cancer, its location, and metastatic spread. Lung

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Which Interventions Improve Well-Being in Lung Cancer?

Clinical Question

In patients with lung cancer (P), what is the effectiveness of nonpharmacologic interventions (I) on symptoms, psychologic functioning, and quality of life (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs) and quasi-randomized clinical trials

Critical Appraisal and Synthesis of Evidence

- Fifteen trials ($n = 1440$) of patients diagnosed with lung cancer receiving various nonpharmacologic interventions, including exercise and nutrition, breathlessness and pain management, progressive muscle relaxation, foot reflexology, and counseling.
- Significant benefits resulted from nurse-led breathlessness programs.
- Counseling may assist patients in coping with emotional symptoms.
- Exercise and nutrition interventions did not improve quality of life in the long term.
- Reflexology may provide short-term help for pain and anxiety.

Conclusion

- Nonpharmacologic interventions can improve anxiety, depression, and symptoms such as breathlessness.

Implications for Nursing Practice

- Encourage patients to participate in programs that help reduce breathlessness and other distressful symptoms.
- Follow-up with patients who are self-managing their symptoms.
- Engage in educational programs to increase your ability to deliver high-quality supportive care.

TABLE 28-16 COLLABORATIVE CARE

Lung Cancer

Diagnostic	Collaborative Therapy
• History and physical examination • Chest x-ray • Cytologic study of sputum, bronchial washings, or pleural space fluid • Bronchoscopy • Computed tomography (CT) scan • Magnetic resonance imaging (MRI) • Positron emission tomography (PET) • Mediastinoscopy • Video-assisted thoracoscopic surgery (VATS) • Transbronchial or percutaneous fine-needle aspiration	• Surgery • Radiation therapy • Chemotherapy • Biologic and targeted therapy • Prophylactic cranial radiation • Bronchoscopic laser therapy • Photodynamic therapy • Airway stenting • Cryotherapy

cancer frequently manifests as a lobar pneumonia that does not respond to treatment.

One of the most common symptoms of lung cancer, and often the one reported first, is a persistent cough. Blood-tinged sputum may be produced because of bleeding caused by the malignancy. The patient may complain of dyspnea or wheezing. Chest pain, if present, may be localized or unilateral, ranging from mild to severe.

Later manifestations include nonspecific systemic symptoms such as anorexia, fatigue, weight loss, and nausea and vomiting. Hoarseness may be present as a result of laryngeal nerve involvement. Unilateral paralysis of the diaphragm, dysphagia, and superior vena cava obstruction may occur because of intrathoracic spread of the malignancy. Sometimes there are palpable lymph nodes in the neck or axillae. Mediastinal involvement may lead to pericardial effusion, cardiac tamponade, and dysrhythmias.

Diagnostic Studies

A chest x-ray is the initial diagnostic test used for patients with suspected lung cancer. Approximately 5% of cases are found incidentally on a chest x-ray performed for unrelated conditions.[22] The x-ray may identify a lung mass or infiltrate. Evidence of metastasis to the ribs or vertebrae and a pleural effusion may also be seen on chest x-ray. CT scanning is used to further evaluate the lung mass. CT scans can identify the location and extent of masses in the chest, any mediastinal involvement, and lymph node enlargement.

Sputum cytologic studies can identify malignant cells, but results are positive in only 20% to 30% of specimens because the malignant cells are not always present in the sputum. Biopsy is necessary for a definitive diagnosis. Cells for biopsy can be obtained by CT-guided needle aspiration, bronchoscopy, mediastinoscopy, or video-assisted thoracoscopic surgery (VATS) (see Chapter 26). If a thoracentesis is performed to relieve a pleural effusion, the fluid is also analyzed for malignant cells.

Accurate assessment of lung cancer is critical for staging and determining appropriate treatment. Bone scans and CT scans of the brain, pelvis, and abdomen are used to determine if metastatic disease is present. A complete history and physical examination, CBC with differential, chemistry panel, LFTs, renal function tests, and pulmonary function tests are necessary. Magnetic resonance imaging (MRI) and/or positron emission tomography (PET) may also be used to evaluate and stage lung cancer. Table 28-16 summarizes the diagnostic management of lung cancer.

TABLE 28-17 STAGING OF NON–SMALL CELL LUNG CANCER

Stages		Characteristics
I		Tumor is small and localized to lung. No lymph node involvement.
	A	Tumor <3 cm.
	B	Tumor 3-5 cm and invading surrounding local areas.
II		Increased tumor size, some lymph node involvement.
	A	Tumor 3-5 cm with invasion of lymph nodes on same side of chest OR Tumor 5-7 cm without lymph node involvement.
	B	Tumor 5-7 cm involving the bronchus and lymph nodes on same side of chest and tissue of other local organs OR Tumor >7 cm without lymph node involvement.
III		Increased spread of tumor
	A	Tumor spread to the nearby structures (chest wall, pleura, pericardium) and regional lymph nodes.
	B	Extensive tumor involving heart, trachea, esophagus, mediastinum, malignant pleural effusion, contralateral lymph nodes, scalene or supraclavicular lymph nodes.
IV		Distant metastasis.

Staging. Staging of NSCLC is performed according to the TNM staging system (see Table 16-5). Under the TNM system, the tumor is grouped into four stages with A or B subtypes. A simplified version of staging of NSCLC is presented in Table 28-17. Patients with stages I, II, and IIIA disease may be surgical candidates. However, stage IIIB or IV disease is usually inoperable and has a poor prognosis.

Staging of SCLC by TNM has not been useful because this cancer is aggressive and is always considered systemic. The stages of SCLC are *limited* and *extensive*. Limited means that the tumor is confined to one side of the chest and regional lymph nodes. Extensive SCLC means that the cancer extends beyond the limited stage. Approximately 65% to 70% of patients with SCLC have extensive disease. On average, patients with extensive SCLC survive only 12 months with treatment and 6 weeks without.[25]

Screening for Lung Cancer. Screening for high-risk patients is supported by the recent National Lung Screening Trial (NLST). This study showed a 20% decrease in deaths from lung cancer in patients who underwent screening with low-dose spiral CT scanning, compared with those who had chest x-rays.[26] Only those patients who meet the following criteria should be considered for screening: 55 to 74 years old, current or former smokers with at least a 30 pack-year smoking history, former smokers who quit within the past 15 years, no history of lung cancer, not on home O_2 therapy.[27-29]

Collaborative Care

Surgical Therapy. Surgical resection is the treatment of choice in NSCLC stages I to IIIA without mediastinal involvement, since resection provides the best chance for a cure. The 5-year survival rate in stage I and II disease ranges from 30% to 50%. Factors that affect survival include the size of the primary tumor and co-morbidities. For other NSCLC stages, patients may require surgery in conjunction with radiation therapy and/or chemotherapy. Fifty percent of NSCLCs are not resectable at the time of diagnosis.

The surgical procedures that may be performed include pneumonectomy (removal of one entire lung), lobectomy (removal of one or more lobes of the lung), or segmental or wedge resection procedures. VATS may be used to treat lung cancers near the outside of the lung. Surgery is generally not indicated for SCLC because of its rapid growth and dissemination at the time of diagnosis.

When the tumor is considered operable, the patient's cardiopulmonary status must be evaluated to determine the ability to withstand surgery. Pulmonary function studies and ABGs are often used to assess the patient's cardiopulmonary status.

Radiation Therapy. Radiation therapy may be used as treatment for both NSCLC and SCLC. Radiation therapy may be given as curative therapy, palliative therapy (to relieve symptoms), or adjuvant therapy in combination with surgery or chemotherapy.

Radiation therapy may be used as primary therapy in the individual who is unable to tolerate surgical resection because of co-morbidities. Radiation therapy also relieves symptoms of dyspnea and hemoptysis resulting from bronchial obstructive tumors and treats superior vena cava syndrome. It can also be used to treat pain that is caused by metastatic bone lesions or cerebral metastasis. Sometimes radiation is used preoperatively to reduce the tumor mass before surgical resection. Complications of radiation therapy include esophagitis, skin irritation, nausea and vomiting, anorexia, and radiation pneumonitis (see Chapter 16).

Stereotactic Body Radiotherapy. Stereotactic body radiotherapy (SBRT), also called stereotactic surgery or radiosurgery, is a new lung cancer treatment. It is a type of radiation therapy that uses high doses of radiation delivered accurately to the tumor. SBRT provides an option for patients with early stage lung cancers who are not surgical candidates for other medical reasons. SBRT is an outpatient procedure that uses special positioning procedures and radiology techniques so that a higher dose of radiation can be delivered to the tumor, and only a small part of the healthy lung is exposed. Therapy is given over 1 to 3 days.

Chemotherapy. Chemotherapy is the primary treatment for SCLC. In NSCLC, chemotherapy may be used in the treatment of nonresectable tumors or as adjuvant therapy to surgery. A variety of chemotherapy drugs and multidrug regimens (i.e., protocols) have been used. Chemotherapy for lung cancer typically consists of combinations of two or more of the following drugs: etoposide (VePesid), carboplatin (Paraplatin), cisplatin (Platinol), paclitaxel (Taxol), vinorelbine (Navelbine), cyclophosphamide (Cytoxan), ifosfamide (Ifex), docetaxel (Taxotere), gemcitabine (Gemzar), and pemetrexed (Alimta).

Targeted Therapy. Targeted therapy uses drugs that block the growth of molecules involved in specific aspects of tumor growth (see Chapter 16). Because it inhibits growth rather than directly kills cancer cells, targeted therapy may be less toxic than chemotherapy. One type of targeted therapy for patients with NSCLC inhibits tyrosine kinase, an enzyme associated with epidermal growth factor receptor. These drugs (e.g., erlotinib [Tarceva]) block signals for growth in the cancer cells.

Another kinase inhibitor, crizotinib (Xalkori), is used to treat patients with NSCLC who have an abnormal anaplastic lymphoma kinase *(ALK)* gene. This drug directly inhibits the kinase protein produced by the *ALK* gene that is responsible for cancer development and growth.

Other drugs, such as bevacizumab (Avastin), inhibit the growth of new blood vessels (angiogenesis) by targeting vascular endothelial growth factor.

Other Therapies

Prophylactic Cranial Radiation. Patients with SCLC have early metastases, especially to the central nervous system. Most chemotherapy does not penetrate the blood-brain barrier. Therefore after successful systemic treatment, the patient is at risk for cerebral metastases. Prophylactic radiation has been shown to decrease the incidence of cerebral metastases and improve the survival rate in patients with limited SCLC.[22]

Bronchoscopic Laser Therapy. Bronchoscopic laser therapy makes it possible to remove obstructing bronchial lesions. The neodymium : yttrium-aluminum-garnet (Nd:YAG) laser is most commonly used for laser resection using either the flexible or the rigid bronchoscope. The laser's thermal energy is transmitted to the target tissue. It is a safe and effective treatment of endobronchial obstructions from tumors. Symptoms of airway obstruction are relieved as a result of thermal necrosis and shrinkage of the tumor. The procedure may be repeated as needed.[27]

Photodynamic Therapy. Photodynamic therapy can be used to treat very early stage lung cancers that are confined to the outer layers of the airways. It can also remove lesions obstructing the airway. Porfimer (Photofrin) is injected IV and selectively concentrates in tumor cells. After a set time (usually 48 hours), the tumor is exposed to laser light via bronchoscopy, activating the drug and causing cell death. Necrotic tissue is removed with bronchoscopy a few days later.[27] This process can also be repeated as needed.

Airway Stenting. Stents are used alone or in combination with other techniques for relief of dyspnea, cough, or respiratory insufficiency. The advantage of an airway stent is that it supports the airway wall against collapse or external compression and can delay extension of tumor into the airway lumen.

Radiofrequency Ablation. Radiofrequency ablation therapy is being used to treat small NSCLC lung tumors that are near the outer edge of the lungs. This therapy is an alternative to surgery in patients who cannot or elect not to have surgery. A thin, needle-like probe is inserted through the skin into the tumor. CT scans are used to guide placement. An electric current is then passed through the probe, which heats and destroys tumor cells. Local anesthesia is used for this outpatient procedure.[27]

NURSING MANAGEMENT LUNG CANCER

NURSING ASSESSMENT

It is important to determine the patient and caregiver's understanding of diagnostic tests (those completed as well as those planned), the diagnosis or potential diagnosis, the treatment options, and the prognosis. At the same time, assess the patient's level of anxiety and support provided by the patient's significant others. Subjective and objective data that should be obtained from a patient with lung cancer are presented in Table 28-18.

NURSING DIAGNOSES

Nursing diagnoses for the patient with lung cancer may include, but are not limited to, the following:

- Ineffective airway clearance *related to* increased tracheobronchial secretions and presence of tumor

TABLE 28-18 NURSING ASSESSMENT

Lung Cancer

Subjective Data

Important Health Information

Past health history: Exposure to secondhand smoke, airborne carcinogens (e.g., asbestos, radon, hydrocarbons), or other pollutants; urban living environment; chronic lung disease (e.g., TB, COPD, bronchiectasis)

Medications: Cough medicines or other respiratory medications

Functional Health Patterns

Health perception–health management: Smoking history, including amount per day and number of years; family history of lung cancer; frequent respiratory tract infections

Nutritional-metabolic: Anorexia, nausea, vomiting, dysphagia (late); weight loss; chills

Activity-exercise: Fatigue; persistent cough (productive or nonproductive); dyspnea at rest or with exertion, hemoptysis (late symptom)

Cognitive-perceptual: Chest pain or tightness, shoulder and arm pain, headache, bone pain (late symptom)

Objective Data

General

Fever, neck and axillary lymphadenopathy, paraneoplastic syndrome (e.g., syndrome of inappropriate ADH secretion)

Integumentary

Jaundice (liver metastasis); edema of neck and face (superior vena cava syndrome), digital clubbing

Respiratory

Wheezing, hoarseness, stridor, unilateral diaphragm paralysis, pleural effusions (late signs)

Cardiovascular

Pericardial effusion, cardiac tamponade, dysrhythmias (late signs)

Neurologic

Unsteady gait (brain metastasis)

Musculoskeletal

Pathologic fractures, muscle wasting (late)

Possible Diagnostic Findings

Observance of lesion on chest x-ray, CT scan, or PET scan; MRI findings of vertebral, spinal cord, or mediastinal invasion; positive sputum or bronchial washings for cytologic studies; positive fiberoptic bronchoscopy and biopsy findings

ADH, Antidiuretic hormone.

- Anxiety *related to* lack of knowledge of diagnosis or unknown prognosis and treatments
- Ineffective self-health management *related to* lack of knowledge about the disease process and therapeutic regimen
- Ineffective breathing pattern *related to* decreased lung capacity
- Impaired gas exchange *related to* tumor obstructing airflow

PLANNING

The overall goals are that the patient with lung cancer will have (1) effective breathing patterns, (2) adequate airway clearance, (3) adequate oxygenation of tissues, (4) minimal to no pain, and (5) a realistic attitude about treatment and prognosis.

NURSING IMPLEMENTATION

HEALTH PROMOTION. The best way to halt the epidemic of lung cancer is to prevent people from starting to smoke and help smokers stop smoking. Because most smokers start in the teenage years, prevention of teen smoking has the most significant role in reducing the incidence of lung cancer. A wealth of material is available to the smoker who is interested in smoking cessation. The CDC provides an index of tools *(www.cdc.gov/tobacco/quit_smoking/cessation/index.htm)*. (Smoking cessation is discussed in Chapter 11.)

Modeling healthy behavior by not smoking, promoting smoking cessation programs, and actively supporting education and policy changes related to smoking are important nursing activities. Many changes have occurred as a result of the recognition that passive smoke is a health hazard. Laws prohibit smoking in most public places and limit public smoking to designated areas. Most hospital environments are now completely smoke-free, prohibiting smoking by employees and patients. A new trend is for hospitals to refuse employment to anyone testing positive for nicotine. This includes not only smokers but also nonsmokers who are routinely exposed to secondhand smoke.

ACUTE INTERVENTION. Care of the patient with lung cancer initially involves support and reassurance during the diagnostic evaluation. It is important to recognize the multiple stressors that occur when someone is diagnosed with lung cancer. The stress response is a normal and adaptive response, but can become detrimental when it is overwhelming and intense. Patients suffer the stress of their symptoms, including dyspnea and cough. Diagnostic and therapeutic procedures provide additional stress by placing patients in unfamiliar environments with unusual and perhaps painful results. Emotional stressors include the knowledge of the high mortality rate of lung cancer and the causal effect of cigarette smoking. Worries about role performance and ability to care for their family while undergoing cancer treatment provide further stress. Carefully assess each individual, since he or she will experience unique stressors. The insight gained will help the patient and caregiver cope with the stress of the illness and treatment.[30]

Care of the patient undergoing thoracic surgery is discussed later in this chapter on p. 548. Care of the patient undergoing radiation therapy and chemotherapy is discussed in Chapter 16. Individualized care depends on the plan for treatment. Assessment and intervention in symptom management are pivotal, as is teaching the patient to recognize signs and symptoms that may indicate progression or recurrence of disease. Provide patient comfort, teach methods to reduce pain, monitor for side effects of prescribed medications, foster appropriate coping strategies for the patient and caregiver, assess smoking cessation readiness, and help patients access resources to deal with the illness.

AMBULATORY AND HOME CARE. Teach signs and symptoms to report, such as hemoptysis, dysphagia, chest pain, and hoarseness. Counseling patients on smoking cessation and prevention is essential in decreasing morbidity and mortality risks associated with lung cancer. Encourage the patient and the family to provide a smoke-free environment. This may include smoking cessation for multiple family members. If the treatment plan includes home oxygen, the teaching plan must include the safe use of oxygen.

For many individuals who have lung cancer, little can be done to significantly prolong their lives. Radiation therapy and chemotherapy can provide palliative relief from distressing

symptoms. Constant pain may become a major problem. (Measures used to relieve pain are discussed in Chapter 9. Care of the patient with cancer is discussed in Chapter 16.) The palliative care team should be involved as the patient and the family move toward the end of life (see Chapter 10). The team can provide information about disability, financial planning, and community resources for end-of-life care such as hospice.

EVALUATION

The expected outcomes are that the patient with lung cancer will have

- Adequate breathing patterns
- Adequate oxygenation
- Minimal to no pain
- Realistic attitude about prognosis

OTHER TYPES OF LUNG TUMORS

SCLC and NSCLC account for 95% of lung tumors. The other 5% include the following:

- *Hamartomas*, the most common benign tumor, is a slow-growing congenital tumor composed of fibrous tissue, fat, and blood vessels.
- *Mucous gland adenoma* is a benign tumor arising in the bronchi that consists of columnar cystic spaces.
- *Mesotheliomas* are either malignant or benign and originate from the visceral pleura. Malignant mesotheliomas are associated with exposure to asbestos. Benign mesotheliomas are localized lesions.
- Secondary metastases from other malignancies can occur. Malignant cells from another part of the body reach the lungs via the pulmonary capillaries or the lymphatic network. The primary malignancies that spread to the lungs often originate in the GI or genitourinary tract and in the breast. General symptoms of lung metastases are chest pain and nonproductive cough.

CHEST TRAUMA AND THORACIC INJURIES

Traumatic injuries to the chest contribute to 75% of all traumatic deaths.[31] Thoracic injuries range from simple rib fractures to complex life-threatening rupture of organs. The mechanisms of injuries causing chest trauma are separated into two categories: blunt trauma and penetrating trauma.

Blunt trauma occurs when the chest strikes or is struck by an object. The impact can cause deceleration, acceleration, shearing, and compression of thoracic structures. The external injury may appear minor, but internally the organs may have severe injuries. The injuries can occur on the same side as the impact and on the opposite side as the tissue moves back and forth. Rib and sternal fractures can lacerate lung tissue. In a high-velocity impact the shearing force may result in laceration or tearing of the aorta. Compression of the chest may result in contusion, crush injury, and organ rupture.

Penetrating trauma is an open injury in which a foreign body impales or passes through the body tissues, creating an open wound. Examples include knife wounds, gunshot wounds, and injuries with other sharp objects. eTable 28-2 (available on the website for this chapter) describes traumatic injuries as they relate to the categories of trauma and the mechanism of injury. Emergency care of the patient with a chest injury is presented in Table 28-19.

The most common thoracic emergencies and their management are described in Table 28-20.

TABLE 28-19 EMERGENCY MANAGEMENT

Chest Trauma

Etiology	Assessment Findings	Interventions
Blunt • Motor vehicle accident • Pedestrian accident • Fall • Assault with blunt object • Crush injury • Explosion **Penetrating** • Knife • Gunshot • Stick • Arrow • Other missiles	**Respiratory** • Dyspnea, respiratory distress • Cough with or without hemoptysis • Cyanosis of mouth, face, nail beds, mucous membranes • Tracheal deviation • Audible air escaping from chest wound • Decreased breath sounds on side of injury • Decreased O_2 saturation • Frothy secretions **Cardiovascular** • Rapid, thready pulse • Decreased BP • Narrowed pulse pressure • Asymmetric BP values in arms • Distended neck veins • Muffled heart sounds • Chest pain • Crunching sound synchronous with heart sounds • Dysrhythmias **Surface Findings** • Bruising • Abrasions • Open chest wound • Asymmetric chest movement • Subcutaneous emphysema	**Initial** • Ensure patent airway. • Administer O_2 to keep SpO_2 >90%. • Establish IV access with two large-bore catheters. Begin fluid resuscitation as appropriate. • Remove clothing to assess injury. • Cover sucking chest wound with nonporous dressing taped on three sides. • Stabilize impaled objects with bulky dressings. *Do not remove object.* • Assess for other significant injuries and treat appropriately. • Stabilize flail rib segment with hand followed by application of large pieces of tape horizontal across the flail segment. • Place patient in a semi-Fowler's position or position patient on the injured side if breathing is easier *after* cervical spine injury has been ruled out. • Prepare for emergency needle decompression if tension pneumothorax or cardiac tamponade present. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, cardiac rhythm, respiratory status, and urine output. • Anticipate intubation for respiratory distress. • Release dressing if tension pneumothorax develops after sucking chest wound is covered.

TABLE 28-20 EMERGENCY MANAGEMENT

Thoracic Injuries

Injury	Definition	Manifestations	Interventionist
Pneumothorax	Air in pleural space (see Fig. 28-4).	Dyspnea, decreased movement of involved chest wall, diminished or absent breath sounds on the affected side, hyperresonance to percussion	Chest tube insertion with flutter valve or chest drainage system.
Hemothorax	Blood in the pleural space, may or may not occur in conjunction with pneumothorax.	Dyspnea, diminished or absent breath sounds, dullness to percussion, decreased Hgb, shock depending on blood volume lost	Chest tube insertion with chest drainage system. Autotransfusion of collected blood, treatment of hypovolemia as necessary.
Tension pneumothorax	Air in pleural space that does not escape. The increased air in the pleural space shifts organs and increases intrathoracic pressure (see Fig. 28-5).	Cyanosis, air hunger, violent agitation, tracheal deviation away from affected side, subcutaneous emphysema, neck vein distention, hyperresonance to percussion	Medical emergency: needle decompression followed by chest tube insertion with chest drainage system.
Flail chest	Fracture of two or more adjacent ribs in two or more places with loss of chest wall stability (see Fig. 28-6).	Paradoxic movement of chest wall, respiratory distress. May be associated hemothorax, pneumothorax, pulmonary contusion	O_2 as needed to maintain O_2 saturation, analgesia. Stabilize flail segment with positive pressure ventilation (CPAP, BiPAP) or intubation and mechanical ventilation. Treat associated injuries. Surgical fixation.
Cardiac tamponade	Blood rapidly collects in pericardial sac, compresses myocardium because the pericardium does not stretch, and prevents ventricles from filling.	Muffled, distant heart sounds, hypotension, neck vein distention, increased central venous pressure	Medical emergency: pericardiocentesis with surgical repair as appropriate.

BiPAP, Bilevel positive airway pressure; *CPAP,* continuous positive airway pressure.

PNEUMOTHORAX

A **pneumothorax** is caused by air entering the pleural cavity. Normally, negative pressure exists between the visceral pleura (surrounding the lung) and the parietal pleura (lining the thoracic cavity), allowing the lung to be filled by chest wall expansion. The pleural space contains only a few milliliters of lubricating fluid to reduce friction when the tissues move. When air enters this space, the change to positive pressure causes a partial or complete lung collapse. As the volume of air in the pleural space increases, the lung volume decreases. This condition should be suspected after any trauma to the chest wall. Pneumothorax can be classified as *open* (air entering through an opening in the chest wall) or *closed* (no external wound).

If a pneumothorax is small, mild tachycardia and dyspnea may be the only manifestations. If the pneumothorax occupies a large area, respiratory distress may be present, including shallow, rapid respirations; dyspnea; air hunger; and oxygen desaturation. Chest pain and a cough with or without hemoptysis may be present. On auscultation, no breath sounds are detected over the affected area. A chest x-ray shows air or fluid in the pleural space and reduction in lung volume.

Types of Pneumothorax

Spontaneous Pneumothorax. A spontaneous pneumothorax typically occurs due to the rupture of small blebs (air-filled blisters) located on the apex of the lung. These blebs can occur in healthy, young individuals *(primary spontaneous pneumothorax)* or as a result of lung disease such as COPD, asthma, cystic fibrosis, and pneumonia *(secondary spontaneous pneumothorax).* Smoking increases the risk for bleb formation. Other risk factors include being tall and thin, male gender, family history, and previous spontaneous pneumothorax.

Iatrogenic Pneumothorax. *Iatrogenic pneumothorax* can occur due to laceration or puncture of the lung during medical procedures. Transthoracic needle aspiration is the leading cause of iatrogenic pneumothorax.[32] Other causes include subclavian catheter insertion, thoracentesis, pleural biopsy, and transbronchial lung biopsy. Barotrauma from excessive ventilatory pressure during manual or mechanical ventilation can rupture alveoli or bronchioles. Esophageal procedures may also be involved in the development of a pneumothorax. Tearing during insertion of a gastric tube can allow air from the esophagus to enter the mediastinum and the pleural space.

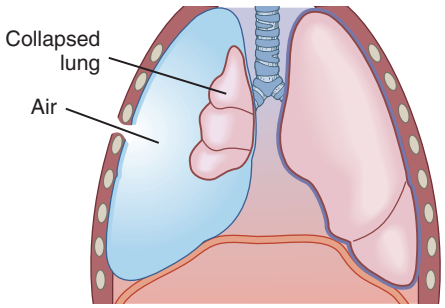

FIG. 28-4 Open pneumothorax resulting from collapse of lung due to disruption of chest wall and outside air entering.

Traumatic Pneumothorax. *Traumatic pneumothorax* can occur from either penetrating (open) or nonpenetrating (closed) chest trauma. Penetrating trauma allows air to enter the pleural space through an opening in the chest wall (Fig. 28-4). Examples include stab or gunshot wounds and surgical thoracotomy. A penetrating chest wound may be referred to as a *sucking chest wound,* since air enters the pleural space through the chest wall during inspiration.

Emergency treatment consists of covering the wound with an occlusive dressing that is secured on three sides (vent dressing). During inspiration, as negative pressure is created in the chest, the dressing pulls against the wound, preventing air from entering the pleural space. During expiration, as the pressure rises in the pleural space, the dressing is pushed out and air escapes through the wound and from under the dressing. If the

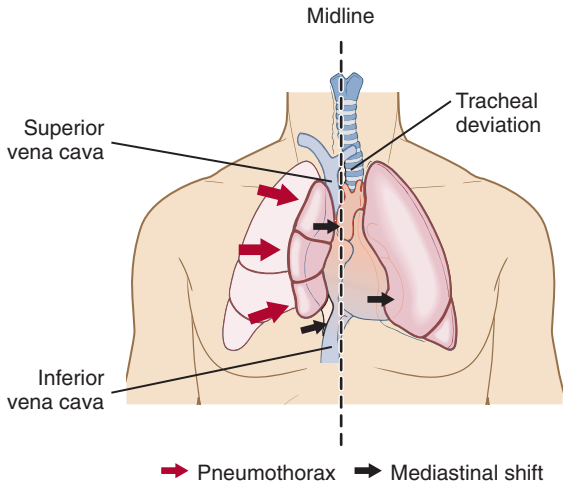

FIG. 28-5 Tension pneumothorax. As pleural pressure on the affected side increases, mediastinal displacement ensues with resultant respiratory and cardiovascular compromise. Tracheal deviation is an external manifestation of the mediastinal shift.

object that caused the open chest wound is still in place, do not remove it until a physician is present. Stabilize the impaled object with a bulky dressing.

Nonpenetrating chest trauma, such as rib fractures, can lacerate the lung and cause air to enter the pleural space. Blunt trauma can also cause alveolar rupture secondary to sudden chest compression.

Tension Pneumothorax. Tension pneumothorax occurs when air enters the pleural space but cannot escape. The continued accumulation of air in the pleural space causes increasingly elevated intrapleural pressures. This results in compression of the lung on the affected side and pressure on the heart and great vessels, pushing them away from the affected side (Fig. 28-5). The mediastinum shifts toward the unaffected side, compressing the "good" lung, which further compromises oxygenation. As the pressure increases, venous return is decreased and cardiac output falls. Tension pneumothorax may result from either an open or a closed pneumothorax. In an open chest wound, a flap may act as a one-way valve. Thus air can enter on inspiration but cannot escape. Tension pneumothorax can occur with mechanical ventilation and resuscitative efforts. It can also occur if chest tubes are clamped or become blocked in a patient with a pneumothorax. Unclamping the tube or relieving the obstruction will remedy this situation.

Tension pneumothorax is a medical emergency, with both the respiratory and cardiovascular systems affected. Manifestations include dyspnea, marked tachycardia, tracheal deviation, decreased or absent breath sounds on the affected side, neck vein distention, cyanosis, and profuse diaphoresis.[32] If the tension in the pleural space is not relieved, the patient is likely to die from inadequate cardiac output or severe hypoxemia.

Hemothorax. Hemothorax is an accumulation of blood in the pleural space resulting from injury to the chest wall, diaphragm, lung, blood vessels, or mediastinum.[32] When it occurs with pneumothorax, it is called a *hemopneumothorax*. The patient with a traumatic hemothorax requires immediate insertion of a chest tube for evacuation of the blood, which can be recovered and reinfused for a short time after the injury. (Autotransfusion is discussed in Chapter 31.)

Chylothorax. *Chylothorax* is the presence of lymphatic fluid in the pleural space. The thoracic duct is disrupted either traumatically or from a malignancy, and the lymphatic fluid fills the pleural space. This milky white fluid is high in lipids. Normal lymphatic flow through the thoracic duct is 1500 to 2500 mL/day. This amount can be increased up to tenfold after ingestion of fats. Fifty percent of cases heal with conservative treatment (chest drainage, bowel rest, and parenteral nutrition). Octreotide has been used with some success to reduce the flow of lymphatic fluid.[29] Surgery and pleurodesis are options if conservative therapy fails. *Pleurodesis* is the artificial production of adhesions between the parietal and visceral pleura, usually done with a chemical sclerosing agent, such as talc or doxycycline.

Collaborative Care

Treatment of a pneumothorax depends on its severity and the underlying disease. If the patient is stable and minimal air and fluid is accumulated in the intrapleural space, no treatment may be necessary, since the condition may resolve spontaneously. The pleural space can also be aspirated with a large-bore needle. This procedure is called a thoracentesis.

The most definitive and common treatment of pneumothorax and hemothorax is to insert a chest tube and connect it to water-seal drainage. Repeated spontaneous pneumothorax may need to be treated surgically by a partial pleurectomy, stapling, or pleurodesis to promote adherence of the pleurae to one another. Tension pneumothorax is a medical emergency, requiring urgent needle decompression followed by chest tube insertion to water-seal drainage.

FRACTURED RIBS

Rib fractures are the most common type of chest injury resulting from blunt trauma. Ribs 5 through 9 are most frequently fractured because they are the least protected by chest muscles. If the fractured rib is splintered or displaced, it may damage the pleura and lungs.

Clinical manifestations of fractured ribs include pain at the site of injury, especially during inspiration and coughing. The patient splints the affected area and takes shallow breaths to try to decrease the pain. Atelectasis and pneumonia may develop because of decreased ventilation and retained secretions.

The main goal in treatment is to decrease pain so that the patient can breathe adequately and clear secretions. Strapping the chest with tape or using a binder is not recommended, since it limits chest expansion and predisposes the individual to atelectasis. Nonsteroidal antiinflammatory drugs (NSAIDs), opioids, and nerve blocks can be used to reduce pain and aid with deep breathing and coughing. Patient teaching should emphasize deep breathing, coughing, incentive spirometry, and appropriate use of pain medications.

FLAIL CHEST

Flail chest results from the fracture of several consecutive ribs, in two or more separate places, causing an unstable segment (Fig. 28-6). It can also be caused by fracture of the sternum and several consecutive ribs. The resultant instability of the chest wall causes paradoxic movement during breathing. The affected (flail) area moves in the opposite direction with respect to the intact portion of the chest. During inspiration, the affected portion is sucked in, and during expiration, it bulges out. This paradoxic chest movement prevents adequate ventilation of the lung in the injured area and increases the work of breathing.

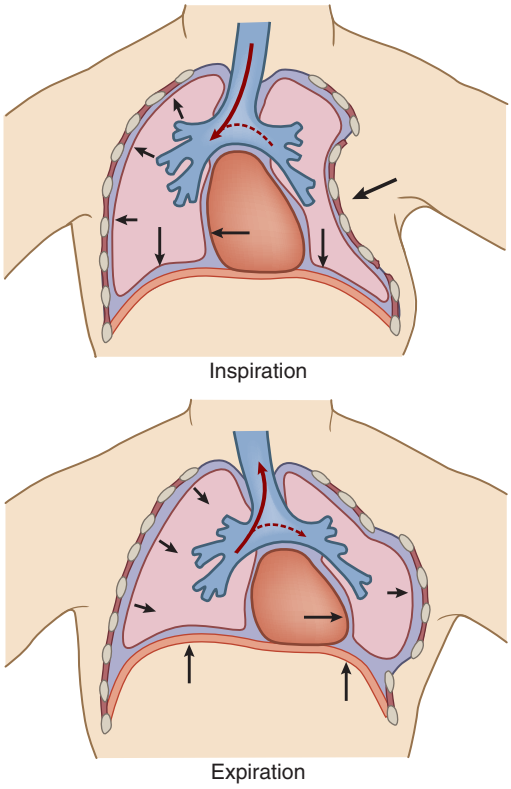

FIG. 28-6 Flail chest produces paradoxic respiration. On inspiration, the flail section sinks in with mediastinal shift to the uninjured side. On expiration, the flail section bulges outward with mediastinal shift to the injured side.

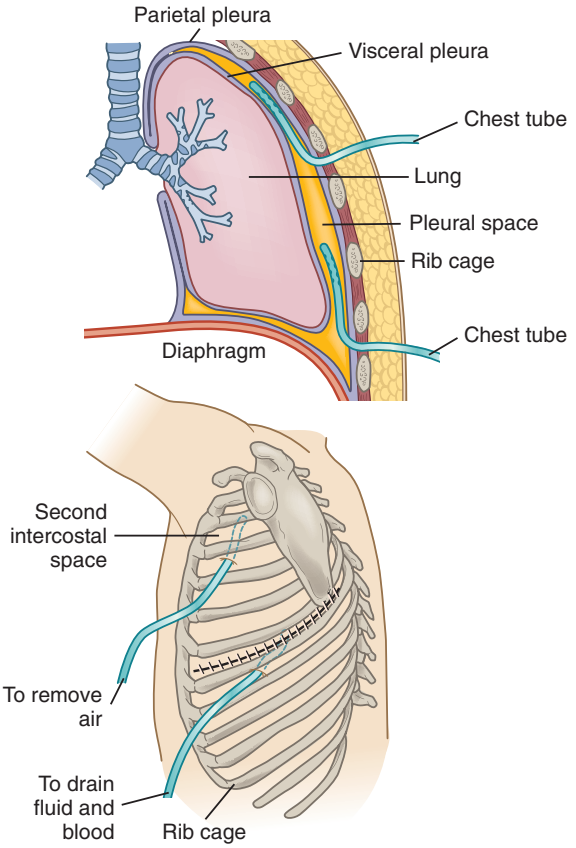

FIG. 28-7 Placement of chest tubes.

The underlying lung may have a pulmonary contusion aggravating hypoxemia.

In an unconscious patient a flail chest is usually apparent on visual examination. The patient manifests rapid, shallow respirations and tachycardia. In a conscious patient a flail chest may not be initially apparent as a result of splinting of the chest wall. The patient moves air poorly, and movement of the thorax is asymmetric and uncoordinated. Palpation of abnormal respiratory movements, evaluation for crepitus near the rib fractures, chest x-ray, and ABGs all assist in the diagnosis.

Initial therapy consists of airway management, adequate ventilation, supplemental oxygen therapy, careful administration of IV solutions, and pain control. The definitive therapy is to reexpand the lung and ensure adequate oxygenation. Although many patients can be managed without mechanical ventilation, intubation and ventilation may be necessary. Surgical fixation of the flail segment may be done.[33] The lung parenchyma and fractured ribs heal with time. Some patients continue to experience intercostal pain after the flail chest has resolved.

CHEST TUBES AND PLEURAL DRAINAGE

Whenever fluid or air accumulates in the pleural space, the pressure becomes positive instead of negative and the lungs collapse. Chest tubes are inserted to drain the pleural space and reestablish negative pressure, allowing for proper lung expansion. Tubes may also be inserted in the mediastinal space to drain air and fluid postoperatively.

Chest tubes are approximately 20 inches (51 cm) long and vary in size from 12F to 40F. The size inserted is determined by the patient's condition. Large (36F to 40F) tubes are used to drain blood, medium (24F to 36F) tubes are used to drain fluid, and small (12F to 24F) tubes are used to drain air.[34] Pigtail tubes are very small (10F to 14F) tubes with a curly end designed to keep them in place. They are a safe and effective alternative to larger-bore chest tubes for treatment of pneumothorax.[35]

Chest Tube Insertion

Insertion of a chest tube can take place in the emergency department, at the patient's bedside, or in the operating room. The patient is positioned with the arm raised above the head on the affected side to expose the midaxillary area, the standard site for insertion. Elevate the patient's head 30 to 60 degrees, when possible, to lower the diaphragm and reduce the risk of injury.

A chest x-ray is used to confirm the affected side. The area is cleansed with an antiseptic solution. The chest wall is prepared with a local anesthetic, and a small incision is made over a rib. The chest tube is advanced up and over the top of the rib to avoid the intercostal nerves and blood vessels that are behind the rib inferiorly (Fig. 28-7). Once inserted, the tube is connected to a pleural drainage system (Fig. 28-8). Two tubes may be connected to the same drainage unit with a Y-connector.

The incision is closed with sutures, and the chest tube is secured. The wound is covered with an occlusive dressing. Some clinicians prefer to seal the wound around the chest tube with petroleum gauze. Proper tube placement is confirmed by chest x-ray.

The insertion of a chest tube and its presence in the pleural space are painful. Monitor the patient's comfort at frequent intervals and use the appropriate pain-relieving interventions.

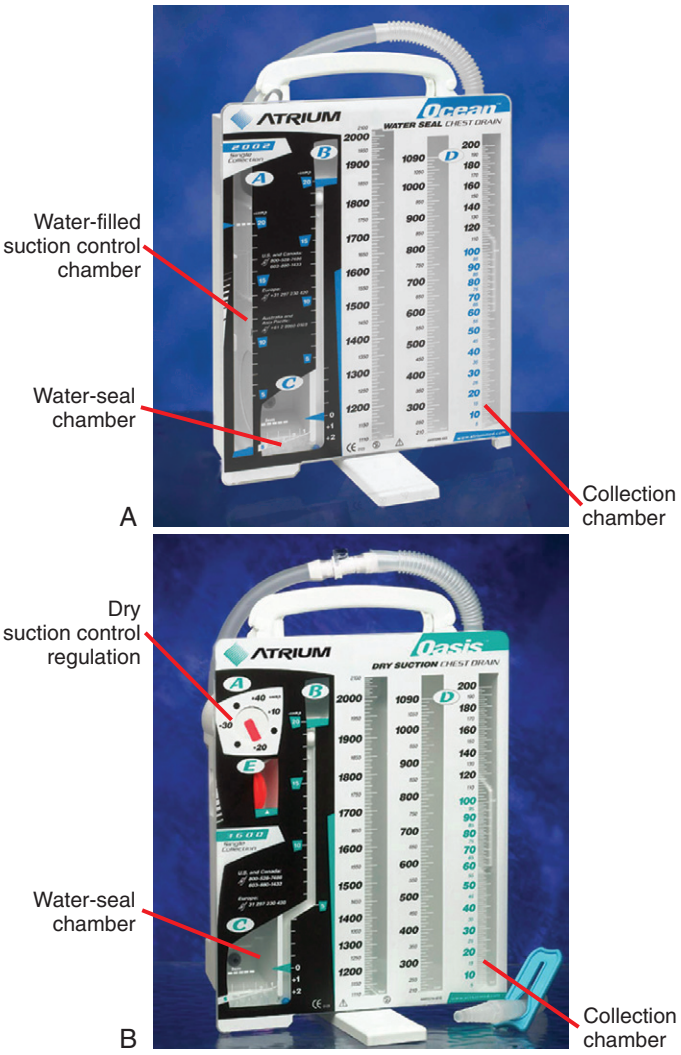

FIG. 28-8 Chest drainage unit. Both units have three chambers: (1) collection chamber; (2) water-seal chamber; and (3) suction control chamber. Suction control chamber requires a connection to a wall suction source that is dialed up higher than the prescribed suction for the suction to work. **A,** Water suction. This unit uses water in the suction control chamber to control the wall suction pressure. **B,** Dry suction. This unit controls wall suction by using a regulator control dial.

Flutter or Heimlich Valve

A flutter valve (also called the Heimlich valve after its inventor) is used to evacuate air from the pleural space (Fig. 28-9). This device consists of a one-way rubber valve within a rigid plastic tube. It is attached to the external end of the chest tube. The valve opens whenever the pressure in the chest is greater than atmospheric pressure, such as during expiration, and it closes when intrathoracic pressure is less than atmospheric pressure, such as during inspiration.

The flutter valve can be used for emergency transport and for a small- to moderate-sized pneumothorax. It also allows for patient mobility, since the smaller drainage bag can be hidden under the clothes while the patient ambulates. Drainage bags attached to the flutter valve must have a vent to the atmosphere to prevent a potential tension pneumothorax. This can be accomplished by simply cutting a small slit in the top of any drainage bag that does not have a built-in vent. Patients may go home with a flutter valve in place.

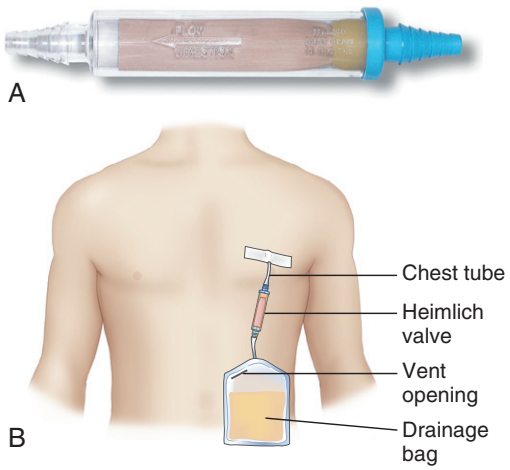

FIG. 28-9 **A,** Heimlich chest drain valve is a specially designed flutter valve that is used in place of a chest drainage unit for small uncomplicated pneumothorax with little or no drainage and no need for suction. The valve allows for escape of air but prevents the reentry of air into the pleural space. **B,** Placement of valve between chest tube and vented drainage bag, which can be worn under a person's clothes.

Pleural Drainage

The second type of chest drainage is larger and less portable, and it contains three basic compartments, each with a separate function (see Fig. 28-8). The *first compartment*, or collection chamber, receives fluid and air from the pleural or mediastinal space. The drained fluid stays in this chamber while the air vents to the second compartment.

The *second compartment,* called the water-seal chamber, contains 2 cm of water, which acts as a one-way valve. The incoming air enters from the collection chamber and bubbles up through the water. The water prevents backflow of air into the patient from the system. Initially, brisk bubbling of air occurs in this chamber when a pneumothorax is evacuated. Intermittent bubbling during exhalation, coughing, or sneezing (when the patient's intrathoracic pressure is increased) will continue as long as there is air in the pleural space. As the source of the air in the pleural space gets smaller, it will take more and more positive intrapleural pressure to force air out. Eventually, the air leak seals and the lung is fully expanded.

Normal fluctuation of the water within the water-seal chamber is called *tidaling*. This up and down movement of water in concert with respiration reflects the intrapleural pressure changes during inspiration and expiration. Investigate any sudden cessation of tidaling, since this may signify an occluded chest tube. Gradual reduction and eventual cessation of tidaling are expected as the lung reexpands. The parietal and visceral pleura will form a tight seal around the chest tube openings, obliterating the response to changes in intrapleural pressures with respiration.

The *third compartment,* the suction control chamber, applies suction to the chest drainage system. There are two types of suction control: water and dry. The water suction control chamber uses a column of water with the top end vented to the atmosphere to control the amount of suction from the wall regulator. The chamber is typically filled with 20 cm of water. When the negative pressure generated by the suction source exceeds the set 20 cm, air from the atmosphere enters the chamber through the vent on top and the air bubbles up through

TABLE 28-21 CHEST TUBES AND WATER-SEAL DRAINAGE

Set-Up and Insertion

1. Make sure patient is aware of the procedure and informed consent is obtained.
2. Gather equipment.
   - Thoracotomy tray
   - Chest drainage unit (CDU)
   - Chest tube
   - Bottle of sterile water
   - 1% lidocaine
   - Suction tubing and collection container
   - Occlusive dressing
3. Prepare CDU.
   - Wet suction: add sterile water to 2-cm mark in water-seal chamber and to 20-cm mark (or as ordered) in suction control chamber.
   - Dry suction: add sterile water to the fill line of the air leak meter. Attach suction tubing and increase suction until the bellows-like float moves across the display window.
4. Position and support the patient to minimize movement during procedure.

Drainage System

1. Keep all tubing loosely coiled below chest level. Tubing should drop straight from bed or chair to drainage unit. Do not let it be compressed.
2. Keep all connections between chest tubes, drainage tubing, and the drainage collector tight, and tape at connections.
3. Observe for air fluctuations (tidaling) and bubbling in the water-seal chamber.
   - If tidaling (rising with inspiration and falling with expiration in the spontaneously breathing patient) is not observed, the drainage system is blocked, the lungs are reexpanded, or the system is attached to suction.
   - If bubbling increases, there may be an air leak in the drainage system or a leak from the patient (bronchopleural leak).
4. If the chest tube is connected to suction, disconnect from wall suction to check for tidaling.
5. Suspect a system leak when bubbling is continuous.
   - Retape tubing connections.
   - Ensure that dressing is air-occlusive.
   - If leak persists, briefly clamp the chest tube at the patient's chest. If the leak stops, then the air is coming from the patient.
   - If the air leak persists, briefly and methodically move the clamps down the tubing away from the patient until the air leak stops. The leak will then be present between the last two clamp points. If the air leak persists all the way to the drainage unit, replace the unit.
6. High fluid levels in the water seal indicate residual negative pressure.
   - The chest system may need to be vented by using the high-negativity release valve available on the drainage system to release residual pressure from the system.
   - Do not lower water-seal column when wall suction is not operating or when patient is on gravity drainage.

Patient's Clinical Status

1. Monitor the patient's clinical status. Assess vital signs, lung sounds, and pain.
2. Assess for manifestations of reaccumulation of air and fluid in the chest (↓ or absent breath sounds), significant bleeding (>100 mL/hr), chest drainage site infection (drainage, erythema, fever, ↑ WBC), or poor wound healing. Notify physician for management plan.
3. Evaluate for subcutaneous emphysema at chest tube site.
4. Encourage the patient to breathe deeply periodically to facilitate lung expansion and encourage range-of-motion exercises to the shoulder on the affected side. Encourage use of incentive spirometry every hour while awake to prevent atelectasis or pneumonia.

Chest Drainage

1. Never elevate the drainage system to the level of the patient's chest because this will cause fluid to drain back into the lungs. Secure the unit to the drainage stand. Change the unit if the collection chamber is full. Do not try to empty it.
2. Mark the time of measurement and the fluid level on the drainage unit according to the unit standards. Report any change in the quantity or characteristics of drainage (e.g., clear yellow to bloody) to the physician and record the change. Notify physician if >100 mL/hr drainage.
3. Check the position of the chest drainage container. If the drainage system is overturned and the water seal is disrupted, return it to an upright position and encourage the patient to take a few deep breaths, followed by forced exhalations and cough maneuvers.
4. If the drainage system breaks, place the distal end of the chest tubing connection in a sterile water container at a 2-cm level as an emergency water seal.
5. Milking or stripping chest tubes is no longer recommended, since these practices can dangerously increase intrapleural pressures and damage lung tissues. Position tubing so that drainage flows freely to negate need for milking or stripping. If ordered by physician to milk or strip tubes, do so GENTLY.
   - *Milking:* Alternately fold or squeeze and then release drainage tubing. Milk only if drainage and evidence of clots or obstruction. Take 15-cm strips of the chest tube and squeeze and release starting close to the chest and repeating down the tube distally.
   - *Stripping:* Squeeze drainage tube with thumb and forefinger and use gentle pulling motion down tube with other hand, then release the tubing.

Monitoring Wet vs. Dry Suction Chest Drainage Systems

Suction Control Chamber in Wet Suction System

1. Keep the suction control chamber at the appropriate water level by adding sterile water as needed to replace water lost to evaporation.
2. Keep the muffler covering the suction control chamber in place to prevent more rapid evaporation of water and to decrease the noise of the bubbling.
3. After filling the suction control chamber to the ordered suction amount (generally 20 cm H_2O suction), connect the suction tubing to the wall suction.
4. Dial the wall suction regulator until continuous gentle bubbling is seen in the suction control chamber (generally 80-120 mm Hg). Vigorous bubbling is not necessary and will increase the rate of evaporation.
5. If no bubbling is seen in the suction control chamber, (1) there is no suction, (2) suction is not high enough, or (3) the pleural air leak is so large that suction is not high enough to evacuate it.

Suction Control Chamber in Dry Suction System (see manufacturer's directions)

1. After connecting patient to system, turn the dial on the chest drainage system to amount ordered (generally –20 cm pressure), connect suction tubing to wall suction source, and increase the suction until the correct amount of negative pressure is indicated.
2. If ordered to decrease suction, turn the dial down, depress the high-negativity vent, and assess for a rise in the water level of the water-seal chamber.

Chest Tube Dressings

1. Change dressing according to unit protocol and physician preference.
2. Remove old dressing carefully to avoid removing unsecured chest tube. Assess the site and culture site as indicated.
3. Cleanse the site according to protocol, maintaining asepsis.
4. Redress with occlusive dressing (e.g., Opsite or gauze with occlusive tape). Some physicians prefer the use of petroleum gauze dressing around the tube to prevent air leak. Date the dressing and document dressing change.

INFORMATICS IN PRACTICE

Chest Drainage System

- You find yourself in a situation where you need to set up a chest drainage system. You have not done this since simulation lab in nursing school.
- On the Internet, find a procedure manual or watch a video or podcast on the procedure.

the water, causing a suction-breaker effect. As a result, excess pressure is relieved.

The amount of suction applied is regulated by the amount of water in this chamber and not by the amount of suction applied to the system. An increase in suction does not result in an increase in negative pressure to the system because any excess suction merely draws in air through the vent on the top of the third chamber. The suction pressure is usually ordered to be −20 cm H_2O, although higher pressures (−40 cm H_2O) are sometimes necessary to evacuate the pleural space; lower pressure (−10 cm H_2O) may be used for frail patients at risk for tissue damage with higher pressures.

To initiate suction, turn up the vacuum source until gentle bubbling is present in the chamber. Excessive bubbling does not increase the amount of applied suction, but does increase the rate of evaporation of the column of water and the amount of noise made by the device.

The dry suction control chamber system contains no water. It has a visual alert that indicates if the suction is working. It uses either a restrictive device or a regulator to dial the desired negative pressure; this is internal in the chest drainage system. To increase the suction pressures, turn the dial on the drainage system. Increasing the vacuum source does not increase the pressure. When decreasing suction, depress the manual vent to reduce excess vacuum to the lower prescribed level.

The addition of wall suction (active suction) to the chest drainage unit may actually promote the development of air leaks and thus prolong the number of days the chest tube needs to remain in place.[36] Patients with just water-seal drainage (passive suction) have a shorter duration of air leaks. Although the majority of clinicians continue to use active suction, the use of water-seal drainage alone is gaining popularity.

A variety of commercial disposable plastic chest drainage systems are available. Manufacturers include directions for set-up and use with each unit. Atrium Medical Corporation offers online educational videos of the principles of chest drainage and products at *www.atriummed.com/Products/Chest_Drains/education.asp*.

NURSING MANAGEMENT
CHEST DRAINAGE

General guidelines for nursing care of the patient with chest tubes and water-seal drainage systems are presented in Table 28-21.

Clamping of chest tubes during transport or when the tube is accidentally disconnected is no longer advocated. The danger of rapid accumulation of air in the pleural space, causing tension pneumothorax, is far greater than that of a small amount of atmospheric air entering the pleural space. If a chest tube becomes disconnected, immediately reestablish the water-seal system and attach a new drainage system as soon as possible. In some hospitals, when disconnection occurs, the chest tube is immersed in sterile water (about 2 cm) until the system can be reestablished. It is important to know the unit protocol, individual clinical situation (whether an air leak exists), and physician preference before resorting to prolonged chest tube clamping.

Chest tubes may be momentarily clamped to change the drainage apparatus or to check for air leaks. Appearance of a new air leak warrants assessment of the drainage system to identify whether the air leak is coming from the patient or the system. Although it is controversial, some clinicians clamp the chest tube for a few hours before removal. This is done to assess how the patient will tolerate chest tube removal. Generally this occurs 4 to 6 hours before the tube is removed, and the patient is monitored closely for any signs of respiratory distress.

Closely monitor the patient for complications associated with chest tube placement and drainage. If volumes from 1 to 1.5 L of pleural fluid are removed rapidly, reexpansion pulmonary edema or a vasovagal response with symptomatic hypotension can occur. Subcutaneous emphysema can occur from air leaking into the tissue surrounding the chest tube insertion site. A "crackling" sensation will be felt when palpating the skin. A small amount of subcutaneous air is harmless and will be reabsorbed. However, severe subcutaneous emphysema can cause drastic swelling of the head and the neck with potential airway compromise.[37]

Meticulous sterile technique during dressing changes can reduce the incidence of infected sites. Nursing care and patient teaching can minimize the risk of atelectasis and shoulder stiffness. Encourage coughing, deep breathing, incentive spirometer use, and range-of-motion exercises.

CHEST TUBE REMOVAL

The chest tubes are removed when the lungs are reexpanded and fluid drainage has ceased or is minimal. Generally suction is discontinued and the chest drain is on gravity drainage for 24 hours before the tube is removed. Give the patient pain medication about 30 to 60 minutes before tube removal. Gather dressing supplies and petroleum jelly dressing. Explain the procedure to the patient. The tube is removed by the physician or an advanced practice nurse in most settings. The suture is cut, and a sterile airtight petroleum jelly gauze dressing is prepared. With the patient holding his or her breath or bearing down (Valsalva maneuver), the tube is removed. The site is immediately covered with the airtight dressing to prevent air from entering the pleural space. The pleura will seal off, and the wound usually heals in several days. A chest x-ray is done to evaluate for pneumothorax or reaccumulation of fluid. Observe the wound for drainage, and reinforce the dressing if necessary. Assess the patient for respiratory distress, which may signify a recurrence of the original problem.

CHEST SURGERY

Chest surgery is performed for various reasons, including lung, heart, vascular, and esophageal disorders. The most common types of chest surgery are described in Table 28-22.

Preoperative Care

The patient's cardiopulmonary status is assessed to determine his or her ability to tolerate the surgery and to provide a baseline reference for postoperative care. Diagnostic studies include pulmonary function studies, chest x-ray, electrocardiogram (ECG),

TABLE 28-22 CHEST SURGERIES

Type	Indications	Description
Lobectomy Removal of one lobe of lung	Lung cancer, bronchiectasis, TB, emphysematous bullae, benign lung tumors, fungal infections	Most common lung surgery. Need chest tubes postoperatively. Lung tissue expands to fill up space left by resected lobe.
Pneumonectomy Removal of entire lung	Lung cancer (most common)	Done only when lobectomy or segmental resection will not remove all diseased lung. May have clamped chest tube postoperatively. Fluid will gradually fill space where lung has been removed. Position patient on operative side to facilitate expansion of remaining lung.
Segmental resection Removal of one or more lung segments	Lung cancer, bronchiectasis	Done to remove bronchovascular lung segment. Need chest tubes postoperatively. Remaining lung tissue expands to fill space. Indicated for a patient unable to handle more extensive surgery.
Wedge resection Removal of small, localized lesion that occupies only part of a segment	Lung biopsy, excision of small nodules	Most conservative approach. Need chest tubes postoperatively. Done to remove small peripheral nodules or for patients unable to handle more extensive surgery.
Decortication Removal or stripping of thick, fibrous membrane from visceral pleura	Empyema or other inflammatory process unresponsive to conservative management	Need chest tubes postoperatively.
Exploratory thoracotomy Incision into thorax to look for injured or bleeding tissues	Chest trauma	Need chest tubes postoperatively.
Thoracotomy (not involving lungs) Incision into thorax for surgery on other organs	Hiatal hernia repair, open heart surgery, esophageal surgery, tracheal resection, thoracic aorta repair	Postoperative care related to thoracotomy and to primary reason for surgical procedure; need chest tubes postoperatively.
Video-assisted thoracoscopic surgery (VATS)	VATS done under general anesthesia in operating room Procedures performed using VATS include lung biopsy, lobectomy, resection of nodules, repair of fistulas	Video-assisted technique with a rigid scope with a distal lens inserted into the pleura and image shown on a monitor screen. Allows surgeon to manipulate instruments passed into the pleural space through separate small intercostal incisions. Need one chest tube postoperatively.
Lung volume reduction surgery (LVRS)	Advanced bullous emphysema, α_1-antitrypsin emphysema	Involves reducing lung volume by multiple wedge excisions or VATS.

ABGs, blood urea nitrogen (BUN), serum creatinine, blood glucose, serum electrolytes, prothrombin time/international normalized ratio (PT/INR), activated partial thromboplastin time (aPTT), and CBC. Additional cardiac function studies are often done for the patient who is to undergo a pneumonectomy. An anesthesia consult is also completed.

The patient should be in optimal health and stop smoking, if applicable, before elective surgery. Anxiety associated with anticipated surgery makes smoking cessation more difficult. Provide encouragement, support, and teaching regarding various methods to help stop smoking (see Chapter 11).

Teach the patient what to expect postoperatively, including the use of oxygen, possible intubation, administration of blood and fluids, and the purpose and function of chest tubes. Reassure the patient that adequate medication will be used to reduce pain. Explain how to use patient-controlled analgesia (PCA), if planned. Preoperative teaching also includes exercises for effective deep breathing and use of incentive spirometry. If the patient practices these techniques before surgery, they will be easier to perform postoperatively. Show the patient how to splint the incision with a pillow to facilitate deep breathing. Teach and have the patient provide a return demonstration of range-of-motion exercises on the surgical side (similar to those for the mastectomy patient [see Fig. 52-9]).

The thought of losing part of a vital organ is frequently frightening. Reassure the patient that the lungs have a large degree of functional reserve. Even after the removal of one lung, enough lung tissue is left to maintain adequate oxygenation. Be available to answer the patient and caregiver's questions. Answer questions honestly. Try to facilitate the expression of concerns, feelings, and questions. (General preoperative care and teaching are discussed in Chapter 18.)

Surgical Procedures

Thoracotomy. A **thoracotomy** is a surgical incision into the chest to gain access to the heart, lungs, esophagus, thoracic aorta, or anterior spine. The two most common approaches to a thoracotomy are the medial sternotomy and the lateral thoracotomy. The medial sternotomy involves splitting the sternum and is primarily used for surgery involving the heart. The lateral thoracotomy incision can be done using a posterolateral or anterolateral incision. The *posterolateral incision* is used for most surgeries involving the lung. The incision is made from front to back at the level of the fourth, fifth, or sixth intercostal space. Strong mechanical retractors are used to separate the ribs and gain access to the lung. The *anterolateral incision* is made in the fourth or fifth intercostal space from the sternal border to the midaxillary line. This procedure is commonly used for surgery or trauma victims, mediastinal operations, and wedge resections of the upper and middle lobes of the lung.

Video-Assisted Thoracic Surgery. *Video-assisted thoracoscopic surgery* (VATS) is a widely used, minimally invasive surgical approach. It provides a real-time two-dimensional video image of the inside of the chest cavity. It is used for diagnosis and treatment of diseases of the pleura, pulmonary masses

and nodules, mediastinal masses, and interstitial lung disease. Through incisions just large enough to insert the instruments, the surgeon can inspect the chest cavity, biopsy suspicious areas, obtain samples of fluids for analysis, and remove tissue. VATS is increasingly being used for patients with thoracic trauma. The surgeon can inspect, diagnose, and manage intrathoracic injuries in both blunt and penetrating trauma, including injuries to the diaphragm. A chest tube is placed in the pleural space through one or more of the incisions at the end of the procedure, secured with sutures, and connected to a drainage unit in the usual manner.

The advantages of minimally invasive surgery include less discomfort, faster return to normal activity level, reduced length of hospital stay, lower postoperative morbidity risk, and fewer complications.[38] Patients who have marginal respiratory reserve or are too debilitated to tolerate an open thoracotomy approach may benefit from the VATS procedure.

Postoperative Care

Postoperative pain after a thoracotomy is typically intense because respiratory muscles are cut during surgery. Adequate pain management is a priority to prevent respiratory compromise. The use of PCA and intercostal nerve blocks enables the patient to breathe deeply, cough, and move the arm and shoulder on the operative side.

For most chest surgeries, chest tubes are placed in the pleural space to allow for lung reexpansion. In a pneumonectomy, chest tubes may or may not be placed in the space from which the lung was removed. If a chest tube is used, it is clamped and only released by the surgeon to adjust the volume of serosanguineous fluid that will fill the space vacated by the lung. If the cavity overfills, it could compress the remaining lung and compromise the cardiovascular and pulmonary function. Daily chest x-rays assess the volume and space.

Nursing care priorities in the postoperative period include assessment of respiratory function, including observation of respiratory rate and effort, sputum volume and color, breath sounds, and chest tube function and drainage. Assessment of pain, monitoring of temperature, and observation of the surgical site are similar to care provided for other postoperative patients (see Chapter 20). Care after thoracotomy is presented in eNursing Care Plan 28-2 (available on the website for this chapter).

RESTRICTIVE RESPIRATORY DISORDERS

Disorders that impair the ability of the chest wall and diaphragm to move with respiration are called *restrictive respiratory disorders*. There are two categories: *extrapulmonary conditions,* in which the lung tissue is normal, and *intrapulmonary conditions,* in which the cause is the lung or the pleura. Examples of extrapulmonary conditions that alter respirations are listed in Table 28-23. These disorders are further described in their respective chapters.

Examples of intrapulmonary causes are listed in Table 28-24. Lung damage can be caused by inflammation and scarring of lung tissue (interstitial lung disease), air spaces (pneumonitis), or pleura (empyema).

Pulmonary function tests are the best means of differentiating between restrictive and obstructive respiratory disorders. Restrictive lung disorders are characterized by reduced vital capacity (VC) and total lung capacity (TLC).[39] Mixed obstructive and restrictive disorders sometimes occur together. For example, a patient may have both chronic bronchitis (an obstructive problem) and pulmonary fibrosis (a restrictive problem).

TABLE 28-23 EXTRAPULMONARY CAUSES OF RESTRICTIVE LUNG DISEASE*

Central Nervous System (CNS)
- Head injury, CNS lesion (e.g., tumor, stroke)
- Opioid and barbiturate use

Neuromuscular System
- Spinal cord injury
- Guillain-Barré syndrome
- Amyotrophic lateral sclerosis
- Myasthenia gravis
- Muscular dystrophy

Chest Wall
- Chest wall trauma (e.g., flail chest, fractured rib)
- Obesity-hypoventilation syndrome (Pickwickian syndrome)
- Kyphoscoliosis

*See eTable 28-3 for more detailed descriptions on extrapulmonary causes of restrictive lung disease.

TABLE 28-24 INTRAPULMONARY CAUSES OF RESTRICTIVE LUNG DISEASE*

Pleural Disorders
- Pleural effusion
- Pleurisy (pleuritis)
- Pneumothorax

Parenchymal Disorders
- Atelectasis
- Pneumonia
- Interstitial lung diseases
- Acute respiratory distress syndrome (ARDS)

*See eTable 28-3 for more detailed descriptions on intrapulmonary causes of restrictive lung disease.

PLEURAL EFFUSION

Types

The pleural space normally contains 5 to 15 mL of fluid that acts as a lubricant between the chest wall (parietal pleura) and the lung (visceral pleura). **Pleural effusion** is an abnormal collection of fluid in this space. It is not a disease but rather an indication of disease. A balance between hydrostatic pressure, oncotic pressure, and membrane permeability governs movement of fluid in and out of the pleural space. Fluid accumulation can be a result of increased pulmonary capillary pressure, decreased oncotic pressure, increased pleural membrane permeability, or obstruction of lymphatic flow.[40]

Pleural effusion is classified as transudative or exudative according to the protein content. A *transudate* occurs primarily in noninflammatory conditions and is an accumulation of protein-poor, cell-poor fluid. Transudative pleural effusions are clear, pale yellow, and caused by (1) increased hydrostatic pressure found in heart failure or (2) decreased oncotic pressure (from hypoalbuminemia) found in chronic liver or renal disease. An *exudative effusion* results from increased capillary permeability characteristic of the inflammatory reaction. It is most commonly associated with infections and malignancies.

An **empyema** is the collection of purulent fluid in the pleural space. It is caused by conditions such as pneumonia, TB, lung

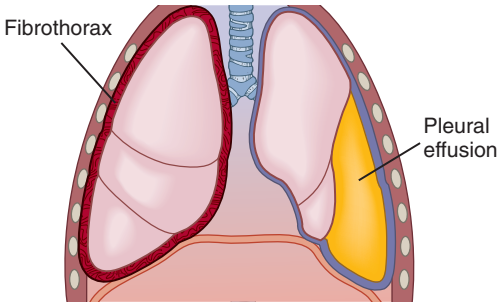

FIG. 28-10 Fibrothorax resulting from an organization of inflammatory exudate and pleural effusion.

abscess, and infection of surgical wounds of the chest. A complication of empyema is *fibrothorax,* in which there is fibrous fusion of the visceral and parietal pleurae (Fig. 28-10).

Clinical Manifestations

Common clinical manifestations of pleural effusion are dyspnea; cough; and occasional sharp, nonradiating chest pain that is worse on inhalation. Physical examination of the chest may indicate decreased movement of the chest on the affected side, dullness to percussion, and diminished breath sounds over the affected area. A chest x-ray and CT reveal the volume and location of the effusion. Manifestations of empyema include the manifestations of pleural effusion, as well as fever, night sweats, cough, and weight loss.

Thoracentesis

Thoracentesis is aspiration of intrapleural fluid for diagnostic and therapeutic purposes. For a thoracentesis, the patient sits on the edge of a bed and leans forward over a bedside table. Chest x-ray results, ultrasound images, and percussion of chest for maximal dullness are used to determine the optimal puncture site. The skin is cleansed with an antiseptic solution and injected with a local anesthetic. The thoracentesis needle is inserted into the intercostal space. Fluid is aspirated with a syringe, or tubing is connected to the needle to allow fluid to drain into a sterile container. After the fluid is removed, the needle is withdrawn, and a bandage is applied over the insertion site.

Usually only 1000 to 1200 mL of pleural fluid is removed at one time. Rapid removal of a large volume can result in hypotension, hypoxemia, or pulmonary edema. A chest x-ray may be done after the procedure to assess for possible complications such as pneumothorax or pulmonary edema. During and after the procedure, monitor vital signs and pulse oximetry, and observe the patient for any manifestations of respiratory distress.

Collaborative Care

The management of pleural effusions is to treat the underlying cause. For example, adequate treatment of heart failure with diuretics and sodium restriction will result in decreased incidence of pleural effusion. The treatment of pleural effusions secondary to malignant disease represents a more difficult problem. These types of pleural effusions are frequently recurrent and accumulate quickly after thoracentesis.

Chemical pleurodesis is performed to obliterate the pleural space and prevent reaccumulation of effusion fluid in both malignant and nonmalignant pleural effusions. This procedure first requires chest tube drainage of the effusion. Once the fluid is drained, a chemical slurry is instilled into the pleural space. Talc is the most effective agent for pleurodesis.[41] Other agents such as doxycycline and bleomycin can also be used. The chest tube is clamped for 8 hours while the patient is turned in different positions to allow the chemical to contact the entire pleural space. After 8 hours the chest tube is unclamped and attached to a drainage unit. Fever and chest pain are the most common side effects associated with pleurodesis. Chest tubes are left in place until fluid drainage is less than 150 mL/day and no air leaks are noted.

Treatment of empyema is generally with chest tube drainage. Appropriate antibiotic therapy is also necessary to eradicate the causative organism. Intrapleural fibrinolytic therapy (instilled via the chest tube) may be considered for some patients to dissolve fibrous adhesions. If this therapy is unsuccessful, a *decortication* surgical procedure may be needed to remove the pleural peel.

PLEURISY

Pleurisy (pleuritis) is an inflammation of the pleura. Inflammation can be caused by infectious diseases, neoplasms, autoimmune disorders, chest trauma, GI disease, and certain medications. The inflammation usually subsides with adequate treatment of the primary disease. The pain of pleurisy is typically abrupt and sharp in onset and is aggravated by inspiration. The patient's breathing is shallow and rapid to avoid unnecessary movement of the pleura and chest wall. A pleural friction rub may occur, which is the sound over areas where inflamed visceral pleura and parietal pleura rub over one another during inspiration. This sound, like a squeaking door, is usually loudest at peak inspiration but may be heard during exhalation as well.

Treatment of pleurisy is aimed at treating the underlying disease and providing pain relief. Taking NSAIDs or analgesics and lying on or splinting the affected side may provide some relief. Teach the patient to splint the rib cage when coughing. Intercostal nerve blocks may be done if the pain is severe.

ATELECTASIS

Atelectasis is a lung condition characterized by collapsed, airless alveoli. There may be diminished or absent breath sounds and dullness to percussion over the affected area. The most common cause of atelectasis is obstruction of the small airways with secretions. This is common in bedridden patients and in postoperative abdominal and thoracic surgery patients. Normally the pores of Kohn (see Fig. 26-1) provide collateral passage of air from one alveolus to another. Deep inspiration is necessary to open the pores effectively. For this reason, deep-breathing exercises and coughing are important to prevent atelectasis and treat the patient at risk. (The prevention and treatment of atelectasis are discussed in Chapter 20.)

INTERSTITIAL LUNG DISEASES

Interstitial lung disease (ILD), also called *diffuse parenchymal lung disease,* refers to more than 200 lung disorders in which the tissue between the air sacs of the lungs (the interstitium) is affected by inflammation or scarring (fibrosis). ILDs can be caused by inhalation of occupational and environmental toxins, certain medications, radiation therapy, connective tissue disor-

ders, malignancy, and infection. Treatment is aimed at reducing exposure to the causative agent and/or treating the underlying disease process. Although scarring is irreversible, treatment with corticosteroids and immunosuppressant drugs can minimize progression. A lung transplant may be an option for some patients.

Many times the cause of ILD is unknown. The most common ILDs of unknown etiology are idiopathic pulmonary fibrosis and sarcoidosis.

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis (IPF) is a chronic, progressive disorder characterized by chronic inflammation and formation of scar tissue in the connective tissue. A history of cigarette smoking is a risk factor for IPF. It affects more men than women and typically first appears between the ages of 50 and 70 years.

Clinical manifestations of IPF include exertional dyspnea, nonproductive cough, clubbing of the fingers, and inspiratory crackles. Fatigue, weakness, anorexia, and weight loss may occur as the disease progresses. Chest x-ray shows changes characteristic of IPF. High-resolution CT scan provides detailed images. Pulmonary function tests are abnormal with evidence of restriction (reduced vital capacity) and impaired gas exchange. Open lung biopsy using VATS often helps to confirm the pathology and is considered the "gold standard" for diagnosis.

The clinical course of IPF is variable and the prognosis is poor, with a 5-year survival rate of 30% to 50% after diagnosis. Many people diagnosed with IPF are initially treated with a corticosteroid (prednisone), sometimes in combination with other drugs that suppress the immune system (e.g., methotrexate, cyclosporine). None of these combinations has proved very effective.[42] O_2 therapy should be prescribed for all patients. Lung transplantation is an option for those who meet the criteria. (Lung transplantation is discussed later in this chapter on p. 556.)

SARCOIDOSIS

Sarcoidosis is a chronic, multisystem granulomatous disease of unknown cause that primarily affects the lungs. The disease may also involve the skin, eyes, liver, kidney, heart, and lymph nodes. African Americans and those with a family history are at higher risk for developing sarcoidosis. Signs and symptoms vary depending on what organs are affected. Pulmonary symptoms include dyspnea, cough, and chest pain. Many patients do not have symptoms.

The disease is staged and treatment decisions are based on pulmonary function and progression of the disease. Some patients have a spontaneous remission. Treatment is aimed at suppression of the inflammatory response. Patients are followed every 3 to 6 months with pulmonary function tests, chest x-ray, and CT scan to monitor disease progression.

VASCULAR LUNG DISORDERS

PULMONARY EDEMA

Pulmonary edema is an abnormal accumulation of fluid in the alveoli and interstitial spaces of the lungs. It is a complication of various heart and lung diseases (Table 28-25). Pulmonary edema is considered a life-threatening medical emergency.

TABLE 28-25 CAUSES OF PULMONARY EDEMA

- Heart failure
- Overhydration with IV fluids
- Hypoalbuminemia: nephrotic syndrome, hepatic disease, nutritional disorders
- Altered capillary permeability of lungs: inhaled toxins, inflammation (e.g., pneumonia), severe hypoxia, near-drowning
- Malignancies of the lymph system (e.g., non-Hodgkin's lymphoma)
- Respiratory distress syndrome (e.g., O_2 toxicity)
- Unknown causes: neurogenic condition, opioid overdose, reexpansion pulmonary edema, high altitude

The most common cause of pulmonary edema is left-sided heart failure. (Pathophysiology, clinical manifestations, and management of pulmonary edema are described in Chapter 35.)

PULMONARY EMBOLISM

Etiology and Pathophysiology

Pulmonary embolism (PE) is the blockage of pulmonary arteries by a thrombus, fat or air embolus, or tumor tissue. The word *embolus* derives from a Greek word meaning "plug" or "stopper." *Emboli* are mobile clots that generally do not stop moving until they lodge at a narrowed part of the circulatory system. A pulmonary embolus consists of material that gains access to the venous system and then to the pulmonary circulation. The embolus travels with the blood flow through ever-smaller blood vessels until it lodges and obstructs perfusion of the alveoli (Fig. 28-11). Because of higher blood flow, the lower lobes of the lung are commonly affected. Approximately 10% of patients with PE die within the first hour. An additional 30% die from recurrent embolism. Treatment with anticoagulants reduces the mortality rate to less than 5%.[43]

More than 90% of pulmonary emboli arise from deep vein thrombosis (DVT) in the deep veins of the legs.[7] *Venous thromboembolism* (VTE) is the preferred term to describe the spectrum of pathologic conditions from DVT to PE (see Table 38-7). Lethal pulmonary emboli most commonly originate in the femoral or iliac veins. Generally, DVTs that are below the knee are not considered a risk factor for PE, since they rarely migrate to the pulmonary circulation without first extending above the knee. The highest rate of DVT is in spinal cord injury patients (60% to 80%).[43]

Other sites of origin of PE include the right side of the heart (especially with atrial fibrillation), the upper extremities (rare),

FIG. 28-11 Large embolus from the femoral vein lying in the main left and right pulmonary arteries.

and the pelvic veins (especially after surgery or childbirth). Upper extremity DVT occasionally occurs in the presence of central venous catheters or cardiac pacing wires. These cases may resolve with the removal of the catheter.

In addition to dislodged thrombi, less common causes of PE include fat emboli (from fractured long bones), air emboli (from improperly administered IV therapy), bacterial vegetations, amniotic fluid, and tumors. Risk factors for PE include immobility or reduced mobility, surgery within the last 3 months (especially pelvic and lower extremity surgery), history of DVT, malignancy, obesity, oral contraceptives and hormone therapy, heavy cigarette smoking, prolonged air travel, heart failure, pregnancy, and clotting disorders.

Clinical Manifestations

The signs and symptoms in PE are varied and nonspecific, making diagnosis difficult. Symptoms may begin slowly or suddenly. Dyspnea is the most common presenting symptom, occurring in 85% of patients with PE.[7] A mild to moderate hypoxemia with a low $PaCO_2$ is a common finding. Other manifestations are tachypnea, cough, chest pain, hemoptysis, crackles, wheezing, fever, accentuation of the pulmonic heart sound, tachycardia, syncope, and sudden change in mental status as a result of hypoxemia.

Clinical manifestations depend on the size and extent of emboli. Massive emboli may produce abrupt hypotension and shock. The mortality rate for massive PE is 30% to 60%, with most deaths occurring within 1 to 2 hours of onset.[43]

Conversely, small emboli may go undetected or produce vague, transient symptoms. The exception to this is the patient with underlying cardiopulmonary disease. In these patients, even small or medium-sized emboli may result in severe cardiopulmonary compromise. Repeated pulmonary emboli gradually cause a reduction in the capillary bed and eventual pulmonary hypertension. Right ventricular hypertrophy can develop secondary to pulmonary hypertension.

Complications

Pulmonary infarction (death of lung tissue) is most likely when the following factors are present: (1) occlusion of a large or medium-sized pulmonary vessel (more than 2 mm in diameter), (2) insufficient collateral blood flow from the bronchial circulation, or (3) preexisting lung disease. Infarction results in alveolar necrosis and hemorrhage. Occasionally the necrotic tissue becomes infected, and an abscess may develop. Concomitant pleural effusion is frequent.

Pulmonary hypertension results from hypoxemia or from involvement of more than 50% of the area of the normal pulmonary bed. As a single event, an embolus does not cause pulmonary hypertension unless it is massive. Recurrent emboli may result in chronic pulmonary hypertension. Pulmonary hypertension eventually results in dilation and hypertrophy of the right ventricle. Depending on the degree of pulmonary hypertension and its rate of development, outcomes can vary, with some patients dying within months of the diagnosis and others living for decades.

Diagnostic Studies

D-dimer is a laboratory test that measures the amount of cross-linked fibrin fragments. These fragments are the result of clot degradation and are rarely found in healthy individuals. The disadvantage of D-dimer is that it is neither specific (other conditions cause elevation) nor sensitive, because up to 50% of patients with small pulmonary emboli have normal results. Patients with suspected PE and an elevated D-dimer level but normal venous ultrasound may need a spiral CT or lung scan.

A *spiral (helical) CT scan* (also known as CT angiography or CTA) is the most frequently used test to diagnose PE (Table 28-26). An IV injection of contrast media is required to view the blood vessels. The scanner continuously rotates while obtaining slices and does not start and stop between each slice. This allows visualization of all anatomic regions of the lungs. The computer reconstructs the data to provide a three-dimensional picture and assist in emboli visualization.

If a patient cannot have contrast media, a ventilation-perfusion (V/Q) scan is done. The V/Q scan has two components and is most accurate when both are performed:

1. *Perfusion scanning* involves IV injection of a radioisotope. A scanning device images the pulmonary circulation.
2. *Ventilation scanning* involves inhalation of a radioactive gas such as xenon. Scanning reflects the distribution of gas through the lung. The ventilation component requires the patient's cooperation and may be impossible to perform in the critically ill patient, particularly if the patient is intubated.

Pulmonary angiography is the most sensitive and specific test for PE. However, it is an expensive and invasive procedure that involves insertion of a catheter through the antecubital or femoral vein, advancement to the pulmonary artery, and injection of contrast medium. The reliability of the spiral CT has greatly diminished the need for pulmonary angiography.

ABG analysis is important, but not diagnostic. The PaO_2 is low because of inadequate oxygenation secondary to an occluded pulmonary vasculature preventing matching of perfusion to ventilation. The pH remains normal unless respiratory alkalosis develops as a result of prolonged hyperventilation or to compensate for lactic acidosis caused by shock. Abnormal findings are usually reported on the chest x-ray (atelectasis, pleural effusion) and the ECG (ST segment and T wave changes), but they are not diagnostic for PE. Serum troponin levels and b-type natriuretic peptide (BNP) levels are frequently elevated. Although not diagnostic, elevated levels of these markers are associated with increased mortality in patients with PE.[44]

TABLE 28-26 COLLABORATIVE CARE

Acute Pulmonary Embolism

Diagnostic	Collaborative Therapy
• History and physical examination • Chest x-ray • Continuous ECG monitoring • ABGs • Venous ultrasound • CBC count with WBC differential • Spiral (helical) CT scan • Ventilation-perfusion (V/Q) lung scan • D-dimer level • Troponin level, BNP level • Pulmonary angiography	• Supplemental O_2, intubation if necessary • Fibrinolytic agent • Unfractionated heparin IV • Low-molecular-weight heparin (e.g., enoxaparin [Lovenox]) • Warfarin (Coumadin) for long-term therapy • Monitoring of aPTT and INR levels • Limited activity • Opioids for pain relief • Inferior vena cava filter • Pulmonary embolectomy in life-threatening situation

ABGs, Arterial blood gases; *aPTT,* activated partial thromboplastin time; *BNP,* b-type natriuretic peptide; *INR,* international normalized ratio.

Collaborative Care

Prevention of PE begins with prevention of DVT. DVT prophylaxis includes the use of sequential compression devices, early ambulation, and anticoagulant medications.

To reduce mortality risk, treatment is begun as soon as PE is suspected (see Table 28-26). The objectives are to (1) prevent further growth or multiplication of thrombi in the lower extremities, (2) prevent embolization from the upper or lower extremities to the pulmonary vascular system, and (3) provide cardiopulmonary support if indicated.

Supportive therapy for the patient's cardiopulmonary status varies according to the severity of the PE. O_2 can be given via mask or cannula, and the concentration is determined by ABG analysis. In some situations, endotracheal intubation and mechanical ventilation are necessary to maintain adequate oxygenation. Respiratory measures such as turning, coughing, deep breathing, and using incentive spirometry are important to help prevent or treat atelectasis. If manifestations of shock are present, IV fluids are administered followed by vasopressor agents as needed to support perfusion (see Chapter 67). If heart failure is present, diuretics are used (see Chapter 35). Pain resulting from pleural irritation or reduced coronary blood flow is treated with opioids (usually morphine).

Drug Therapy. Immediate anticoagulation is required for patients with PE. Subcutaneous administration of low-molecular-weight heparin (LMWH) (e.g., enoxaparin [Lovenox]) has been found to be safer and more effective than use of unfractionated heparin. It is the recommended choice of treatment for patients with nonmassive PE. Unfractionated IV heparin can be as effective but is more difficult to titrate to therapeutic levels. Monitoring the aPTT is not necessary or useful when using LMWH.

Warfarin (Coumadin) should be initiated within the first 3 days of heparinization and is typically administered for 3 to 6 months. Some health care providers use direct thrombin inhibitors (see Table 38-10) in the treatment of PE. Anticoagulant therapy may be contraindicated if the patient has complicating factors such as blood dyscrasias, hepatic dysfunction causing alteration in the clotting mechanism, injury to the intestine, overt bleeding, a history of hemorrhagic stroke, or neurologic conditions.

Fibrinolytic agents, such as tissue plasminogen activator (tPA) or alteplase (Activase), dissolve the pulmonary embolus and the source of the thrombus in the pelvis or deep leg veins, thereby decreasing the likelihood of recurrent emboli. Indications for thrombolytic therapy in PE include hemodynamic instability and right ventricular dysfunction. (Fibrinolytic therapy is discussed in Chapter 34.)

Surgical Therapy. Hemodynamically unstable patients with massive PE with contraindications for fibrinolytic therapy are candidates for immediate pulmonary embolectomy. This can be achieved via a vascular (catheter) or surgical approach. Pulmonary embolectomy has a high mortality rate and is thus not recommended for patients who can be successfully treated otherwise.

To prevent further emboli, an inferior vena cava (IVC) filter may be the treatment of choice in patients who remain at high risk and patients for whom anticoagulation is contraindicated. This device is percutaneously placed at the level of the diaphragm in the inferior vena cava via the femoral vein. It prevents migration of large clots into the pulmonary system. The complications associated with this device are rare and include misplacement, migration, and perforation.

NURSING MANAGEMENT PULMONARY EMBOLISM

NURSING IMPLEMENTATION

Nursing measures aimed at prevention of PE are similar to those for prophylaxis of DVT (see Chapter 38, pp. 849-850).

The prognosis of a patient with PE is good if therapy is promptly instituted. Keep the patient on bed rest in a semi-Fowler's position to facilitate breathing. Maintain an IV line for medications and fluid therapy. Administer oxygen therapy as ordered. Assess the patient's cardiopulmonary status with careful monitoring of vital signs, cardiac rhythm, pulse oximetry, ABGs, and lung sounds. Monitor laboratory results to ensure therapeutic ranges of INR (for warfarin) and aPTT (for IV heparin). Monitor the patient for complications of anticoagulant and fibrinolytic therapy (e.g., bleeding, hematomas, bruising). Provide appropriate interventions related to immobility and fall precautions.

The patient is usually anxious because of pain, a sense of doom, inability to breathe, and fear of death. Carefully explain the situation and provide emotional support and reassurance to help relieve the patient's anxiety.

Patient teaching regarding long-term anticoagulant therapy is critical. Anticoagulant therapy continues for at least 3 to 6 months. Patients with recurrent emboli are treated indefinitely. INR levels are drawn at intervals and warfarin dosage is adjusted. Some patients are monitored by nurses in an anticoagulation clinic.

Long-term management is similar to that for the patient with DVT (see discussion of DVT in Chapter 38 on pp. 847-856). Discharge planning is aimed at limiting progression of the condition and preventing complications and recurrence. Reinforce the need for the patient to return to the health care provider for regular follow-up examinations.

EVALUATION

The expected outcomes are that the patient who has a PE will have

- Adequate tissue perfusion and respiratory function
- Adequate cardiac output
- Increased level of comfort
- No recurrence of PE

PULMONARY HYPERTENSION

Pulmonary hypertension is characterized by elevated pulmonary artery pressure, resulting from an increase in resistance to blood flow through the pulmonary circulation. Normally the pulmonary circulation is characterized by low resistance and low pressure. In pulmonary hypertension the pulmonary pressures are elevated with the mean pulmonary artery pressure greater than 25 mm Hg at rest (normal is 12 to 16 mm Hg) or greater than 30 mm Hg with exercise.

The disease commonly manifests with shortness of breath and fatigue. Pulmonary hypertension can occur as a primary disease *(idiopathic pulmonary arterial hypertension)* or as a secondary complication of a respiratory, cardiac, autoimmune, hepatic, or connective tissue disorder *(secondary pulmonary arterial hypertension)*.

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

Idiopathic pulmonary arterial hypertension (IPAH) is pulmonary hypertension that occurs without an apparent cause. (It was previously known as *primary pulmonary hypertension* [PPH].) If untreated, this disorder can be rapidly progressive, causing right-sided heart failure and death within a few years. Although new drug therapy has greatly improved survival, the disease remains incurable.

Etiology and Pathophysiology

The etiology of IPAH is unknown. It affects females more than males. The pathophysiology of IPAH is poorly understood. Some type of insult (e.g., hormonal, mechanical) to the pulmonary endothelium may occur, causing a cascade of events leading to vascular scarring, endothelial dysfunction, and smooth muscle proliferation[44] (Fig. 28-12).

Clinical Manifestations and Diagnostic Studies

Classic symptoms of pulmonary hypertension are dyspnea on exertion and fatigue. Exertional chest pain, dizziness, and exertional syncope are other symptoms. These symptoms are related to the inability of cardiac output to increase in response to increased oxygen demand. Eventually, as the disease progresses, dyspnea occurs at rest. Pulmonary hypertension increases the workload of the right ventricle and causes right ventricular hypertrophy (a condition called *cor pulmonale*) and eventually heart failure.

Right-sided cardiac catheterization is the definitive test to diagnose any type of pulmonary hypertension. In addition to providing an accurate measurement of pulmonary artery pressures, it also determines cardiac output and pulmonary vascular resistance. Confirmation of IPAH requires a thorough workup to exclude conditions that may cause secondary pulmonary hypertension. Diagnostic evaluation includes ECG, chest x-ray, pulmonary function tests, echocardiogram, and CT scans.

The mean time between onset of symptoms and the diagnosis is about 2 years. By the time patients become symptomatic, the disease is already in the advanced stages and the pulmonary artery pressure is two to three times normal.

PATHOPHYSIOLOGY MAP

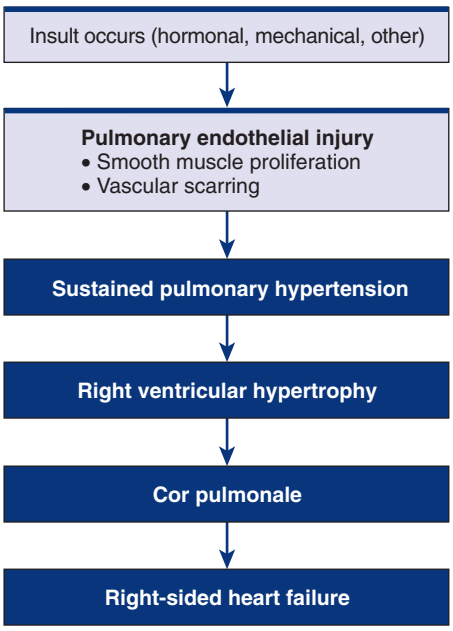

FIG. 28-12 Pathogenesis of pulmonary hypertension and cor pulmonale.

NURSING AND COLLABORATIVE MANAGEMENT PULMONARY HYPERTENSION

Early recognition of pulmonary hypertension is essential to interrupt the vicious cycle responsible for progression of the disease (see Fig. 28-12). Patients are classified using the New York Heart Association functional classification (see Chapter 35, Table 35-5).

Although IPAH has no cure, treatment can relieve symptoms, improve quality of life, and prolong life. Drug therapy consists of several drug classifications that promote vasodilation of the pulmonary blood vessels, reduce right ventricular overload, and reverse remodeling (Table 28-27). Diuretics are used to manage peripheral edema. The use of anticoagulants is also beneficial in pulmonary complications related to thrombus formation. Because hypoxia is a potent pulmonary vasoconstrictor, low-flow O_2 provides symptomatic relief. The goal is to keep O_2 saturation at 90% or greater.

Surgical interventions for pulmonary hypertension include atrial septostomy (AS) and lung transplantation. AS is a palliative procedure that involves the creation of an intraatrial right-to-left shunt to decompress the right ventricle. It is used for a select group of patients awaiting lung transplantation.

Lung transplantation is indicated for those patients who do not respond to drug therapy and progress to severe right-sided heart failure. Recurrence of the disease has not been reported in individuals who have undergone transplantation. A patient teaching and support website for pulmonary hypertension is located at *www.phassociation.org*.

SECONDARY PULMONARY ARTERIAL HYPERTENSION

Secondary pulmonary arterial hypertension (SPAH) occurs when a primary disease causes a chronic increase in pulmonary artery pressures. SPAH can develop as a result of parenchymal lung disease, left ventricular dysfunction, intracardiac shunts, chronic pulmonary thromboembolism, or systemic connective tissue disease. The specific primary disease pathology can result in anatomic or vascular changes causing the pulmonary hypertension.

The symptoms can reflect the underlying disease, but some are directly attributable to SPAH, including dyspnea, fatigue, lethargy, and chest pain. The initial physical findings can include right ventricular hypertrophy and signs of right ventricular failure (increased pulmonic heart sound, right-sided fourth heart sound, peripheral edema, and hepatomegaly).

Diagnosis of SPAH is similar to that of IPAH. Treatment of SPAH consists mainly of treating the underlying primary disorder. When irreversible pulmonary vascular damage has occurred, therapies used for IPAH are initiated. A pulmonary thromboendarterectomy (PTE) may offer a cure for patients with chronic pulmonary hypertension caused by thromboembolism. It is a technically demanding procedure and is performed only at selected centers.

TABLE 28-27 DRUG THERAPY

Pulmonary Hypertension

Drug	Mechanism of Action	Considerations
Calcium Channel Blockers		
nifedipine (Adalat CC, Nifedical XL, Procardia) diltiazem (Cardizem, Cardizem LA, Cartia XT, Tiazac)	• Act on vascular smooth muscle, causing dilation • Lower pulmonary artery pressure	• Can only be used in patients who do not have right-sided heart failure. • Used at high doses in comparison to other uses of calcium channel blockers.
Phosphodiesterase (Type 5) Enzyme Inhibitors		
sildenafil (Revatio) tadalafil (Adcirca)	• Promote selective smooth muscle relaxation in lung vasculature	• Given orally. • Contraindicated in patients taking nitroglycerin, since may cause refractory hypotension.
Vasodilators (Parenteral)		
epoprostenol (Flolan, Veletri) treprostinil (Remodulin) adenosine (Adenocard)	• Prostacyclin analog • Promote pulmonary vasodilation and reduce pulmonary vascular resistance	• Given IV to patients who do not respond to calcium channel blockers or have New York Heart Association (NYHA) class III or IV right-sided heart failure. • Given by continuous IV (central line) or continuous subcutaneous route (see Fig. 28-13). Half life of epoprostenol is short. Potential clinical deterioration from abrupt withdrawal if infusion disrupted.
Vasodilators (Inhaled)		
iloprost (Ventavis) treprostinil (inhaled) (Tyvaso)	• Synthetic analogs of prostacyclin (PGI_2) • Dilate systemic and pulmonary arterial vasculature	• Indicated for patients with NYHA class III or IV heart failure. • Administered 6-9 times a day using a disk inserted into a nebulizer. • Can cause orthostatic hypotension. Do not give to patients with systolic BP <85 mm Hg.
Endothelin Receptor Antagonists		
bosentan (Tracleer) ambrisentan (Letairis)	• Bind to endothelin-1 receptors, causing a reduction in pulmonary artery pressure, pulmonary vascular resistance, and mean atrial pressure • Significantly increase cardiac index	• Given orally. • Indicated for patients with NYHA class II to IV symptoms. • Hepatotoxic. • Monitor liver function tests monthly.

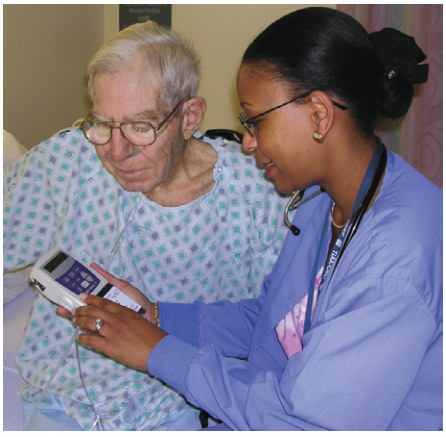

FIG. 28-13 A patient with pulmonary hypertension who is on continuous epoprostenol infusion is being taught how to use the portable infusion pump.

COR PULMONALE

Cor pulmonale is enlargement of the right ventricle caused by a primary disorder of the respiratory system. Pulmonary hypertension is usually a preexisting condition in cor pulmonale. Cor pulmonale may be present with or without overt cardiac failure. The most common cause of cor pulmonale is COPD. Almost any disorder that affects the respiratory system can cause cor pulmonale. Fig. 28-12 outlines the etiology and pathogenesis of pulmonary hypertension and cor pulmonale.

Clinical Manifestations and Diagnostic Studies

Clinical manifestations are subtle and often masked by the symptoms of the pulmonary condition. Common symptoms include exertional dyspnea, tachypnea, cough, and fatigue. Physical signs include evidence of right ventricular hypertrophy on ECG and an increase in intensity of the second heart sound. Chronic hypoxemia leads to polycythemia and increased total blood volume and viscosity of the blood. (Polycythemia is often present in cor pulmonale secondary to COPD.)

If heart failure accompanies cor pulmonale, additional manifestations such as peripheral edema; weight gain; distended neck veins; full, bounding pulse; and enlarged liver will also be found. (Heart failure is discussed in Chapter 35.) Various laboratory tests and imaging studies are used to confirm the diagnosis of cor pulmonale (Table 28-28).

Collaborative Care

The primary management of cor pulmonale is directed at treating the underlying pulmonary problem (see Table 28-28). Long-term O_2 therapy to correct the hypoxemia reduces vasoconstriction and pulmonary hypertension. If fluid, electrolyte, and acid-base imbalances are present, they must be corrected. Diuretics and a low-sodium diet help decrease the plasma volume and reduce the workload on the heart. Bronchodilator therapy is indicated if the underlying respiratory problem is due to an obstructive disorder. Other treatments include those for pulmonary hypertension, such as vasodilator therapy, calcium channel blockers, and anticoagulants. Theophylline may help

TABLE 28-28 COLLABORATIVE CARE

Cor Pulmonale

Diagnostic	Collaborative Therapy
• History and physical examination	• O_2 therapy
• ABGs, SpO_2	• Bronchodilators
• Serum and urine electrolytes	• Diuretics
• b-Type natriuretic peptide (BNP)	• Low-sodium diet
• ECG	• Vasodilators (if indicated)
• Chest x-ray	• Calcium channel blockers (if indicated)
• Echocardiography	• Inotropic agents
• CT scans	
• MRI	
• Cardiac catheterization	

due to its weak inotropic effect on the heart. Digitalis may also be used to increase cardiac contractility. Phlebotomy is indicated in patients with chronic cor pulmonale and chronic hypoxia causing severe polycythemia (hematocrit 65% or greater). Chronic management of cor pulmonale resulting from COPD is similar to that described for COPD (see Chapter 29).

LUNG TRANSPLANTATION

Lung transplantation has become an important mode of therapy for patients with end-stage lung disease. The limiting factor for this therapy is the availability of donors. A variety of pulmonary disorders are potentially treatable with lung transplantation (Table 28-29). Improved patient selection criteria, technical advances, and better methods of immunosuppression have resulted in improved survival rates.

Preoperative Care

Patients being considered for lung transplantation need to undergo extensive evaluation. Absolute contraindications for lung transplant include malignancy within past 2 years (except for skin cancer), chronic active hepatitis B or C, HIV, untreatable advanced dysfunction of another major organ system (e.g., liver or renal failure), current smoker, poor nutritional status, poor rehabilitation potential, and significant psychosocial problems. The patient and the family must be able to cope with a complex postoperative regimen (e.g., strict adherence to immunosuppressive therapy, continuous monitoring for early signs of infection, prompt reporting of manifestations of infection). Many transplant centers require preoperative outpatient pulmonary rehabilitation to maximize physical conditioning.

The United Network for Organ Sharing (UNOS) designates recipients of donor lungs based on a lung allocation score (LAS). The LAS prioritizes waiting list recipients based on the urgency of need and posttransplant survival expectations.

TABLE 28-29 INDICATIONS FOR LUNG TRANSPLANTATION*

- Chronic obstructive pulmonary disease
- Idiopathic pulmonary fibrosis
- Cystic fibrosis
- Idiopathic pulmonary arterial hypertension
- α_1-Antitrypsin deficiency

* These are the most common indications.

Patients who are accepted as good potential transplant candidates must carry a pager with them at all times in case a donor organ becomes available. These patients must be prepared to move to their chosen transplant center at a moment's notice. Such patients may be encouraged to limit their travel within a certain geographic region to facilitate rapid transportation to a transplant center.

Surgical Procedure

Four types of transplant procedures are available: single-lung transplantation, bilateral lung transplantation, heart-lung transplantation, and transplantation of lobes from a living-related donor. *Single-lung transplantation* involves an incision on the side of the chest. The opposite lung is ventilated while the diseased lung is excised. The lung is removed and the donor lung implanted. Three anastomoses are done: the bronchus, the pulmonary artery, and the pulmonary veins. In *bilateral lung transplantation* the incision is made across the sternum, and the donor lungs are implanted separately. A median sternotomy incision is used for a *heart-lung transplant* procedure. *Lobar transplantation* from living donors is reserved for candidates who urgently need transplantation and are unlikely to survive until a donor becomes available. The majority of these transplant recipients are patients with cystic fibrosis, and their parents or relatives are donors. Once anastomosis is complete, the lung is gently reinflated, perfusion is reestablished, two chest tubes are placed, and the surgical incision is closed.

Postoperative Care

Early postoperative care includes ventilatory support, fluid and hemodynamic management, immunosuppression, nutritional support, detection of early rejection, and prevention or treatment of infection. Pulmonary clearance measures, including aerosolized bronchodilators, chest physiotherapy, and deep-breathing and coughing techniques, minimize potential complications. Maintenance of fluid balance is vital in the postoperative phase.

Lung transplant recipients are at high risk for bacterial, viral, fungal, and protozoal infections. Infections are the leading cause of death in the early period after the transplant. Bacterial pneumonia, the most common infection, occurs in more than 35% of patients within the first year posttransplant.[45] Cytomegalovirus (CMV), the second most common cause of pneumonia, is the most common opportunistic infection, usually occurring 1 to 4 months postoperatively. Infection by *Aspergillus* organisms is the most common fungal infection.

Immunosuppressive therapy usually includes a three-drug regimen of tacrolimus, mycophenolate mofetil (CellCept), and prednisone. (The mechanisms of action of these drugs are discussed in Table 14-16 and Fig. 14-13.) Drug levels are monitored on a regular basis. Lung transplant recipients usually receive higher levels of immunosuppressive therapy than other organ recipients.

Acute rejection is fairly common in lung transplantation, typically occurring in the first 5 to 10 days after surgery. Low-grade fever, fatigue, dyspnea, dry cough, and O_2 desaturation are signs of rejection. Accurate diagnosis of rejection is by transtracheal biopsy. Treatment is high doses of IV corticosteroids administered for 3 days, followed by high doses of oral prednisone. In patients with persistent or recurrent acute rejection, antilymphocyte therapy may be useful.

Bronchiolitis obliterans (BOS) is a manifestation of chronic rejection in lung transplant patients. BOS is characterized by airflow obstruction that progresses over time. The onset is often subacute, with gradual development of exertional dyspnea, nonproductive cough, wheezing, and/or low-grade fever. The airway obstruction is not responsive to bronchodilators and corticosteroid therapy. Although not proven effective, additional immunosuppressive agents are used in the treatment of chronic rejection. Because acute rejection is a major risk factor for BOS, prevention of acute rejection is key to decreasing the incidence of chronic rejection.

Before discharge, the patient needs to be able to perform self-care activities, including medication management and activities of daily living, and to accurately identify when to call the transplant team. Patients are placed in an outpatient rehabilitation program to improve physical endurance. Home spirometry is useful in monitoring trends in lung function. Teach patients to keep medication logs, laboratory results, and spirometry records.

After discharge, the transplant team follows patients for transplant-related issues. Patients return to their primary care team for health maintenance and routine illnesses. As transplant procedures become more frequent, transplant patients will return to hospitals for other routine procedures. Coordination of care between the transplant team, primary care team, and inpatient teams is essential for ongoing successful management of these patients. (Organ transplantation, histocompatibility, rejection, and immunosuppressive therapy are discussed in Chapter 14.)

CASE STUDY

Pneumonia and Lung Cancer

iStockphoto/Thinkstock

Patient Profile

J.H. is a 52-year-old white man who comes to the emergency department complaining of shortness of breath. He has not seen a health care provider for many years.

Subjective Data

- Has a 38 pack-year history of cigarette smoking
- States he has always been slender but has had 25-lb weight loss despite a normal appetite in the past few months
- Admits to a "smoker's cough" for the past 2 to 3 years; recently coughing up blood
- Is married and the father of three adult children

Objective Data

Physical Examination

- Thin, pale man looking older than stated age
- Height 6 ft; weight 135 lb (61.2 kg)
- Intermittently confused and anxious with rapid shallow respirations
- Vital signs: temperature 102.6° F (39.2° C), heart rate 120, respiratory rate 36
- Chest wall has limited excursion on right side; auscultation of left side reveals coarse crackles but clear with cough; right side has diminished breath sounds

Diagnostic Studies

- Arterial blood gases: pH 7.21, PaO_2 58 mm Hg, $PaCO_2$ 82 mm Hg, HCO_3^- 33 mEq/L, O_2 saturation 84%
- Chest x-ray: consolidation of the right lung, especially in the base with possible mass in the area of right bronchus; pleural effusion on the right side
- Bronchoscopy with biopsy of mass: small cell lung carcinoma

Collaborative Care

- Diagnosis: pneumonia with small cell lung cancer
- Follow-up with patient and family to consider treatment options

Discussion Questions

1. How would you classify J.H.'s pneumonia? Why is this important?
2. What is your analysis of J.H.'s arterial blood gas results?
3. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
4. ***Priority Decision:*** What are the priority nursing interventions for J.H.?
5. ***Delegation Decision:*** Identify activities that can be delegated to unlicensed assistive personnel (UAP).
6. You are planning a meeting with J.H. and his family to discuss their needs. The physician tells you that J.H. is terminally ill. Who will you include in this meeting?
7. ***Evidence-Based Practice:*** J.H.'s children tell you that they are worried they will get lung cancer, since their father has it and they grew up around his secondhand smoke. They want to know what kind of screening is available for them. How will you respond?
8. What is the goal if radiation therapy is used for J.H.?
9. What issues should be addressed in your teaching of J.H. and his wife as you prepare him for discharge and care at home?

evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. When caring for a patient with acute bronchitis, the nurse will prioritize
   - **a.** auscultating lung sounds.
   - **b.** encouraging fluid restriction.
   - **c.** administering antibiotic therapy.
   - **d.** teaching the patient to avoid cough suppressants.

2. For which patients with pneumonia would the nurse suspect aspiration as the likely cause of pneumonia *(select all that apply)*?
   - **a.** Patient with seizures
   - **b.** Patient with head injury
   - **c.** Patient who had thoracic surgery
   - **d.** Patient who had a myocardial infarction
   - **e.** Patient who is receiving nasogastric tube feeding

3. An appropriate nursing intervention for a patient with pneumonia with the nursing diagnosis of ineffective airway clearance related to thick secretions and fatigue would be to
   a. perform postural drainage every hour.
   b. provide analgesics as ordered to promote patient comfort.
   c. administer O_2 as prescribed to maintain optimal oxygen levels.
   d. teach the patient how to cough effectively to bring secretions to the mouth.
4. A patient with TB has been admitted to the hospital and is placed in an airborne infection isolation room. What should the patient be taught *(select all that apply)*?
   a. Expect routine TST to evaluate infection.
   b. Visitors will not be allowed while in airborne isolation.
   c. Take all medications for full length of time to prevent multidrug-resistant TB.
   d. Wear a standard isolation mask if leaving the airborne infection isolation room.
   e. Maintain precautions in airborne infection isolation room by coughing into a paper tissue.
5. A patient has been receiving high-dose corticosteroids and broad-spectrum antibiotics for treatment secondary to a traumatic injury and infection. The nurse plans care for the patient knowing that the patient is most susceptible to
   a. candidiasis.
   b. aspergillosis.
   c. histoplasmosis.
   d. coccidioidomycosis.
6. When caring for a patient with a lung abscess, what is the nurse's priority intervention?
   a. Postural drainage
   b. Antibiotic administration
   c. Obtaining a sputum specimen
   d. Patient teaching regarding home care
7. The emergency department nurse is caring for patients exposed to a chlorine leak from a local factory. The nurse would closely monitor these patients for
   a. pulmonary edema.
   b. anaphylactic shock.
   c. respiratory alkalosis.
   d. acute tubular necrosis.
8. The nurse receives an order for a patient with lung cancer to receive influenza vaccine and pneumococcal vaccines. The nurse will
   a. call the health care provider to question the order.
   b. administer both vaccines at the same time in different arms.
   c. administer the flu shot and tell the patient to come back 1 week later to receive the pneumococcal vaccine.
   d. administer the pneumococcal vaccine and suggest FluMist (nasal vaccine) instead of the influenza injection.
9. The nurse identifies a flail chest in a trauma patient when
   a. multiple rib fractures are determined by x-ray.
   b. a tracheal deviation to the unaffected side is present.
   c. paradoxic chest movement occurs during respiration.
   d. there is decreased movement of the involved chest wall.
10. The nurse notes tidaling of the water level in the tube submerged in the water-seal chamber in a patient with closed chest tube drainage. The nurse should
    a. continue to monitor the patient.
    b. check all connections for a leak in the system.
    c. lower the drainage collector further from the chest.
    d. clamp the tubing at progressively distal points away from the patient until the tidaling stops.
11. An appropriate nursing intervention for a patient postpneumonectomy is
    a. monitoring chest tube drainage and functioning.
    b. positioning the patient on the unaffected side or back.
    c. doing range-of-motion exercises on the affected upper limb.
    d. auscultating frequently for lung sounds on the affected side.
12. A priority nursing intervention for a patient who has just undergone a chemical pleurodesis for recurrent pleural effusion is
    a. administering ordered analgesia.
    b. monitoring chest tube drainage.
    c. sending pleural fluid for laboratory analysis.
    d. monitoring the patient's level of consciousness.
13. When planning care for a patient at risk for pulmonary embolism, the nurse prioritizes
    a. maintaining the patient on bed rest.
    b. using sequential compression devices.
    c. encouraging the patient to cough and deep breathe.
    d. teaching the patient how to use the incentive spirometer.
14. Which statement(s) describe(s) the management of a patient following lung transplantation *(select all that apply)*?
    a. The lung is biopsied using a transtracheal method.
    b. High doses of oxygen are administered around the clock.
    c. The use of a home spirometer will help to monitor lung function.
    d. Immunosuppressant therapy usually involves a three-drug regimen.
    e. Most patients experience an acute rejection episode in the first 3 days.

1. a, 2. a, b, e, 3. d, 4. c, d, e, 5. a, 6. b, 7. a, 8. b, 9. c, 10. a, 11. c, 12. a, 13. b, 14. a, c, d

LEARNING OUTCOMES

1. Describe the etiology, pathophysiology, clinical manifestations, and collaborative care of asthma.
2. Describe the nursing management of the patient with asthma.
3. Describe the etiology, pathophysiology, clinical manifestations, and collaborative care of the patient with chronic obstructive pulmonary disease (COPD).
4. Describe the effects of cigarette smoking on the lungs.
5. Identify the indications for O_2 therapy, methods of delivery, and complications of O_2 administration.
6. Explain the nursing management of the patient with COPD.
7. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with cystic fibrosis.
8. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with bronchiectasis.

Imagine needing to consciously think about every breath that you take for minutes, hours, or days. Many individuals with obstructive lung disease have this experience. Approximately 31.5 million adult Americans are living with asthma or chronic obstructive pulmonary disease (COPD).[1,2]

Obstructive pulmonary disease, the most common chronic lung disease, is characterized by increased resistance to airflow as a result of airway obstruction or airway narrowing. Types of obstructive lung diseases include asthma, COPD, cystic fibrosis (CF), and bronchiectasis. *Asthma* is a chronic inflammatory lung disease that results in variable episodes of airflow obstruction, but it is usually reversible. *COPD* is an obstructive pulmonary disease with progressive limitation in airflow that is not fully reversible. The patient with asthma has

CULTURAL & ETHNIC HEALTH DISPARITIES

Obstructive Pulmonary Diseases

Asthma
- Asthma prevalence rates are more than 38% higher among African Americans than whites.
- Puerto Ricans have higher asthma prevalence rates and age-adjusted death rates than all other racial and ethnic subgroups.
- Female African Americans have the highest mortality rates from asthma among all ethnic/gender groups.

Chronic Obstructive Pulmonary Disease (COPD)
- Whites have the highest incidence of COPD in spite of higher rates of smoking among other ethnic groups.
- Hispanics have lower death rates related to COPD than other ethnic groups.

Cystic Fibrosis
- Whites have the highest incidence of cystic fibrosis.
- Cystic fibrosis is uncommon among African Americans, Hispanics, and Asian Americans.

variations in airflow over time, usually with normal lung function between exacerbations, whereas the limitation in expiratory airflow in the patient with COPD is generally more constant. The pathology of asthma and the response to therapy differ from those associated with COPD. However, the patient with a diagnosis of obstructive pulmonary disease may have features of both asthma and COPD. Patients with asthma who have less responsive reversible airflow obstruction are difficult to distinguish from COPD patients.

Cystic fibrosis, another form of obstructive pulmonary disease, is a genetic disorder that produces airway obstruction because of changes in exocrine glandular secretions, resulting in increased mucus production. *Bronchiectasis* is an obstructive disease characterized by dilated bronchioles. It most frequently results from untreated or poorly treated pulmonary infections that cause an increase in sputum production.

ASTHMA

Asthma is a chronic inflammatory disorder of the airways. The chronic inflammation leads to recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night or in the early morning. These episodes are associated with widespread but variable airflow obstruction that is usually reversible, either spontaneously or with treatment. The clinical course of asthma is unpredictable, ranging from periods of adequate control to exacerbations with poor control of symptoms.[3]

GENDER DIFFERENCES

Asthma

Men	Women
• Before puberty, more boys are affected than girls.	• After puberty and into adulthood, more women are affected than men. • Women who are admitted to the emergency department are more likely to need hospitalization than men. • Death rate from asthma is greater in women than in men.

Asthma affects an estimated 18.8 million adult Americans. Among adults, women are 62% more likely to have asthma than men. Asthma is a public health concern, with more than 14.2 million lost workdays in adults. However, the good news is that after a long period of an increasing incidence of asthma, the mortality and use of health care services are continuing to plateau and/or decrease. Despite the decline in the number of deaths from asthma over the past 10 years, more than 3300 people still die from asthma yearly.[1]

Risk Factors for Asthma and Triggers of Asthma Attacks

Risk factors for asthma and triggers of asthma attacks can be related to the patient (e.g., genetic factors) or the environment (e.g., pollen) (Table 29-1). Male gender is a risk factor for asthma in children (but not adults). Obesity is also a risk factor for asthma.[4] Other factors and triggers are discussed in this section.

Genetics. Asthma has a component that is inherited, but the genetics are complex. Numerous genes may be involved in the development of asthma and a person's response to various asthma medications.[3,4] *Atopy,* the genetic predisposition to develop an allergic (immunoglobulin E [IgE]–mediated) response to common allergens, is a major risk factor for asthma.

TABLE 29-1 TRIGGERS OF ASTHMA ATTACKS

Allergen inhalation
- Animal dander (e.g., cats, mice, guinea pigs)
- House dust mite
- Cockroaches
- Pollens
- Molds

Air pollutants
- Exhaust fumes
- Perfumes
- Oxidants
- Sulfur dioxides
- Cigarette smoke
- Aerosol sprays

Inflammation and infection
- Viral upper respiratory tract infection
- Sinusitis, allergic rhinitis

Drugs
- Aspirin
- Nonsteroidal antiinflammatory drugs
- β-Adrenergic blockers

Occupational exposure
- Agriculture, farming
- Paints, solvents
- Laundry detergents
- Metal salts
- Wood and vegetable dusts
- Industrial chemicals and plastics
- Pharmaceutical agents

Food additives
- Sulfites (bisulfites and metabisulfites)
- Beer, wine, dried fruit, shrimp, processed potatoes
- Monosodium glutamate
- Tartrazine

Other factors
- Exercise and cold, dry air
- Stress
- Hormones, menses
- Gastroesophageal reflux disease (GERD)

Immune Response. The *hygiene hypothesis* suggests that a newborn baby's immune system must be educated so it will function properly during infancy and the rest of life. People who are exposed to certain infections early in life, use few antibiotics, are exposed to other children (e.g., siblings, day care), or live in the country or with pets have a lower incidence of asthma. People for whom these factors are not present in childhood have a higher incidence of asthma.[3]

Allergens. Indoor and outdoor allergens, such as cockroaches, furry animals, fungi, and molds, can trigger asthma attacks. However, their role in the actual development of asthma is not as clear.[3,4]

Exercise. Asthma that is induced or exacerbated during physical exertion is called *exercise-induced asthma* (EIA). Typically, EIA occurs after vigorous exercise, not during it (e.g., jogging, aerobics, walking briskly, climbing stairs). Symptoms of EIA are pronounced during activities where there is exposure to cold, dry air. For example, swimming in an indoor heated pool is less likely to produce symptoms than downhill skiing. Airway obstruction may occur due to changes in the airway mucosa caused by hyperventilation during exercise, with either cooling or rewarming of air and capillary leakage in the airway wall.

Air Pollutants. Various air pollutants, such as cigarette or wood smoke or vehicle exhaust, can trigger asthma attacks. In heavily industrialized or densely populated areas, climatic conditions often lead to concentrated pollution in the atmosphere, especially with thermal inversions and stagnant air masses. Ozone alert days are regularly noted on the news reports, and patients should minimize outdoor activity during these times. Cigarette smoking is associated with an accelerated decline of lung functioning in a person with asthma, increases the severity of the disease, may cause the patient to be less responsive to treatment, and reduces the chance of the asthma being controlled. Despite the relationship of pollutants in triggering asthma attacks, the role of outdoor air pollution as a cause of asthma development remains controversial.[4]

Occupational Factors. *Occupational asthma* is the most common occupational respiratory disorder, with up to 15% of new asthma cases arising from job-related exposures to more than 300 agents.[4,5] Irritants cause a change in the responsiveness of the airways. However, the development of symptoms from this alteration may not occur until the patient has had months to years of exposure. Agricultural worker, baker, hospital worker, plastics manufacturer, and beautician are occupations with a high risk of occupational asthma. Characteristically people with occupational asthma give a history of arriving at work feeling well but gradually develop symptoms by the end of the day.

Respiratory Tract Infections. Respiratory tract infections (i.e., viral and not bacterial) are often the major precipitating factor of an acute asthma attack. Acute infection can increase airway narrowing and airway hyperresponsiveness. Viral-induced alterations of epithelial cells, increased inflammatory cell accumulation, edema of airway walls, and exposure of airway nerve endings contribute to altered airway function. These alterations in airway function may exacerbate asthma.

Nose and Sinus Problems. Most patients with asthma have a history of allergic rhinitis. Treatment of allergic rhinitis usually improves the symptoms of asthma. Additional information on the relationship of rhinitis and asthma can be found at *www.whiar.org*.

Acute and chronic sinusitis may worsen asthma. Some patients with asthma have chronic sinus problems that cause inflammation of the mucous membranes. Sinusitis must be treated and large nasal polyps removed for an asthma patient to have good control. (Sinusitis is discussed in Chapter 27.)

Drugs and Food Additives. Sensitivity to specific drugs may occur in some people, especially those with nasal polyps and sinusitis. Some people with asthma have what is termed the *asthma triad:* nasal polyps, asthma, and sensitivity to aspirin and nonsteroidal antiinflammatory drugs (NSAIDs). Salicylic acid can be found in many over-the-counter (OTC) drugs and some foods, beverages, and flavorings. Some asthmatics who use aspirin or NSAIDs (e.g., ibuprofen [Motrin]) develop wheezing within 2 hours. In addition, there is usually profound rhinorrhea, congestion, tearing, and even angioedema. Avoidance of aspirin and NSAIDs is required. However, patients with aspirin sensitivity under the care of an allergist can be desensitized by daily administration of the drug.

β-Adrenergic blockers in oral form (e.g., metoprolol [Toprol]) or topical eyedrops (e.g., timolol) may trigger asthma because they can cause bronchospasm. Angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril [Prinivil]) may produce cough in susceptible individuals, thus making asthma symptoms worse.

Other agents that may precipitate asthma in the susceptible patient are tartrazine (yellow dye no. 5, found in many foods) and sulfiting agents widely used in the food and pharmaceutical industries as preservatives and sanitizing agents. Sulfiting agents are commonly found in fruits, beer, and wine and used extensively in salad bars to protect vegetables from oxidation. Asthma exacerbations have been reported after the use of sulfite-containing preservatives found in topical ophthalmic solutions, IV corticosteroids, and some inhaled bronchodilator solutions.

Food allergies triggering asthma reactions in adults are rare. Avoidance diets are not recommended until an allergy has been demonstrated, usually by oral challenges.

Gastroesophageal Reflux Disease. Gastroesophageal reflux disease (GERD) is more common in people with asthma than in the general population. GERD may worsen asthma symptoms. Reflux may trigger bronchoconstriction and cause aspiration. On the other hand, asthma medications may worsen GERD symptoms. β_2-Agonists (especially given orally), which are used to treat asthma, relax the lower esophageal sphincter, thus allowing stomach contents to reflux into the esophagus and possibly be aspirated into the lungs. Medications used to treat GERD usually do not reduce asthma symptoms in most people.[4,6] (GERD is discussed in Chapter 42.)

Psychologic Factors. Asthma is not a psychosomatic disease. However, many people with asthma report that symptoms worsen with stress. Certainly psychologic factors cause bronchoconstriction via stimulation of the cholinergic reflex pathways. Extreme emotional expressions (e.g., crying, laughing, anger, fear) can lead to hyperventilation and hypocapnia, which can cause airway narrowing.[4]

An asthma attack caused by any triggering event can produce panic, stress, and anxiety. However, it varies from patient to patient and in the same patient from episode to episode.

Pathophysiology

The primary pathophysiologic process in asthma is persistent but variable inflammation of the airways. The airflow is limited

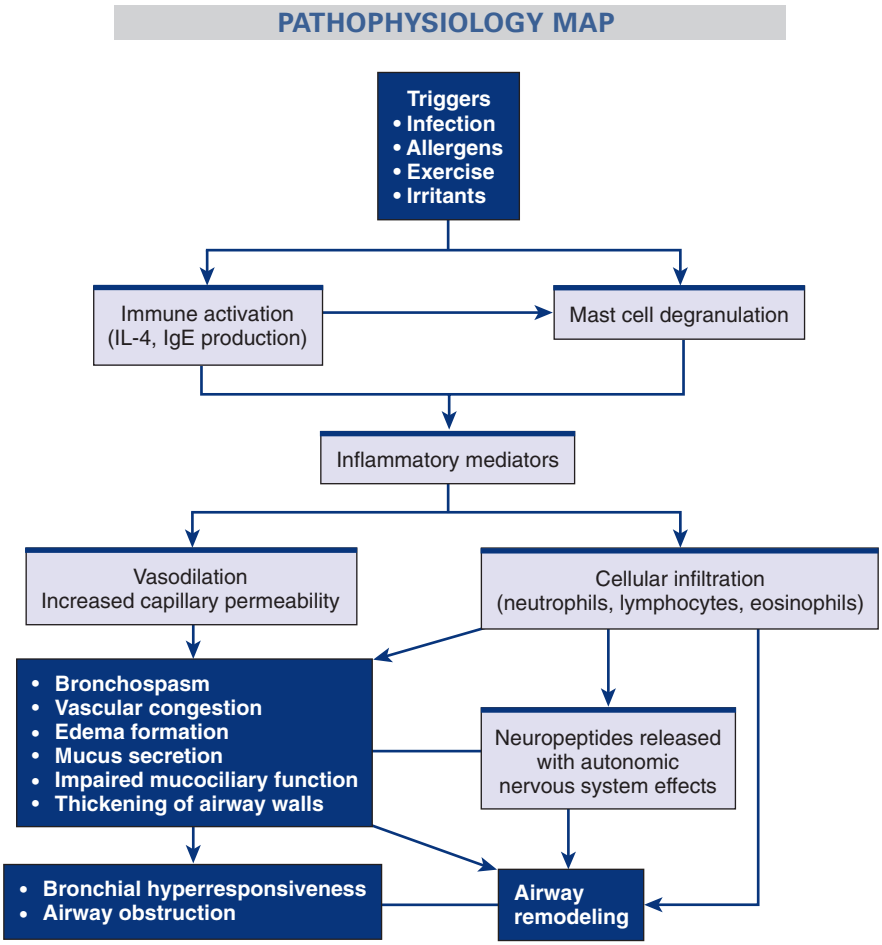

FIG. 29-1 Pathophysiology of asthma. *IL,* Interleukin.

because the inflammation results in bronchoconstriction, airway hyperresponsiveness (hyperreactivity), and edema of the airways. Exposure to allergens or irritants initiates the inflammatory cascade (Fig. 29-1). A variety of inflammatory cells are involved, including mast cells, macrophages, eosinophils, neutrophils, T and B lymphocytes, and epithelial cells of the airways.[3]

As the inflammatory process begins, mast cells (found beneath the basement membrane of the bronchial wall) degranulate and release multiple inflammatory mediators (Fig. 29-2). IgE antibodies are linked to mast cells, and the allergen cross-links the IgE. Then inflammatory mediators such as leukotrienes, histamine, cytokines, prostaglandins, and nitric oxide are released. Some inflammatory mediators have effects on the blood vessels, causing vasodilation and increasing capillary permeability. Some mediators result in the airways being infiltrated by eosinophils, lymphocytes, and neutrophils. The resulting inflammatory process causes vascular congestion, edema, production of thick and tenacious mucus, bronchial muscle spasm, thickening of airway walls, and increased bronchial hyperresponsiveness (Fig. 29-3). This whole process is sometimes referred to as the *early-phase response* in asthma. Clinically it can occur within 30 to 60 minutes after exposure to an allergen or irritant.

Symptoms can recur 4 to 6 hours after the early response because of the influx of many inflammatory cells, which are set

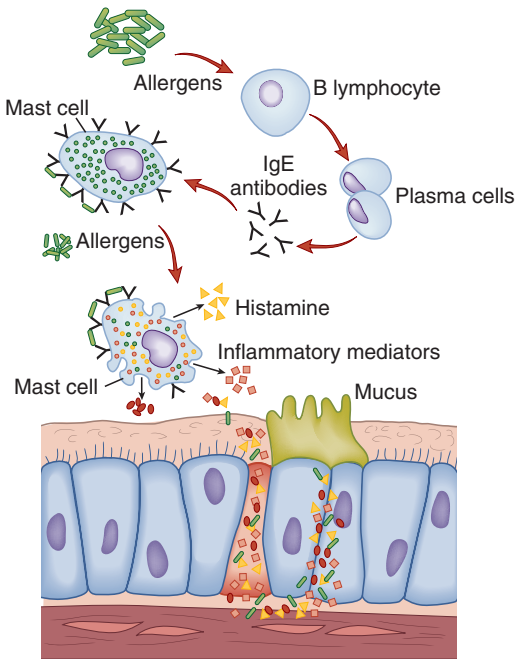

FIG. 29-2 Allergic asthma is triggered when an allergen cross-links IgE receptors on mast cells, which are then activated to release histamine and other inflammatory mediators (early-phase response). A late-phase response may occur due to further inflammation.

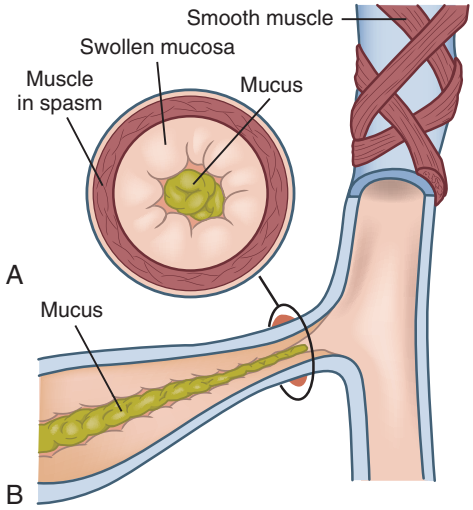

FIG. 29-3 Factors causing obstruction (especially expiratory obstruction) in asthma. **A,** Cross section of a bronchiole occluded by muscle spasm, swollen mucosa, and mucus in the lumen. **B,** Longitudinal section of a bronchiole.

in motion by the initial response. At this later time the patient may develop symptoms again or worsening of symptoms. This is called the *late-phase response,* which occurs in about 50% of individuals with asthma. In this late-phase response, more inflammatory cells are recruited and activated, with continuing inflammation of the airways. Thus bronchoconstriction with symptoms persists for 24 hours or more. Corticosteroids are effective in treating this inflammation.

Alterations in the neural control of the airways also occur in asthma. The autonomic nervous system, consisting of the parasympathetic and sympathetic systems, innervates the bronchi. Airway smooth muscle tone is regulated by the parasympathetic nervous system. In asthma the parasympathetic nervous system is overactive. When airway nerve endings are stimulated by mechanical or chemical stimuli (e.g., air pollution, cold air, dust, allergens), increased release of acetylcholine results in increased smooth muscle contraction and mucus secretion, ultimately leading to bronchoconstriction.

Chronic inflammation may result in structural changes in the bronchial wall known as *remodeling.* A progressive loss of lung function occurs that is not prevented or fully reversed by therapy. The changes in structure may include fibrosis of the subepithelium, smooth muscle hypertrophy of the airways, mucus hypersecretion, continued inflammation, and *angiogenesis* (proliferation of new blood vessels). Remodeling is thought to explain why some individuals have persistent asthma and limited response to therapy.[3,4]

Hyperventilation occurs during an asthma attack as lung receptors respond to increased lung volume from trapped air and airflow limitation. Decreased perfusion and ventilation of the alveoli and increased alveolar gas pressure lead to ventilation-perfusion abnormalities in the lungs. The patient is hypoxemic early on with decreased $PaCO_2$ and increased pH (respiratory alkalosis) because he or she is hyperventilating. As the airflow limitation worsens with air trapping, the patient works much harder to breathe. The $PaCO_2$ normalizes as the patient tires, and then it increases to produce respiratory acidosis, which is an ominous sign of respiratory failure.[6]

Clinical Manifestations

Asthma is characterized by an unpredictable and variable course, with a person's asthma attacks ranging from seemingly minor interferences in breathing to life-threatening episodes. Depending on an individual's response, asthma can rapidly progress from normal breathing to acute severe asthma. Recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning, are typical in asthma.

An attack of asthma may have an abrupt onset, but usually symptoms occur more gradually. Attacks may last for a few minutes to several hours. Between attacks the patient may be asymptomatic with normal or near-normal pulmonary function, depending on the severity of disease. However, in some people, compromised pulmonary function may result in a state of continuous symptoms and chronic debilitation characterized by irreversible airway disease.

The characteristic clinical manifestations of asthma are wheezing, cough, dyspnea, and chest tightness after exposure to a precipitating factor or trigger. Expiration may be prolonged. Instead of a normal inspiratory-expiratory ratio of 1:2, it may be prolonged to 1:3 or 1:4. Normally the bronchioles constrict during expiration. However, as a result of bronchospasm, edema, and mucus in the bronchioles, the airways become narrower than usual. Thus it takes longer for the air to move out of the bronchioles. This produces the characteristic wheezing, air trapping, and hyperinflation.

Wheezing is an unreliable sign to gauge the severity of an attack. Many patients with minor attacks wheeze loudly, whereas others with severe attacks do not wheeze. The patient with severe asthma attacks may have no audible wheezing because of the marked reduction in airflow. For wheezing to occur, the patient must be able to move enough air to produce the sound. Wheezing usually occurs first on exhalation. As asthma progresses, the patient may wheeze during inspiration and expiration. The term *wheezing* may also be used to describe sounds arising from the nose and upper airways.[7]

In some patients with asthma, cough is the only symptom, and this is termed *cough variant asthma.* The bronchospasm may not be severe enough to cause airflow obstruction, but it can increase bronchial tone and cause irritation with stimulation of the cough receptors. The cough may be nonproductive. Secretions may be thick, tenacious, white, gelatinous mucus, which makes their removal difficult.

The person with asthma has difficulty with air movement in and out of the lungs, which creates a feeling of suffocation. Patients may express, "I can't get a deep breath." Therefore during an acute attack, the person with asthma usually sits upright or slightly bent forward using the accessory muscles of respiration to try to get enough air. The more difficult the breathing becomes, the more anxious the patient feels.

Examination of the patient during an acute attack usually reveals signs of hypoxemia, which may include restlessness, anxiety, inappropriate behavior, and increased pulse and blood pressure (BP). As the patient worsens, it becomes difficult to speak in complete sentences. The respiratory rate is significantly increased (greater than 30 breaths/minute) with the use of accessory muscles. Percussion of the lungs indicates hyperresonance, and auscultation indicates inspiratory or expiratory wheezing. As the episode resolves, coughing produces thick, stringy mucus.

TABLE 29-2 CLASSIFICATION OF ASTHMA SEVERITY

Components of Severity	Asthma Severity			
	Intermittent	Persistent		
		Mild	Moderate	Severe
Impairment				
Symptoms	≤2 days/wk	>2 days/wk, not daily	Daily	Continuous
Nighttime awakenings	≤2/mo	3-4/mo	>1/wk, not nightly	Often, 7/wk
SABA use for symptoms	≤2 days/wk	>2 days/wk, not daily	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function*	Normal FEV_1 between exacerbations FEV_1 >80% FEV_1/FVC normal	FEV_1 >80% predicted FEV_1/FVC normal	FEV_1 60%-80% predicted FEV_1/FVC reduced by 5%	FEV_1 <60% predicted FEV_1/FVC reduced by 5%
Risk				
Exacerbations requiring oral corticosteroids	0-1/yr	≥2/yr even in the absence of impairment →		
	Consider severity and interval since last exacerbation →			
	Frequency and severity may fluctuate over time →			
	Relative annual risk of exacerbation may be related to FEV_1 →			
Recommended Step for Initiating Treatment	Step 1	Step 2	Step 3†	Step 4 or 5†
	Reevaluate asthma control in 2-6 wk and adjust therapy accordingly			

Guidelines for Using Table

- Patients should be assigned to the most severe step in which any feature occurs. Clinical features for individual patients may overlap across steps. Determine level of severity by assessment of both impairment and risk. Assess impairment by patient's recall of previous 2-4 wk and spirometry results.
- An individual's classification should change over time as treatment is initiated. After treatment, the focus switches to level of control, not the classification of severity.
- Patients at any level of severity of chronic asthma can have mild, moderate, or severe exacerbations of asthma. Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms.

Source: Adapted from National Asthma Education and Prevention Program, National Heart, Lung, and Blood Institute: *Expert Panel Report 3: guidelines for the diagnosis and management of asthma*, NIH pub no 08-4051, Bethesda, Md, 2007, National Institutes of Health. Retrieved from www.nhlbi.nih.gov/guidelines.
*Percent predicted values for FEV_1 or ratio of FEV_1/FVC. Normal FEV_1/FVC: 8-19 yr, 85%; 20-39 yr, 80%; 40-59 yr, 75%; 60-80 yr, 70%.
†Consider short-term corticosteroid therapy.
FEV_1, Forced expiratory volume in 1 sec; *FVC*, forced vital capacity; *SABA*, short-acting β_2-adrenergic agonist.

Diminished or absent breath sounds may indicate a significant decrease in air movement resulting from exhaustion and an inability to generate enough muscle force to ventilate. Severely diminished breath sounds, often referred to as the "silent chest," are an ominous sign, indicating severe obstruction and impending respiratory failure.

Classification of Asthma

Asthma can be classified as intermittent, mild persistent, moderate persistent, or severe persistent (Table 29-2). The classification system is used to determine the treatment. Patients may move to different asthma classifications over the course of their disease.

Complications

Severe and Life-Threatening Asthma Exacerbations. Severe asthma exacerbations occur when the patient is dyspneic at rest and the patient speaks in words, not sentences, because of the difficulty of breathing. The patient is usually sitting forward to maximize the diaphragmatic movement with prominent wheezing, a respiratory rate higher than 30 breaths/minute, and pulse greater than 120 beats/minute. Accessory muscles in the neck are straining to lift the chest wall, and the patient is often agitated. The peak flow (peak expiratory flow rate [PEFR]) is 40% of the personal best or less than 150 L/minute. Arterial blood gas (ABG) changes are listed in Table 29-3. Neck vein distention may result. These patients usually are seen in emergency departments (EDs) or hospitalized.[6]

A few patients perceive asthma symptoms poorly and may have a significant decrease in lung function without any change in symptoms. Patients with life-threatening asthma are typically too dyspneic to speak and perspire profusely. They may even be drowsy or confused as the ABGs further deteriorate. The breath sounds may be difficult to hear, and no wheezing is apparent because the airflow is exceptionally limited. Peak flow is less than 25% of the personal best. They become bradycardic and are close to respiratory arrest. These patients require ED or hospital care and are often admitted to an intensive care unit.

SAFETY ALERT

- If the patient has been wheezing and then there is an absence of a wheeze (i.e., silent chest) and the patient is obviously struggling, this is a life-threatening situation that may require mechanical ventilation.

Diagnostic Studies

Underdiagnosis of asthma is common. A detailed history is important to determine if a person has had similar attacks, which are often precipitated by a known trigger. (Triggers are discussed on pp. 561-562.) Because wheezing and cough are seen with a variety of disorders (e.g., COPD, GERD, vocal cord dysfunction, heart failure), it is important to determine if asthma is the cause of these problems.

TABLE 29-3 COMPARISON OF ASTHMA AND COPD*

	Asthma	COPD
Clinical Features		
Age	Usually <40 yr (onset).	Usually 40-50 yr (onset).
Smoking history	Not causal.	Often long history (>10-20 pack-years).
Health and family history	Presence of allergy, rhinitis, eczema. Family history of asthma.	Infrequent allergies. May have exposure to environmental pollutants. With α_1-antitrypsin deficiency, family history of lung or liver disease without smoking history.
Clinical symptoms	Intermittent, vary day to day, at night or early morning.	Slowly progressive and persistent.
Dyspnea	Absent except in exacerbations or poor control.	Dyspnea during exercise.
Sputum	Infrequent.	Often.
Disease course	Stable (with exacerbations).	Progressive worsening (with exacerbations).
Diagnostic Study Results		
ABGs	Normal between exacerbations.	Between exacerbations in advanced COPD • Often low-normal pH and PaO_2 • High-normal $PaCO_2$ with high HCO_3^- (compensated respiratory acidosis)
pH	↑ Early in exacerbation, then ↓ if prolonged or severe exacerbation.	N→↓
PaO_2	↓	N→↓
$PaCO_2$	↓ Early in exacerbation, then ↑ if prolonged or severe exacerbation.	N→↑
Chest x-ray	May reveal hyperinflation.	Hyperinflation. May have cardiac enlargement, flattened diaphragm.
Lung volumes	Often normalizes.	Never normalizes.
• Total lung capacity	Increased.	Increased.
• Residual volume	Increased.	Increased.
• FEV_1	Decreased.	Decreased.
• FEV_1/FVC	Normal to decreased.	Decreased (<70%).

*Individuals may have features of both asthma and COPD.
ABGs, Arterial blood gases; *FEV_1*, forced expiratory volume in 1 sec; *FVC*, forced vital capacity.

TABLE 29-4 COLLABORATIVE CARE

Asthma

Diagnostic
- History and physical examination
- Pulmonary function studies, including response to bronchodilator therapy
- Peak expiratory flow rate (PEFR)
- Chest x-ray
- Measurement of oximetry
- Allergy skin testing (if indicated)
- Blood level of eosinophils and IgE (if indicated)

Collaborative Therapy

Intermittent or Persistent Asthma
- Identification and avoidance or elimination of triggers
- Patient and caregiver teaching
- Drug therapy (see Tables 29-6 and 29-7 and Fig. 29-4)
- Asthma action plan (see Table 29-12)
- Desensitization (immunotherapy) if indicated
- Assess for control (e.g., Asthma Control Test [ACT])*

Severe or Life-Threatening Asthma Exacerbation
- SaO_2 monitoring
- ABGs
- Inhaled β_2-adrenergic agonists
- Inhaled anticholinergic agents (only in the initial treatment)
- O_2 by mask or nasal prongs
- IV or oral corticosteroids
- IV fluids
- IV magnesium and/or heliox
- Intubation and assisted ventilation

*See *www.qualitymetric.com/demos/TP_Launch.aspx?SID=52461*.
ABGs, Arterial blood gases; *IgE*, immunoglobulin E; *SaO_2*, O_2 saturation.

Some controversy exists about how to best diagnose asthma. Common diagnostic measures are presented in Table 29-4. In general, the health care provider should consider the diagnosis of asthma if various indicators (i.e., clinical manifestations, health history, peak flow variability or spirometry) are positive. Pulmonary function tests (PFTs) can be used to determine the reversibility of bronchoconstriction (using bronchodilators) and thus establish the diagnosis of asthma.

The peak expiratory flow rate (PEFR) measured by the peak flow meter is an aid to diagnose and monitor asthma. However, PEFR measurements are not interchangeable with other lung measurements of lung function (e.g., forced expiratory volume in 1 second [FEV_1]). PEFR should be compared with patients' own previous best measurements using their own meter, since types of peak flow meters vary.

PFTs are usually normal between asthma attacks if the patient has no other underlying pulmonary disease. However, the patient with asthma may show an obstructive pattern with asthma, including a decrease in forced vital capacity (FVC), FEV_1, PEFR, and FEV_1 to FVC ratio (FEV_1/FVC). (The normal values for PFTs are discussed in Chapter 26.)

When PFTs are scheduled, ask the patient to stop taking any bronchodilator medications for 6 to 12 hours before the tests. PFTs can be done before and after the administration of a bronchodilator to determine the degree of the response. This may help determine reversibility of airway obstruction, which is critical information for diagnosing asthma. A positive response to the bronchodilator is an increase of more than 200 mL and an increase of more than 12% between preadministration and postadministration values.

During an exacerbation of asthma, lung function parameters fall from their baseline levels. Some patients with symptoms of asthma have normal lung function. Therefore measures of airway responsiveness to known bronchial irritants (e.g., methacholine, histamine, exercise) may help establish a diagnosis of asthma.

An elevated serum eosinophil count and elevated serum IgE levels are highly suggestive of *atopy* (genetic predisposition to develop an allergic response), which may be a risk factor for asthma. Allergy skin testing may be of some value to determine sensitivity to specific allergens. However, a positive skin test does not necessarily mean that the allergen is causing the

TABLE 29-5 COMPONENTS OF ASTHMA CONTROL

Components of Control	Classification of Asthma Control: Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment			
Symptoms	≤2 days/wk	>2 days/wk	Throughout the day
Nighttime awakenings	≤2/mo	1-3/wk	≥4/wk
Interference with normal activity	None	Some limitation	Extremely limited
SABA use	≤2 days/wk	>2 days/wk	Several times/day
FEV_1 or peak flow	>80% predicted/personal best	60%-80% predicted/personal best	<60% predicted/personal best
Risk			
Exacerbations requiring oral corticosteroids	0-1/yr	≥2/yr	≥2/yr
Progressive loss of lung function	Consider severity and interval since last exacerbation. →		
Treatment-related adverse effects	Evaluation requires long-term follow-up. →		
	Can vary in intensity from none to very troublesome and worrisome. Level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk. →		
Recommended Action for Treatment			
(Based on assessment of control)	• Maintain current step. • Regular follow-up every 1-6 mo to maintain control. • Consider step down if well controlled for at least 3 mo.	• Step up one step. • Reevaluate in 2-6 wk. • For side effects, consider alternative treatment options.	• Consider oral corticosteroids. • Step up one or two steps and reevaluate in 2 wk. • For side effects, consider alternative treatment options.

FEV_1, Forced expiratory volume in 1 sec; *SABA*, short-acting β_2-adrenergic agonist.

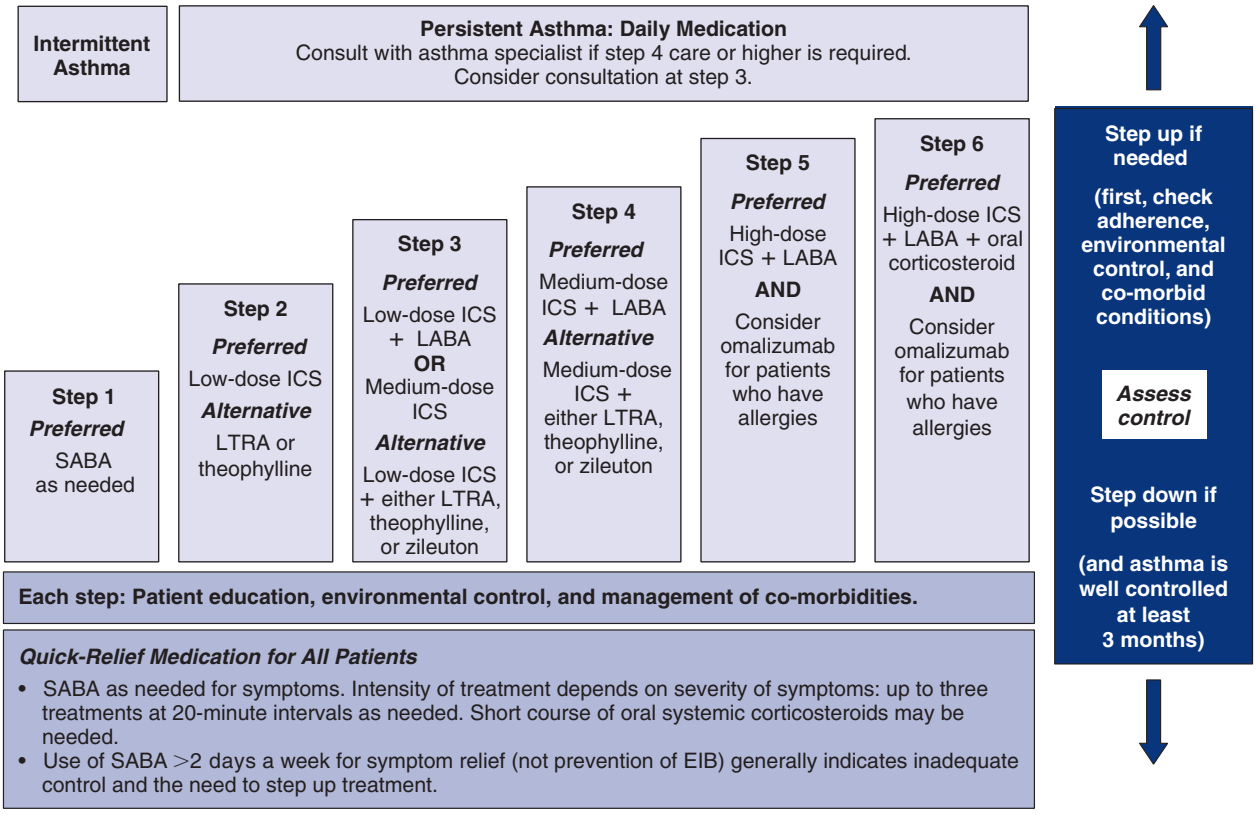
asthma attack. On the other hand, a negative allergy test does not mean that the asthma is not allergy related. (Allergy testing is discussed in Chapter 14.)

A chest x-ray in an asymptomatic patient with asthma is usually normal, but needs to be obtained as a baseline on initial diagnosis. A chest x-ray obtained during an acute attack usually shows hyperinflation and may reveal other complications of asthma such as mucoid impaction, pneumothorax, or atelectasis.

If the patient has wheezing and acute distress, it is not feasible to obtain a detailed health history (although a family member may supply some pertinent information). During an acute attack of asthma, bedside spirometry (specifically FEV_1 or FVC, but usually PEFR) may be used to monitor obstruction. PFT results, serial spirometric parameters, oximetry, and measurement of ABGs provide information about the severity of the attack and the response to therapy. A complete blood cell count (CBC) and serum electrolytes are also obtained to help monitor the course of therapy.

A sputum specimen for culture and sensitivity may be obtained to rule out bacterial infection, especially if the patient has purulent sputum, a history of upper respiratory tract infection, a fever, or an elevated white blood cell (WBC) count. However, the vast majority of asthma exacerbations are viral, and sputum cultures are rarely done on an outpatient basis.

A hand-held, point-of-care device, called Niox Mino, measures airway inflammation related to asthma. It measures fractional exhaled nitric oxide (FENO). Nitric oxide levels are increased in the breath of people with asthma and decreased with oral and inhaled corticosteroid and leukotriene treatment. This allows the health care provider to rely on FENO measures versus a patient's symptoms and lung function. FENO may be used to assess a patient's' adherence to therapy or to determine if he or she needs more antiinflammatory medication. FENO is also a predictor of loss of asthma control and exacerbations.[8]



Collaborative Care

The National Asthma Education and Prevention Program (NAEPP) of the National Heart, Lung, and Blood Institute (NHLBI) convened expert panels to prepare guidelines for the diagnosis and management of asthma.[3] The first NAEPP report served as a basis for the development of reports prepared by asthma experts worldwide, and the Global Initiative for Asthma (GINA) was created. The goals of GINA are to decrease asthma morbidity and mortality rates and improve the management of asthma worldwide.[4] Although the reports of NAEPP and GINA are similar, GINA is updated every year. The NAEPP guidelines are presented in this chapter (e.g., Tables 29-2 and 29-5 and Fig. 29-4).

The goal of asthma treatment is to achieve and maintain control of the disease. Once the patient is diagnosed, the guidelines provide direction on classification of asthma severity (see Table 29-2) and which medications (based on steps 1 through 6) the patient requires (Table 29-5 and Fig. 29-4). The current guidelines focus on (1) assessing the severity of the disease at diagnosis and initial treatment and then (2) monitoring periodically to control the disease.

At the initial diagnosis a patient may have severe asthma and require step 4 or 5 of asthma medication. After treatment the patient's level of control is assessed (i.e., well controlled, not well controlled, or very poorly controlled) (see Table 29-5). The health care provider steps down the medication as the patient achieves control of the symptoms, or steps it up if the symptoms worsen. Achieving rapid control of the symptoms is the goal to return the patient to his or her daily functioning at the best possible level (see Fig. 29-4).

Validated questionnaires (e.g., Asthma Control Test [ACT], *www.qualitymetric.com/demos/TP_Launch.aspx?SID=52461*) can be used to assess quality-of-life issues in asthma patients. The level of control is determined by the patient's current peak

TABLE 29-6 DRUG THERAPY

Long-Term Control Versus Quick Relief of Asthma

Long-Term Control Medications

Antiinflammatory Drugs

Corticosteroids
- Inhaled (e.g., fluticasone [Flovent Diskus or HFA])
- Oral (e.g., prednisone)

Leukotriene modifiers (e.g., montelukast [Singulair])

Anti-IgE (omalizumab [Xolair])

Bronchodilators

Long-acting inhaled β_2-adrenergic agonists (e.g., salmeterol [Serevent])

Long-acting oral β_2-adrenergic agonists (e.g., albuterol [VoSpire ER])

Methylxanthines (e.g., theophylline [Theo-24)

Quick-Relief Medications

Bronchodilators

Short-acting inhaled β_2-adrenergic agonists (e.g., albuterol [Proventil HFA])

Anticholinergics (inhaled) (e.g., ipratropium [Atrovent HFA])*

Antiinflammatory Drugs

Corticosteroids (systemic) (e.g., prednisone)†

*Used as alternative if patient has intolerable side effects to albuterol or in emergency department for moderate to severe exacerbations.
†Considered quick-relief drugs when used in a short burst (3-10 days) at the start of therapy or during a period of gradual deterioration. Corticosteroids are not used for immediate relief of an ongoing attack.

flow or FEV_1. In addition, any exacerbations or adverse effects of treatment will determine the level of control.

Intermittent and Persistent Asthma. The classification of severity of asthma at initial diagnosis helps determine which types of drugs are best suited to control the asthma symptoms (see Tables 29-2 and 29-5). Patients in all classifications of asthma require a short-term (rescue or reliever) medication. The most effective ones are the short-acting β_2-adrenergic agonists (SABAs) (e.g., albuterol [ProAir HFA, Proventil HFA, Ventolin HFA]). Patients with persistent asthma must also be on a long-term or controller medication (Table 29-6). Inhaled corticosteroids (ICSs) (e.g., fluticasone [Flovent Diskus or HFA]) are the most effective class of drugs to treat the inflammation. (See later section on drug therapy in this chapter.)

Acute Asthma Exacerbations. Asthma exacerbations may be mild to life threatening. With *mild exacerbations* the patient has difficulty breathing only with activity and may feel that he or she "can't get enough air." The peak flow is greater than 70% of the patient's personal best, and usually the symptoms are relieved at home promptly with an SABA such as albuterol delivered via a nebulizer or metered-dose inhaler (MDI) with a spacer. For any classification of asthma in a "rescue plan," patients are instructed to take 2 to 4 puffs of albuterol every 20 minutes three times to gain rapid control of symptoms. Occasionally a short course of oral corticosteroids is needed to decrease airway inflammation.

With a *moderate exacerbation,* dyspnea interferes with usual activities and peak flow is 40% to 60% of personal best. In this

situation the patient usually comes to the ED or a health care provider's office to get help. Relief is provided with the SABA delivered as in the mild exacerbation, and oral corticosteroids are needed. Oral routes are usually as effective as IV routes, as well as being less invasive and less expensive. The patient's symptoms may persist for several days even after the corticosteroids are started. Oxygen can be used with both mild and moderate exacerbations to maintain SpO_2 at 90% or greater. The patient's symptoms and peak flow are monitored and lung auscultation is done to ensure the patient is moving air. A good response would be measured by the peak flow (or FEV_1) returning to 70% of personal best, normal airflow on physical examination, alleviation of patient's distress, and findings sustained more than 1 hour after the last treatment.[3]

Severe and Life-Threatening Asthma Exacerbations. Severe and life-threatening asthma exacerbations are discussed on p. 565. Management of the patient with severe and life-threatening asthma focuses on correcting hypoxemia and improving ventilation. The goal is to keep the O_2 saturation at 90% or greater. Continuous monitoring of the patient is critical. Obtaining a peak flow reading during a severe asthma attack is usually not possible. However, if it can be obtained and it is less than 200 L/min, it indicates severe obstruction in all but very small adults.

Many of the therapeutic measures are the same as those for acute asthma. Repetitive or continuous SABA administration is provided in the ED. Initially three treatments of SABA are given, 20 to 30 minutes apart. Then more SABA is given depending on the patient's airflow, improvement, and side effects from the SABA. The person with a severe asthma exacerbation usually has partial relief from the SABA plus ipratropium (Atrovent). However, the patient with life-threatening asthma has minimal if any relief from the same medications.

After the initial treatment, ipratropium is not given during the inpatient stay, since it has not been found to deliver any added benefit. Nebulized SABAs are continued for several days even after clinical improvement is noted.

In severe asthma, oral systemic corticosteroids are given to patients who do not respond to the initial SABA. In life-threatening asthma, IV corticosteroids are administered and are usually tapered rapidly. IV corticosteroids (e.g., methylprednisolone) are administered every 4 to 6 hours, although their peak effect is not apparent for 4 to 12 hours. Then the patient is started on oral corticosteroids. The length of oral prednisone treatment for both severe and life-threatening asthma is usually about 10 days after discharge. ICSs are usually added while the patient is still in the hospital. High-dose ICSs prevent asthma relapse and may be prescribed until the patient can step down to lower doses.

In severe and life-threatening asthma, adjunctive medications such as IV magnesium sulfate may be administered to adults with a very low FEV_1 or peak flow (less than 40% of predicted or personal best) or those who fail to respond to initial treatment. In addition, for hospitalized patients who do not respond to the usual therapy, heliox (a mixture of helium and oxygen) may be used to deliver the nebulized albuterol. Helium has a low density and may improve the bronchodilation effect of albuterol.

Supplemental O_2 is given by mask or nasal prongs to achieve a PaO_2 of at least 60 mm Hg or O_2 saturation greater than 90%. An arterial catheter may be inserted to facilitate frequent ABG monitoring. Because the patient's insensible loss of fluids and metabolic rate are increased, moderate rates of IV fluids are given to provide optimal hydration.

Sodium bicarbonate administration is usually limited to treatment of severe metabolic or respiratory acidosis (pH less than 7.29) in the mechanically ventilated patient because effective bronchodilation by β-adrenergic agonists is not possible if the patient has extreme acidosis. Bronchoscopy, although rarely performed during an acute attack, may be necessary to remove thick mucus plugs.

Occasionally, asthma exacerbations are life threatening and respiratory arrest is pending or actually occurring. The patient requires intubation and mechanical ventilation if there is no response to treatment. The patient is provided with 100% oxygen, hourly or continuously nebulized SABA, IV corticosteroids, and possibly other adjunctive therapies as noted previously.

Theophylline, mucolytics, and sedatives are no longer recommended for asthma exacerbations. Sedatives can result in depression of the respiratory drive and possible death. Antibiotics are not recommended for asthma treatment unless there are signs of pneumonia, fever, and purulent sputum, suggesting bacterial infections. Chest physiotherapy is generally not recommended for asthma because it is too stressful for the breathless patient.[3]

Epinephrine is not routinely indicated for treatment in asthma exacerbations. However, a subcutaneous or intramuscular (IM) injection of epinephrine may be indicated for acute treatment of anaphylaxis. If epinephrine is administered, patients need their BP and electrocardiogram (ECG) monitored closely.

Bronchial thermoplasty is a novel approach that may be used in addition to traditional therapy in those with severe asthma. Via a fiberoptic bronchoscope, a catheter directly applies heat and reduces the muscle mass in the bronchial wall. This benefits the patient by reversing the accumulation of excessive tissue that is part of the remodeling process that causes narrowing of the airway size and adds to bronchoconstriction.[9]

Drug Therapy

A stepwise approach to drug therapy is based initially on the asthma severity and then on the level of control. Persistent asthma requires daily long-term therapy in addition to appropriate medications to manage acute symptoms. Medications are divided into two general classifications: (1) *quick-relief* or *rescue medications* to treat symptoms and exacerbations, such as SABAs; and (2) *long-term control medications* to achieve and maintain control of persistent asthma, such as ICSs (see Table 29-6). Some of the controllers are used in combination to gain better asthma control (e.g., fluticasone and salmeterol [Advair]) (Table 29-7).

Antiinflammatory Drugs

Corticosteroids. Chronic inflammation is a primary component of asthma. Corticosteroids are antiinflammatory medications that reduce bronchial hyperresponsiveness, block the late-phase response, and inhibit migration of inflammatory cells. Corticosteroids are more effective in improving asthma control than any other long-term drug. ICSs are first-line therapy for patients with persistent asthma requiring step 2 through 6 therapies (see Fig. 29-4). Usually, ICSs must be administered for 1 to 2 weeks before maximum therapeutic effects can be seen. Some ICSs (e.g., fluticasone, budesonide [Pulmicort]) begin to have a therapeutic effect

TABLE 29-7 DRUG THERAPY

Asthma and Chronic Obstructive Pulmonary Disease (COPD)*

Drug	Route of Administration	Comments†
Antiinflammatory Agents		
Corticosteroids		
hydrocortisone (Solu-Cortef)	IV	Alternate-day therapy minimizes side effects. Oral dose should be taken in morning with food or milk. When given in high dosages, observe for epigastric distress. Long-term corticosteroid therapy requires supplementation with vitamin D and calcium to prevent osteoporosis. Discontinue gradually over time to prevent adrenal insufficiency. If symptoms recur during tapering, notify health care provider.
methylprednisolone (Medrol, Solu-Medrol)	Oral, IV	
prednisone	Oral	
fluticasone (Flovent HFA, Flovent Diskus)	MDI, DPI	Not recommended for acute asthma attack. Rinse mouth with water or mouthwash after use to prevent oral fungal infections. Use of spacer device with MDI may decrease incidence of oral candidiasis. With ICSs, may not see effects until after at least 2 wk of regular treatment.
beclomethasone (Qvar)	MDI	Same as fluticasone except less oral candidiasis because of very small particle size, which is deposited deeper in the airways.
budesonide (Pulmicort Flexhaler)	DPI	Same as above.
mometasone (Asmanex Twisthaler)	DPI	Same as above.
ciclesonide (Alvesco)	MDI	Oral candidiasis and other localized oropharyngeal effects (e.g., hoarseness). Fewer side effects than other ICSs because of small particle size with minimal activation in oropharynx.
Phosphodiesterase Inhibitor Type 4 (PDE-4)		
roflumilast (Daliresp)	Oral	Only used in severe COPD to reduce exacerbation frequency. Not to be used for acute bronchospasm. GI symptoms occur within 6 mo of initiating medication. Patients to report any psychiatric symptoms (e.g., anxiety, depression, suicidal thoughts). Not to be used with theophylline.
Anticholinergics		
Short Acting		
ipratropium (Atrovent HFA)	Nebulizer, MDI	Approved for COPD. May provide additive benefit to SABA in moderate to severe asthma exacerbations (used in emergency department with no benefit beyond that). Use in asthma as alternative for patients with intolerable side effects with SABA. Temporary blurred vision if sprayed in eyes. Use cautiously in patients with narrow-angle glaucoma or prostatic enlargement.
aclidinium bromide (Tudorza, Pressair)	DPI	Only approved for COPD. Do not administer with other anticholinergics. Not for acute relief of bronchospasm.
Long Acting		
tiotropium (Spiriva HandiHaler)	DPI	Only approved for COPD. Blurred vision if powder comes in contact with eyes. Must discontinue use of ipratropium while on tiotropium. Patients with COPD must use SABA or short-acting anticholinergics for quick-relief medication. Maximum effect 1 wk after initiation of drug.
Anti-IgE		
omalizumab (Xolair)	Subcutaneous injection	Only for moderate to severe persistent allergic asthma with symptoms not adequately controlled by ICSs. Not for acute bronchospasm. Administer only under direct medical supervision and observe patient for a minimum of 2 hr after administration, since anaphylaxis has been reported with use.
Leukotriene Modifiers		
Leukotriene Receptor Blocker		
zafirlukast (Accolate)	Oral tablets	Take at least 1 hr before or 2 hr after meals. Affects metabolism of erythromycin and theophylline. Not used to treat acute asthma episodes.
montelukast (Singulair)	Oral tablets, chewable tablets, oral granules	Not used to treat acute asthma episodes.
Leukotriene Inhibitor		
zileuton (Zyflo, Zyflo CR)	Oral tablets	Monitor liver enzymes. May interfere with metabolism of warfarin (Coumadin) and theophylline. Not used to treat acute asthma episodes.
β_2-Adrenergic Agonists		
Inhaled: Short Acting (SABA)		
albuterol (Proventil HFA, Ventolin HFA, ProAir HFA, AccuNeb, VoSpire ER [oral only])	Nebulizer, MDI, oral tablets, including extended release NOTE: Oral tablets not for acute use, only long acting	Use with caution in patients with cardiac disorders, since β-agonists may cause ↑ BP and heart rate, CNS stimulation/excitation, and ↑ risk of dysrhythmias. Has rapid onset of action (1-3 min). Duration of action is 4-8 hr. Ventolin HFA is the only albuterol MDI with a counter.
levalbuterol (Xopenex, Xopenex HFA)	Nebulizer, MDI	Too frequent use can result in loss of effectiveness. Efficacy no better than other SABA.

*An enhanced version of this table listing side effects of drugs (eTable 29-1) is available on the website.

TABLE 29-7 DRUG THERAPY—cont'd

Asthma and Chronic Obstructive Pulmonary Disease (COPD)*

Drug	Route of Administration	Comments†
Inhaled: Long Acting (LABA)		*In asthma:* Never use as monotherapy. Use in combination with ICSs. *In COPD:* Can be used as monotherapy. Not used for rapid relief of dyspnea.
salmeterol (Serevent Diskus)	DPI	Not to exceed 2 puffs q12hr. Not used for acute exacerbations. Has a counter.
formoterol (Foradil Aerolizer, Perforomist)	DPI, nebulizer (Perforomist)	Can affect blood glucose levels. Use with caution in patients with diabetes.
arformoterol (Brovana)	Nebulizer	See formoterol. For chronic COPD use.
indacaterol (Arcapta Neohaler)	DPI	Only once-daily LABA. For chronic COPD use. Not intended to treat asthma.
Methylxanthines		
IV agent: aminophylline (second-line therapy) *Oral:* theophylline	Oral tablets, IV, elixir, sustained-release tablets	Wide variety of response to drug metabolism exists. Half-life is ↓ by smoking and ↑ by heart failure and liver disease. Cimetidine, ciprofloxacin, erythromycin, and other drugs may rapidly ↑ theophylline levels. Taking drug with food or antacids may help GI effects. Use usually limited to situations when other long-term bronchodilation not available or not affordable.
Combination Agents		Also see each component of medications for SE.
ipratropium/albuterol (Combivent Respimat, DuoNeb)	Nebulizer (DuoNeb), inhalation spray (Combivent Respimat)	Patients must be careful not to overuse. Respimat is an inhaler, but propellant free, unlike an MDI. Respimat is independent of inspiratory flow. Has dose indicator.
fluticasone/salmeterol (Advair Diskus or HFA)	DPI, MDI	See salmeterol and fluticasone. Has a counter. Comes in three different strengths.
budesonide/formoterol (Symbicort)	MDI	See budesonide and formoterol. Has a counter.
mometasone furoate/formoterol fumarate (Dulera)	MDI	
fluticasone/vilanterol (Breo Ellipta)	DPI	Vilanterol is an LABA.

†For patient instructions in English and Spanish for the devices, see *www.chestnet.org/accp/patient-guides/patient-instructions-inhaled-devices-english-and-spanish.*
DPI, Dry powder inhaler; *HFA*, hydrofluoroalkane (propellant); *ICSs*, inhaled corticosteroids; *MDI*, metered-dose inhaler.

in 24 hours. These drugs need to be administered on a fixed schedule.

When ICSs are administered, asthma can usually be controlled without significant systemic side effects, since little systemic drug absorption occurs from these devices. However, ICSs at the highest dosage levels have been associated with side effects (e.g., easy bruising, decreased bone mineral density).[4] Oropharyngeal candidiasis, hoarseness, and dry cough are local side effects caused by inhalation of corticosteroids. These problems can be reduced or prevented by using a spacer (Fig. 29-5) with the MDI and by gargling with water or mouthwash after each use. Using a spacer or holding device for inhalation of corticosteroids can be helpful in getting more medication into the lungs. However, drugs that are activated in the lungs (not the pharynx) (e.g., ciclesonide [Alvesco]) appear to minimize these side effects without the need for a spacer or mouth rinsing.[4]

To gain prompt control, short courses of orally administered corticosteroids are indicated for acute exacerbations of asthma. Maintenance doses of oral corticosteroids may be necessary to control asthma in a minority of patients with severe chronic asthma when long-term therapy is required. A single dose in the morning to coincide with endogenous cortisol production and alternate-day dosing are associated with fewer side effects. (Side effects of long-term corticosteroid therapy are discussed in Chapter 50.)

Women, especially postmenopausal women, who have asthma and who use corticosteroids should take adequate amounts of calcium and vitamin D and participate in regular weight-bearing exercise. (Osteoporosis is discussed in Chapter 64.)

FIG. 29-5 Example of an AeroChamber spacer used with a metered-dose inhaler.

Leukotriene Modifiers. Leukotriene modifiers include leukotriene receptor blockers (antagonists) (zafirlukast [Accolate], montelukast [Singulair]) and leukotriene synthesis inhibitors (zileuton [Zyflo CR]). These drugs interfere with the synthesis or block the action of leukotrienes. Leukotrienes are inflammatory mediators produced from arachidonic acid metabolism (see Fig. 12-2). Leukotrienes are potent bronchoconstrictors, and some also cause airway edema and inflammation, thus

contributing to the symptoms of asthma. Because these drugs block the release of some substances from mast cells and eosinophils, they have both bronchodilator and antiinflammatory effects.

These drugs are not indicated for use in the reversal of bronchospasm in acute asthma attacks. They are used for prophylactic and maintenance therapy. One advantage of leukotriene modifiers is that they are administered orally.

Anti-IgE. Omalizumab (Xolair) is a monoclonal antibody to IgE that decreases circulating free IgE levels. Omalizumab prevents IgE from attaching to mast cells, thus preventing the release of chemical mediators. This drug is indicated for patients with moderate to severe persistent, allergic asthma or those requiring step 5 or 6 care with persistent asthma that cannot be controlled with ICSs. Omalizumab is administered subcutaneously every 2 to 4 weeks. The drug has a risk of anaphylaxis, and patients must receive the medication in a health care provider's office where this potential emergency problem can be handled.

Bronchodilators. Three classes of bronchodilator drugs currently used in asthma therapy are β_2-adrenergic agonists (also referred to as β_2-agonists), methylxanthines and derivatives, and anticholinergics (see Table 29-7).

β_2-Adrenergic Agonist Drugs. These drugs may be short-acting β_2-adrenergic agonists (SABAs) or long-acting β_2-adrenergic agonists (LABAs). Because inhaled SABAs are the most effective drugs for relieving acute bronchospasm (as seen in acute exacerbations of asthma), they are known as rescue medications. Examples of these drugs include albuterol and pirbuterol (Maxair Autohaler). These drugs have an onset of action within minutes and are effective for 4 to 8 hours. These drugs act by stimulating β-adrenergic receptors in the bronchioles, thus producing bronchodilation. They also increase mucociliary clearance.

DRUG ALERT: β_2-Adrenergic Agonists
- Use with caution in patients with cardiac disorders, since both SABAs and LABAs may cause elevated BP and heart rate, central nervous system stimulation or excitation, and increased risk of dysrhythmias.
- Overuse of SABAs may cause rebound bronchospasms.

β_2-Adrenergic agonists are also useful in preventing bronchospasm precipitated by exercise and other stimuli because they prevent the release of inflammatory mediators from mast cells. They do not inhibit the late-phase response of asthma or have antiinflammatory effects. If used frequently, inhaled β_2-adrenergic agonists may produce tremors, anxiety, tachycardia, palpitations, and nausea. Too frequent use of β_2-adrenergic agonists indicates poor asthma control, may mask asthma severity, and may lead to reduced drug effectiveness. The goal in asthma therapy is that the patient with persistent asthma will never need to use SABAs for rescue, but that effective control is achieved with a long-term controller medication.

SABAs are not used for long-term control, and they should not be used alone for persistent asthma. They are used in any stage of asthma for quick relief and should be with the patient at all times for that purpose. Oral β_2-agonists are rarely used because of the cardiovascular side effects, skeletal muscle tremor, and anxiety. However, they may be used for long-term control, but they should not be used alone or as first-line therapy in treating asthma.

LABAs, including salmeterol (Serevent Diskus) and formoterol (Foradil), are effective for 12 hours. LABAs are added to a daily dose of ICSs for long-term control of moderate to severe persistent asthma (i.e., step 3 or higher for long-term control) and prevention of symptoms, particularly at night. When LABAs are added to a patient's daily regimen of corticosteroids, they decrease the need for SABAs and allow patients to achieve better asthma control with a lower dosage of ICSs.[3,4]

LABAs should never be used as monotherapy for asthma, and should only be used if the patient is on ICS. Tell patients that these drugs should not be used to treat acute symptoms or to obtain quick relief from bronchospasm. Teach the patient that these drugs are used only once every 12 hours.

DRUG ALERT: Long-Acting β_2-Adrenergic Agonists (LABAs)
- Should not be the first medicine used to treat asthma.
- Should never be used as the only medication to treat asthma but should be added to the treatment plan only if other controller medicines do not control asthma.
- Should not be used to treat wheezing that is getting worse.
- Always use a SABA to treat sudden wheezing.

Combination therapy using an ICS and LABA is available in several inhalers (e.g., Advair and budesonide/formoterol [Symbicort]). The combinations are more convenient, improve adherence, and ensure that patients receive the LABA together with an ICS.

Methylxanthines. Sustained-release methylxanthine (theophylline) preparations are not a first-line controller medication. They are used only as an alternative therapy for step 2 care in mild persistent asthma. Methylxanthine is a bronchodilator with mild antiinflammatory effects, but the exact mechanism of action is unknown.

DRUG ALERT: Theophylline
- Instruct patient to report signs of toxicity: nausea, vomiting, seizures, insomnia.
- Avoid caffeine to prevent intensifying adverse effects.

The main problems with theophylline are the relatively high incidence of interaction with other drugs and the side effects, which include nausea, headache, insomnia, gastrointestinal distress, tachycardia, dysrhythmias, and seizures. Because theophylline has a narrow margin of safety, monitor serum blood levels regularly to determine if the drug is within therapeutic range.

Anticholinergic Drugs. Anticholinergic agents (e.g., ipratropium) block the bronchoconstricting effect of the parasympathetic nervous system. These drugs are less effective than β_2-adrenergic agonists. Anticholinergic drugs are used for quick relief in those patients unable to tolerate SABAs. In addition, they are used for the patient in severe asthma exacerbation in emergency situations, often nebulized with an SABA. Other than these indications, they have no role in the treatment of asthma.

The onset of action of ipratropium is slower than that of β_2-adrenergic agonists, peaking at 30 minutes to 1 hour and lasting up to 4 to 6 hours. Systemic side effects of inhaled anticholinergics are uncommon because they are poorly absorbed. The most common side effect is a dry mouth.

Inhalation Devices for Drug Delivery. The multiple devices for asthma drug administration can be confusing. The majority of asthma drugs are administered only or preferably by inhalation because systemic side effects are reduced and the onset of action is faster. Inhalation devices include metered-dose inhalers (MDIs), dry powder inhalers (DPIs), and nebulizers.

Inhalers. MDIs are small, hand-held, pressurized devices that deliver a measured dose of drug with each activation.

Dosing is usually accomplished with one or two puffs. Depending on the specific MDI, a spacer or holding chamber (e.g. AeroChamber or InspirEase [see Fig. 29-5]) is used to reduce the amount of drug delivered to the oropharynx and improve the amount of drug delivered to the lungs. In addition, spacers assist people who have hand-breath coordination problems.[10]

All MDIs are mandated by international law to have an ozone-friendly propellant, which is a hydrofluoroalkane (HFA). This propellant is nontoxic, evaporates almost instantly once it forces medicine out of the MDI canister, and is not harmful to the patient. The number of times an MDI needs to be primed and the frequency of priming vary widely, so read the package insert with the patient.[10]

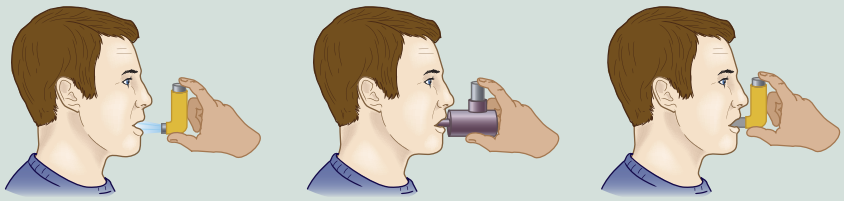
The MDI should be cleaned by removing the dust cap and rinsing the holder (not the medication chamber) in warm water at least two times per week (Fig. 29-6). The patient who needs to use several MDIs is often unclear about the order in which to take the medications. Historically it had been recommended that SABAs should be used first to open up the airway and improve the delivery of subsequent medications. However, this technique is not evidence based. It is a potential source of confusion to patients because the SABAs are usually used on an as-needed (PRN) basis.

One of the major problems with metered-dose drugs is the potential for overuse (more than two canisters per month) rather than seeking needed medical care (Table 29-8). As a patient develops additional asthmatic symptoms, he or she may use the β_2-adrenergic agonist MDI repeatedly. β_2-Adrenergic agonists help by relieving bronchospasm. They do not treat the inflammatory response. Therefore teach the patient the correct therapeutic use of these drugs. The patient also needs to know the correct way to determine whether the MDI is empty (see

Using an inhaler seems simple, but most patients do not use it the right way. When you use your inhaler the wrong way, less medicine gets to your lungs. (Your physician may give you other types of inhalers.)

For the next 2 weeks, read these steps aloud as you do them or ask someone to read them to you. Ask your physician or nurse to check how well you are using your inhaler.

Use your inhaler in one of the three ways pictured below (**A** or **B** is best, but **C** can be used if you have trouble with **A** or **B**).



Steps for Using Your Inhaler

Getting ready	1. Take off the cap and shake the inhaler. 2. Breathe out all the way. 3. Hold your inhaler the way your doctor said (**A, B,** or **C** below).
Breathe in slowly	4. As you start breathing in **slowly** through your mouth, press down on the inhaler **one** time. (If you use a holding chamber, first press down on the inhaler. Within 5 seconds, begin to breathe in slowly.) 5. Keep breathing in **slowly,** as deeply as you can.
Hold your breath	6. Hold your breath as you count to 10 slowly, if you can. 7. For inhaled quick-relief medicine (β_2-agonists), wait about 1 minute between puffs. There is no need to wait between puffs for other medicines.

A. Hold inhaler 1 to 2 inches in front of your mouth (about the width of two fingers).

B. Use a spacer/holding chamber. These come in many shapes and can be useful to any patient.

C. Put the inhaler in your mouth.

Clean Your Inhaler as Needed

Look at the hole where the medicine sprays out from your inhaler. If you see "powder" in or around the hole, clean the inhaler. Remove the metal canister from the L-shaped plastic mouthpiece. Rinse only the mouthpiece and cap in warm water. Let them dry over night. In the morning, put the canister back inside. Put the cap on.

Know When to Replace Your Inhaler

For medicines you take each day (an example): Say your new canister has 200 puffs (number of puffs is listed on canister) and you are told to take 8 puffs per day.

$$8 \text{ puffs per day} \overline{)\ 200 \text{ puffs in canister}} \quad 25 \text{ days}$$

So this canister will last 25 days. If you started using this inhaler on May 1, replace it on or before May 25. You can write the date on your canister.

For **quick-relief medicine take as needed** and count each puff.

Do not put your canister in water to see if it is empty as water may enter MDI and impair inhaler.

FIG. 29-6 How to use your metered-dose inhaler correctly.

TABLE 29-8 PROBLEMS USING A METERED-DOSE INHALER (MDI)

- Failing to coordinate activation with inspiration
- Activating MDI in the mouth while breathing through nose
- Inspiring too rapidly
- Not holding the breath for 10 sec (or as close to 10 sec as possible)
- Holding MDI upside down or sideways
- Inhaling more than 1 puff with each inspiration
- Not shaking MDI before use
- Not waiting a sufficient amount of time between each puff
- Not opening mouth wide enough, causing medication to bounce off teeth, tongue, or palate
- Not having adequate strength to activate MDI
- Being unable to understand and follow directions

FIG. 29-7 Example of a dry powder inhaler (DPI).

Fig. 29-6). In the past, floating the MDI in water was an appropriate way to determine if medication remained in the MDI. Now this is not recommended because it is not accurate and water can enter the MDI. Teach patients that shaking the canister is not an accurate way to determine if the MDI is empty because they may be hearing only the propellant.

DPIs are simpler to use than MDIs (Fig. 29-7 and Table 29-9). The DPI contains dry, powdered medication and is breath activated. No propellant is used. Instead an aerosol is created when the patient inhales through a reservoir containing a dose of powder. The convenient-to-carry diskus has several advantages over MDIs: (1) less manual dexterity is needed, (2) there is no need to coordinate device puffs with inhalation, (3) an easily visible color or number system indicates the number of doses left in the diskus, and (4) no spacer is required. Disadvantages are that commonly prescribed drugs are not yet available in DPIs and the medication may clump if exposed to humidity. Since the medicine is delivered only by the patient's inspiratory effort, patients with a low FEV_1 (less than 1 L) may not be able to inspire the medication adequately.

Differences between MDIs and DPIs are presented in Table 29-10. Aerosolized medication delivery systems, when used with comparable drug doses, provide equivalent efficacy. Therefore patients should use the device best suited to their needs.

TABLE 29-9 PATIENT TEACHING GUIDE

How to Use a Dry Powder Inhaler (DPI)

Include the following instructions when teaching a patient to use a DPI.

1. Remove mouthpiece cap or open the device according to manufacturer's instructions. Check for dust or dirt. If there is an external counter, note the number of doses remaining.
2. Load the medicine into the inhaler or engage the lever to allow the medicine to become available. Some DPIs should be held upright while loading. Others should be held sideways or in a horizontal position.
3. Do not shake your medicine.
4. Tilt your head back slightly and breathe out, getting as much air out of your lungs as you can. Do not breathe into your inhaler because this could affect the dose.
5. Close your lips tightly around the mouthpiece of the inhaler.
6. Breathe in deeply and quickly. This will ensure that the medicine moves down deeply into your lungs. You may not taste or sense the medicine going into your lungs.
7. Hold your breath for 10 seconds or as long as you can to disperse the medicine into your lungs.
8. If there is an external counter, note the number of doses remaining. It should be one less than the number in step 1 above.
9. Do not keep your DPI in a humid place such as a shower room because the medicine may clump.

TABLE 29-10 COMPARISON OF METERED-DOSE AND DRY POWDER INHALERS

	Metered-Dose Inhaler (MDI)	Dry Powder Inhaler (DPI)
Shake before use	Yes, shake well*	No
Inspiration	Slow	Rapid
Spacer	Yes, at least with inhaled corticosteroids*	None permitted
Counting device	Few have external device	Most preloaded forms include counter
Inhalations/dose	Often 2/dose	Often 1/dose
Cleaning	Use water for plastic case	Avoid moisture

Source: National Jewish Health: Inhaled medication instructional videos: asthma and general lung diseases. Retrieved from *www.nationaljewish.org/healthinfo/medications/lung-diseases/devices/instructional-videos*.
*MDIs use hydrofluoroalkane (HFA) as a propellant, and shaking or a spacer may not be needed.

Nebulizers. Nebulizers are small machines used to convert drug solutions into mists. The mist can be inhaled through a face mask or mouthpiece held between the teeth. Nebulizers are usually used for individuals who have severe asthma or difficulty with the MDI inhalation.

Nebulizers are usually powered by a compressed air or O_2 generator. At home the patient may have an air-powered compressor. In the hospital, wall O_2 or compressed air is used to power the nebulizer.

Aerosolized medication orders must include the medication, dose, diluent, and whether it is to be nebulized with O_2 or compressed air. The advantage of nebulization therapy is that it is easy to use. Medications that are routinely nebulized include albuterol and ipratropium.

The patient is placed in an upright position that allows for most efficient breathing to ensure adequate penetration and deposition of the aerosolized medication. The patient must

INFORMATICS IN PRACTICE

Home Monitoring of Asthma

- To reduce the rate of readmission to hospital, the patient with asthma may be discharged with a home monitoring system. These systems provide an easy and inexpensive approach to remotely monitoring patients' lung functions.
- Asthma home monitoring usually consists of peak flow rate, pulse oximetry, vital signs, and lung sounds. This information is sent to the health care provider so that problems are quickly detected.
- As part of your discharge planning, assist the patient with receiving a system and reviewing its proper use.

breathe slowly and deeply through the mouth and hold inspirations for 2 or 3 seconds. Deep diaphragmatic breathing helps ensure deposition of the medication. Instruct the patient to breathe normally in between these large forced breaths to prevent alveolar hypoventilation and dizziness. After the treatment instruct the patient to cough effectively.

A disadvantage of nebulizer equipment use is the potential for bacterial growth. Review cleaning procedures for home respiratory equipment with the patient. A frequently used, effective home-cleaning method is to wash the nebulizer daily in soap and water, rinse it with water, and soak it for 20 to 30 minutes in a 1:1 white vinegar–water solution, followed by a water rinse and air drying. Commercial respiratory cleaning agents may also be used if directions are followed carefully. Cleaning the nebulizer in the top shelf of an automatic dishwasher saves time, and the hot water destroys most organisms.

Patient Teaching Related to Drug Therapy. Information about medications should include the name, purpose, dosage, method of administration, and schedule, taking into consideration activities of daily living (ADLs) that require energy expenditure and thus oxygen (e.g., bathing). Teaching should also include side effects, appropriate action if side effects occur, how to properly use and clean devices, how to prime and the frequency, and consequences of not taking medications as prescribed. One of the major factors determining success in asthma management is the correct administration of drugs.

Several factors can affect the correct use of these devices. These include advanced age, alterations in physical dexterity (e.g., arthritis in hands, coordination), psychologic state (e.g., cognition), affordability, convenience, and administration time and preference.[10]

Poor adherence with asthma therapy is a major challenge in the long-term management of chronic asthma. Lack of adherence often occurs in chronic asthma because the patient is symptom free and does not use the long-term therapy (e.g., ICS) regularly because no immediate benefit is felt. The patient does not realize that ICSs are needed to treat the ongoing inflammatory process.

Explain to the patient the importance and purpose of taking the long-term therapy regularly, emphasizing that maximum improvement may take longer than 1 week. Tell the patient that, without regular use, the swelling in the airways may progress and the asthma will likely worsen over time. Become familiar with the vast array of compassionate use programs offered by pharmaceutical companies to help lower-income patients obtain medications (e.g., *www.needymeds.com*).

In addition to the typical MDI and DPI devices, a variety of other devices are used to deliver inhalant pulmonary medications. Be certain that patients understand exactly how to use the device, and give them printed instructions. (For instructions, see *www.nationaljewish.org/healthinfo/medications/lung-diseases/devices*.) Most inhalant drugs have clear patient instructions, but you need to either use a placebo device or the actual drug to assess the patient's ability to deliver the medication. At every clinic visit or hospitalization reassess the patient's inhaler technique.

New drug delivery devices are becoming available at a rapid pace, and you must keep informed of the correct operation of these. If package inserts are available, you can review them before teaching the patient. The drug company websites have numerous excellent teaching videos available.

Nonprescription Combination Drugs. Several nonprescription combination drugs are available OTC. They are usually combinations of a bronchodilator (ephedrine) and an expectorant (guaifenesin). Inhalers containing epinephrine are also available.[11] These agents are advertised as medications to relieve bronchospasm. Often patients seek OTC drugs because they are less expensive than prescription medication. Many people consider these drugs safe because they can be obtained without a prescription. In general, they should be avoided.

Drugs containing ephedrine and epinephrine are dangerous because they stimulate the central nervous and cardiovascular systems, causing nervousness, heart palpitations and dysrhythmias, tremors, insomnia, and increases in BP. Many respiratory products containing ephedrine are located behind the counter at pharmacies or require a prescription. This limited access is to prevent the diversion of ephedrine to the production of methamphetamine. Also many of the OTC products have been reformulated with phenylephrine, instead of ephedrine, which works well topically but has modest effects in the oral form.

An important teaching responsibility is to warn patients about the dangers associated with nonprescription combination drugs. These drugs are especially dangerous to a patient with underlying cardiac problems because elevated BP and tachycardia often occur. Caution the patient who persists in taking these medications to read and follow the directions on the label.

NURSING MANAGEMENT ASTHMA

NURSING ASSESSMENT

If a patient can speak and is not in acute distress, take a detailed health history, including identification of any precipitating factors and what has helped alleviate attacks in the past. The patient may be using herbs and supplements to treat asthma.[12] When doing the health history, ask about specific herbs or supplements that a patient may be using.

Subjective and objective data that should be obtained from a patient with asthma are presented in Table 29-11. You may also assess the patient's asthma control using one of the validated self-administered questionnaires (e.g., ACT at *www.qualitymetric.com/demos/TP_Launch.aspx?SID=52461*).

NURSING DIAGNOSES

Nursing diagnoses for the patient with asthma may include, but are not limited to, those presented in Nursing Care Plan 29-1.

PLANNING

The overall goals are that the patient with asthma will have asthma control as evidenced by (1) minimal symptoms during the day and night, (2) acceptable activity levels (including

NURSING CARE PLAN 29-1

Patient With Asthma

NURSING DIAGNOSIS **Ineffective airway clearance** *related to* bronchospasm, excessive mucus production, tenacious secretions, and fatigue *as evidenced by* ineffective cough, inability to raise secretions, and/or adventitious breath sounds

PATIENT GOALS
1. Maintains clear airway with removal of excessive secretions
2. Experiences normal breath sounds and respiratory rate

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Respiratory Status: Airway Patency	***Asthma Management***
• Respiratory rate _____ • Respiratory rhythm _____ • Ability to clear secretions _____	• Determine baseline respiratory status *to use as a comparison point.* • Monitor rate, rhythm, depth, and effort of respiration *to determine need for intervention and evaluate effectiveness of interventions.* • Observe chest movement, including symmetry, use of accessory muscles, and supraclavicular and intercostal muscle retractions, *to evaluate respiratory status.* • Auscultate breath sounds, noting areas of decreased or absent ventilation and adventitious sounds, *to evaluate respiratory status.* • Administer medication as appropriate and/or per policy and procedural guidelines *to improve respiratory function.* • Coach in breathing and relaxation techniques *to improve respiratory rhythm and rate.* • Offer warm fluids to drink *to liquefy secretions and promote bronchodilation.*
Measurement Scale 1 = Severe deviation from normal range 2 = Substantial deviation from normal range 3 = Moderate deviation from normal range 4 = Mild deviation from normal range 5 = No deviation from normal range	

NURSING DIAGNOSIS **Anxiety** *related to* difficulty breathing, perceived or actual loss of control, and fear of suffocation *as evidenced by* restlessness and elevated pulse, respiratory rate, and blood pressure

PATIENT GOALS
1. Reports decreased anxiety with increased control of respirations
2. Experiences vital signs within normal limits

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Anxiety Level	***Anxiety Reduction***
• Restlessness _____ • Increased blood pressure _____ • Increased pulse rate _____ • Increased respiratory rate _____ • Verbalized anxiety _____ • Facial tension _____	• Identify when level of anxiety changes *to determine possible precipitating factors.* • Use calm, reassuring approach *to provide reassurance.* • Stay with patient *to promote safety and reduce fear.* • Encourage verbalization of feelings, perceptions, and fears *to identify problem areas so appropriate planning can take place.* • Provide factual information concerning diagnosis, treatment, and prognosis *to help patient know what to expect.* • Instruct patient in the use of relaxation techniques *to relieve tension and to promote ease of respirations.*
Measurement Scale 1 = Severe 2 = Substantial 3 = Moderate 4 = Mild 5 = None	

NURSING DIAGNOSIS **Deficient knowledge** *related to* lack of information and education about asthma and its treatment *as evidenced by* frequent questioning regarding all aspects of long-term management

PATIENT GOALS
1. Describes the disease process and treatment regimen
2. Demonstrates correct administration of aerosol medications
3. Expresses confidence in ability for long-term management of asthma

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Asthma Self-Management	***Asthma Management***
• Describes causal factors _____ • Initiates action to avoid and manage personal triggers _____ • Seeks early treatment of infections _____ • Monitors peak flow routinely _____ • Monitors peak flow when symptoms occur _____ • Makes appropriate medication choices _____ • Demonstrates appropriate use of inhalers, spacers, and nebulizers _____ • Self-manages exacerbations _____ • Reports uncontrolled symptoms to health care provider _____	• Determine patient and family understanding of disease and management *to assess learning needs.* • Teach patient to identify and avoid triggers if possible *to prevent asthma attacks.* • Encourage verbalization of feelings about diagnosis, treatment, and impact on lifestyle *to offer support and increase adherence with treatment.* • Teach patient about the use of the peak expiratory flow rate (PEFR) meter at home *to promote self-management of symptoms.* • Instruct patient and family on antiinflammatory and bronchodilator medications and their appropriate use *to promote understanding of effects.* • Teach proper techniques for using medication and equipment (e.g., inhaler, nebulizer, peak flow meter) *to promote self-care.* • Assist in the recognition of signs and symptoms of impending asthmatic reaction and implementation of appropriate response measures *to prevent escalation of attacks.* • Establish a written plan with the patient for managing exacerbations *to plan adequate treatment of future exacerbations.*
Measurement Scale 1 = Never demonstrated 2 = Rarely demonstrated 3 = Sometimes demonstrated 4 = Often demonstrated 5 = Consistently demonstrated	

*Nursing diagnoses listed in order of priority.

TABLE 29-11 NURSING ASSESSMENT

Asthma

Subjective Data

Important Health Information

Past health history: Allergic rhinitis, sinusitis, or skin allergies; previous asthma attack and hospitalization or intubation; symptoms worsened by triggers in the environment; gastroesophageal reflux disease (GERD); occupational exposure to chemical irritants (e.g., paints, dust)

Medications: Adherence to medication, inhaler technique; use of antibiotics; pattern and amount of short-acting β_2-adrenergic agonist used per week; medications that may precipitate an attack in susceptible asthmatics such as aspirin, nonsteroidal antiinflammatory drugs, β-adrenergic blockers

Functional Health Patterns

Health perception–health management: Family history of allergies or asthma; recent upper respiratory tract or sinus infection

Activity-exercise: Fatigue, decreased or absent exercise tolerance; dyspnea, cough (especially at night), productive cough with yellow or green sputum or sticky sputum; chest tightness, feelings of suffocation, air hunger, talking in short sentences or words or phrases, sitting upright to breathe

Sleep-rest: Awakened from sleep because of cough or breathing difficulties, insomnia

Coping–stress tolerance: Emotional distress, stress in work environment or home

Objective Data

General

Restlessness or exhaustion, confusion, upright or forward-leaning body position

Integumentary

Diaphoresis, cyanosis (circumoral, nail bed), eczema

Respiratory

Nasal discharge, nasal polyps, mucosal swelling; wheezing, crackles, diminished or absent breath sounds, and rhonchi on auscultation; hyperresonance on percussion; sputum (thick, white, tenacious), ↑ work of breathing with use of accessory muscles; intercostal and supraclavicular retractions; tachypnea with hyperventilation; prolonged expiration

Cardiovascular

Tachycardia, pulsus paradoxus, jugular venous distention, hypertension or hypotension, premature ventricular contractions

Possible Diagnostic Findings

Abnormal ABGs during attacks, ↓ O_2 saturation, serum and sputum eosinophilia, ↑ serum IgE, positive skin tests for allergens, chest x-ray demonstrating hyperinflation with attacks, abnormal pulmonary function tests showing ↓ flow rates; FVC, FEV_1, PEFR, and FEV_1/FVC ratio that improve between attacks and with bronchodilators

ABGs, Arterial blood gases; *FEV_1,* forced expiratory volume in 1 sec; *FVC,* forced vital capacity; *IgE,* immunoglobulin E; *PEFR,* peak expiratory flow rate.

exercise and other physical activity), (3) maintenance of greater than 80% of personal best PEFR or FEV_1, (4) few or no adverse effects of therapy, (5) no recurrent exacerbations of asthma, and (6) adequate knowledge to participate in and carry out management.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Your role in preventing asthma attacks or decreasing their severity focuses primarily on teaching the patient and caregiver. Teach the patient to identify and avoid known personal triggers for asthma (e.g., cigarette smoke, pet dander) and irritants (e.g., cold air, aspirin, foods, cats, indoor air pollution) (see Table 29-1). Although special dust covers on mattresses and pillows may reduce exposure to dust mites and improve symptoms, the evidence does not support making this a definitive recommendation.[13] Washing bedclothes in hot water or cooler water with detergent and bleach has some effect on allergen levels. Avoidance of furred animals is suggested, but the allergen of pets is nearly impossible to avoid. Pet allergen can be found in many public areas for months even after removal of the animal. Many people are allergic to cockroach remains and the dried droppings, so measures to avoid or control cockroaches are partly effective in removing allergens.

If cold air cannot be avoided, dressing properly with scarves or using a mask helps reduce the risk of an asthma attack. Aspirin and NSAIDs should be avoided if they are known to precipitate an attack. Many OTC drugs contain aspirin. Therefore teach the patient to read the labels carefully. Nonselective β-blockers (e.g., propranolol [Inderal]) are contraindicated because they inhibit bronchodilation. Selective β-blockers (e.g., atenolol [Tenormin]) should be used with caution. Desensitization (immunotherapy) may be partially effective in decreasing the patient's sensitivity to known allergens (see Chapter 14).

Prompt diagnosis and treatment of upper respiratory tract infections and sinusitis may prevent an exacerbation of asthma. If occupational irritants are involved as etiologic factors, the patient may need to consider changing jobs. Individuals who are obese often find that weight loss improves control of asthma. Encourage the patient to maintain a fluid intake of 2 to 3 L/day, good nutrition, and adequate rest. If exercise is planned or if the patient has asthma only with exercise, the health care provider can suggest a medication regimen for pretreatment or long-term control of symptoms to prevent bronchospasm.

ACUTE INTERVENTION. A goal in asthma care is to maximize the patient's ability to safely manage acute asthma exacerbations using an asthma action plan developed in conjunction with the health care provider (Table 29-12). Action plans are particularly important for individuals with moderate to severe persistent asthma or severe exacerbations. The action plan dictates what symptoms or peak flow reading necessitates a change in asthma care to gain control.

The patient can take 2 to 4 puffs of an SABA every 20 minutes three times as a rescue plan. Depending on the response with alleviation of symptoms or improved peak flow, continued SABA use and/or oral corticosteroids may be a part of the home management plan at this point. If symptoms persist or if the patient's peak flow is less than 50% of the personal best, the health care provider or emergency medical services (EMS) needs to be immediately contacted.

When the patient is in the health care facility with an acute exacerbation, it is important to monitor the patient's respiratory and cardiovascular systems. This includes auscultating lung sounds; taking the heart and respiratory rates and BP; and monitoring ABGs, pulse oximetry, and peak flow.

Louder wheezing may actually occur in airways that are responding to the therapy as airflow increases. As improvement continues and airflow increases, breath sounds increase and wheezing decreases. Remember that, despite the disappearance of most of the bronchospasms, the edema and cellular infiltration of the airway mucosa and the viscous mucous plugs may take several days to improve. Thus intensive therapy must be continued even after clinical improvement.

An important nursing goal during an acute attack is to decrease the patient's sense of panic. A calm, quiet, reassuring attitude may help the patient relax. Position the patient comfortably (usually sitting) to maximize chest expansion. Stay with the patient and be available to provide additional comfort. A technique called "talking down" can help the patient remain calm. In talking down, you gain eye contact with the patient. In a firm, calm voice coach the patient to use pursed-lip breathing, which keeps the airways open by maintaining positive pressure (Table 29-13), and abdominal breathing, which slows the respiratory rate and encourages deeper breaths (see Table 7-5). You or the caregiver should stay with the patient until the respiratory rate (with the assistance of the medications) has slowed.

When the acute attack subsides, provide rest and a quiet, calm environment for the patient. When the patient has recovered from exhaustion, try to obtain the health history and pattern of asthma along with a physical assessment. If the caregiver and other family members are present, they may be able to provide information about the patient's health history (see Table 29-11). This information, which is important in planning an individualized nursing care plan, helps the patient with the goal of control.

AMBULATORY AND HOME CARE. Control of symptoms can also be achieved by teaching the patient about medications. The drug regimen itself can be confusing and complex. Teach patients the importance of monitoring their response to medication. It is easy to undermedicate or overmedicate unless careful monitoring is ongoing. Some patients may benefit from keeping a diary to record medication use, wheezing or coughing, peak flow, the drug's side effects, and activity level. This information will help the health care provider adjust the medication.

TABLE 29-12 ASTHMA ACTION PLAN*

General Information

- Name _____
- Emergency contact _____ Phone numbers _____
- Physician/health care provider _____ Phone numbers _____
- Physician signature _____ Date _____

Severity Classification

❍ Intermittent
❍ Mild persistent
❍ Moderate persistent
❍ Severe persistent

Triggers

❍ Colds ❍ Smoke ❍ Weather
❍ Exercise ❍ Dust ❍ Air pollution
❍ Animals ❍ Food
❍ Other _____

Exercise

1. Premedication (how much and when) _____
2. Exercise modifications _____

Green Zone: Doing Well

Symptoms

- Breathing is good
- No cough or wheeze
- Can work and play
- Sleeps all night

Peak Flow Meter
More than 80% of personal best or _____

Peak Flow Meter Personal Best =

Control Medications:

Medicine	How Much to Take	When to Take It

Yellow Zone: Getting Worse

Symptoms

- Some problems breathing
- Cough, wheeze, or chest tight
- Problems working or playing
- Wake at night

Peak Flow Meter
Between 50% and 80% of personal best or _____ and _____

Contact Physician If Using Quick Relief More Than 2 Times per Week

Continue Control Medicines and Add:

Medicine	How Much to Take	When to Take It

IF your symptoms (and peak flow, if used) return to Green Zone after 1 hour of the quick-relief treatment, THEN

❍ Take quick-relief medication every 4 hours for 1 to 2 days
❍ Change your long-term control medicines by _____
❍ Contact your physician for follow-up care

IF your symptoms (and peak flow, if used) DO NOT return to the Green Zone after 1 hour of the quick-relief treatment, THEN

❍ Take quick-relief treatment again
❍ Change your long-term control medicines by _____
❍ Call your physician/health care provider within _____ hours of modifying your medication routine

Red Zone: Medical Alert

Symptoms

- Lots of problems breathing
- Cannot work or play
- Getting worse instead of better
- Medicine is not helping

Peak Flow Meter
Between 0% and 50% of personal best or _____ and _____

Ambulance/Emergency Phone Number:

Continue Control Medicines and Add:

Medicine	How Much to Take	When to Take It

Go to the hospital or call for an ambulance if

❍ Still in the red zone after 15 minutes
❍ You have not been able to reach your physician/health care provider for help

Call an ambulance immediately if the following danger signs are present

❍ Trouble walking/talking due to shortness of breath
❍ Lips or fingernails are blue

TABLE 29-13 PATIENT TEACHING GUIDE

Pursed-Lip Breathing (PLB)

Teach the patient how to do PLB using the following guidelines.

1. Use PLB before, during, and after any activity causing you to be short of breath.
2. Inhale slowly and deeply through the nose.
3. Exhale slowly through pursed lips, almost as if whistling.
4. Relax your facial muscles without puffing your cheeks—like whistling—while you are exhaling.
5. Make breathing out (exhalation) three times as long as breathing in (inhalation).
6. The following activities can help you get the "feel" of PLB:
   - Blow through a straw in a glass of water with the intent of forming small bubbles.
   - Blow a lit candle enough to bend the flame without blowing it out.
   - Steadily blow a table-tennis ball across a table.
   - Blow a tissue held in the hand until it gently flaps.
7. Practice 8-10 repetitions of PLB three or four times a day.

Good nutrition is important. Physical exercise (e.g., swimming, walking, stationary cycling) within the patient's limit of tolerance is also beneficial and may require pretreatment with an SABA, as noted previously. Sleep that is uninterrupted by asthma symptoms is an important goal. If patients with asthma wake up because of asthma symptoms, their asthma is not under good control and their therapeutic plan should be reevaluated.

Together with the patient and caregiver, develop written asthma action plans (see Table 29-12). Base these plans on the patient's asthma symptoms and PEFR. To follow the management plan, the patient must measure his or her peak flow at least daily. Some patients may want to just monitor symptoms for self-management. Patients with asthma frequently do not perceive changes in their breathing. Therefore peak flow monitoring, when done correctly, can be a reliable, objective measurement of asthma control (Table 29-14).

TABLE 29-14 PATIENT TEACHING GUIDE

How to Use Your Peak Flow Meter

Include the following instructions when teaching the patient to use a peak flow meter.

Why Use a Peak Flow Meter?

- Peak flow meters are used to check your asthma the way that blood pressure cuffs are used to check blood pressure. A peak flow meter is a device that measures how well air moves out of your lungs.
- During an asthma episode, the airways of the lungs usually begin to narrow slowly. The peak flow meter may tell you if there is narrowing in the airways hours, sometimes even days, before you have any asthma symptoms.
- By taking your medicines early (before symptoms), you may be able to stop the episode quickly and avoid a severe asthma episode.
- The peak flow meter also can be used to help you and your health care provider:
  - Learn what makes your asthma worse.
  - Decide if your treatment plan is working well.
  - Decide when to add or stop medicine.
  - Decide when to seek emergency care.

How to Use Your Peak Flow Meter

- Do the following five steps with your peak flow meter:
  1. Move the indicator to the bottom of the numbered scale.
  2. Stand up.
  3. Take a deep breath, filling your lungs completely.
  4. Place the mouthpiece in your mouth and close your lips around it. Do not put your tongue inside the hole.
  5. Blow out as hard and fast as you can in a single blow.
- Write down the number you get. But if you cough or make a mistake, do not write down the number. Do it over again.
- Repeat steps 1 through 5 two more times, and write down the best of the three blows in your asthma diary.

Find Your Personal Best Peak Flow Number

- Your personal best peak flow number is the highest peak flow number you can achieve over a 2-week period when your asthma is under good control. Good control is when you feel good and do not have any asthma symptoms.
- Each patient's asthma is different, and your best peak expiratory flow (PEF) may be higher or lower than the peak flow of someone of your same height, weight, and gender. This means that it is important for you to find your own personal best peak flow number, which is the basis for your treatment plan.
- To find your personal best peak flow number, take peak flow readings:
  - At least twice a day for 2-3 wk, between 12 noon and 2 PM when your peak flow is the highest
  - 15-20 min after taking inhaled short-acting β_2-agonist (SABA) for quick relief
  - As instructed by your health care provider

The Peak Flow Zone System

Once you know your personal best peak flow number, your health care provider will put the peak flow numbers into zones that are set up like a traffic light. This will help you know what to do when your peak flow number changes. For example:

- Green Zone (more than __L/min [80% of your personal best number]) signals good control. No asthma symptoms are present. Take your medicines as usual.
- Yellow Zone (between __ and __L/min [50% to <80% of your personal best number]) signals caution. If you remain in the yellow zone after several measures of peak flow, take an inhaled SABA. If you continue to register peak flow readings in the yellow zone, your asthma may not be under good control. Ask your physician if you need to change or increase your daily medicines.
- Red Zone (<__L/min [<50% of your personal best number]) signals a medical alert. Take an inhaled SABA (quick-relief medicine) right away. Call your health care provider or the emergency department and ask what to do, or go directly to the emergency department.

Use the Diary to Keep Track of Your Peak Flow

- Record your personal best peak flow number and peak flow zones in your asthma diary.
- Measure your peak flow when you wake up, *before* taking medicine. Write down your peak flow number in the diary every day, or as instructed by your health care provider.

Actions to Take When Peak Flow Numbers Change

- PEF goes between __ and __L/min (50% to <80% of personal best, yellow zone).
  ACTION: Take an inhaled SABA (quick-relief medicine) as prescribed by your health care provider.
- PEF increases ≥20% when measured before and after taking an inhaled SABA (quick-relief medicine).
  ACTION: Talk to your physician about adding more medicine to control your asthma better (e.g., an antiinflammatory medication).

Source: Adapted from National Asthma Education and Prevention Program, National Heart, Lung, and Blood Institute: *Expert Panel Report 3: guidelines for the diagnosis and management of asthma*, NIH pub no 08-4051, Bethesda, Md, 2007, National Institutes of Health. Retrieved from www.nhlbi.nih.gov/guidelines.

If a patient's PEFR is within the green zone (usually 80% to 100% of the person's personal best), the patient should remain on her or his usual medications. If the PEFR is within the yellow zone (usually 50% to 80% of personal best), it indicates caution. Something is triggering the patient's asthma (e.g., viral infection).

The patient should have a written asthma action plan that prescribes a step increase in medications during the acute phase of the infection. The dose is stepped down once the viral infection symptoms subside. Based on the asthma management plan, the patient can use different strategies, such as using the SABA more frequently.

If the PEFR is in the red zone (50% or less of personal best), it indicates a serious problem. A rescue plan should be a part of the asthma action plan. Teach the patient and caregiver to take definitive action, as noted previously. Emphasize to the patient the need to monitor PEFR daily or several times a day to have an objective measure that can be correlated with symptoms. Although it may happen, it is unusual for a patient's PEFR to drop from the green zone to the red zone quickly. Usually the patient has time to make changes in medications, avoid triggers, and notify the health care provider.

It is important to involve the patient's caregiver or family. They should know where the patient's inhalers, oral medications, and emergency phone numbers are located. Instruct the caregiver or family on how to decrease the patient's anxiety if an asthma attack occurs. When the patient is stabilized or controlled, the caregiver can gently remind the patient about doing daily PEFR by asking questions such as, "What zone are you in? How's your peak flow today?" A patient and caregiver teaching guide for the patient with asthma is presented in Table 29-15.

An increased number of older adults are diagnosed with asthma. This is a special concern because they have more complicated health issues than younger patients with asthma. Issues that face older adults (especially urban and minority people) are costly medications, nonadherence to medical regimen, and difficulty accessing the health system. Keep these factors in mind when implementing a management plan for older adults.

A variety of factors may contribute to African Americans and Hispanics (especially those from Puerto Rico) having higher rates of poorly controlled asthma and deaths compared with whites. Some factors may be disparities in socioeconomic status and access to proper health care, cultural beliefs about the management of asthma, and underutilization of the long-term controller medications because of high costs. Seek to explore and eliminate any barriers to health care. Also seek out culturally appropriate resources and educational material in languages other than English to improve the asthma control of these individuals.

Relaxation therapies (e.g., yoga, meditation, relaxation techniques, breathing techniques) may help a patient relax respiratory muscles and decrease the respiratory rate. (Chapter 7 discusses relaxation breathing and other relaxation strategies.) A healthy emotional outlook can also be important in preventing future asthma attacks.[14] A variety of websites have excellent resources for patient teaching (see Resources at the end of the chapter). Some communities have asthma support groups.

EVALUATION

The expected outcomes for the patient with asthma are presented in Nursing Care Plan 29-1.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) is a preventable and treatable disease characterized by persistent airflow limitation that is slowly progressive. COPD is associated with an enhanced chronic inflammatory response of the airways and lungs to noxious particles or gases, primarily caused by cigarette smoking. COPD exacerbations and other coexisting illnesses contribute to the overall severity of the disease.[15,16]

Previous definitions of COPD encompassed two types of obstructive airway diseases: chronic bronchitis and emphysema. **Chronic bronchitis** is the presence of chronic productive cough for 3 months in each of 2 consecutive years in a patient in whom other causes of chronic cough have been excluded. **Emphysema** is an abnormal permanent enlargement of the air spaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis. Only about 10% of patients with COPD have pure emphysema. Patients may have a predominance of chronic bronchitis or emphysema, but it is often difficult to determine because the conditions usually coexist. COPD is discussed in this section as one disease state from the viewpoint of pathophysiology and management.[16]

Patients with COPD may have asthma. Although the evidence is not conclusive, asthma may be a risk factor for COPD development. An estimated 12.7 million adults in the United States over age 18 have COPD.[2,15] An additional 24 million people have evidence of impaired lung function. The number of people with COPD is greatly underestimated because the disease is usually not diagnosed until it is moderately advanced. COPD is the third leading cause of death in the United States, killing more than 133,000 Americans each year.[17,18]

Etiology

The many factors involved in the etiology of COPD are discussed in this section.

Cigarette Smoking. Worldwide the major risk factor for developing COPD is cigarette smoking.[18,19] COPD affects about 15% of smokers.[20] An intriguing question is why some smokers develop COPD and others do not. In people over age 40 with a smoking history of 10 or more pack-years, COPD should be considered.[21]

GENDER DIFFERENCES

Chronic Obstructive Pulmonary Disease (COPD)

Men	Women
• COPD is more common in men than in women, but the incidence is not increasing in men. • Fewer men die from COPD than women.	• The number of women with COPD is increasing. • Increase is probably due to increased number of women smoking cigarettes and increased susceptibility (e.g., smaller lungs and airways, lower elastic recoil). • Women with COPD have lower quality of life, more exacerbations, increased dyspnea, and better response to O_2 therapy compared with men.

TABLE 29-15 PATIENT & CAREGIVER TEACHING GUIDE

Asthma

Include the following information in a teaching plan for the patient with asthma and the caregiver. It will help to improve the patient's quality of life and promote lifestyle changes that support successful living with asthma.

Teaching Topic	Resources
What Is Asthma? • Basic anatomy and physiology of lung • Pathophysiology of asthma • Relationship of pathophysiology to signs and symptoms • Measurement and correlation of pulmonary function tests and peak expiratory flow rate	*What Is Asthma?* (National Heart, Lung, and Blood Institute) Retrieved from *www.nhlbi.nih.gov/health/dci/Diseases/Asthma/Asthma_WhatIs.html*. *What Is Asthma?* (Global Initiative for Asthma). Retrieved from *www.ginasthma.org/q-a-general-information-about-asthma.html*. *Asthma: Overview* (National Jewish Health). Retrieved from *www.njhealth.org/healthinfo/conditions/asthma/index.aspx*.
What Is Good Asthma Control?	Resource for patient on personal ideas of good control. *Asthma Control Test.* Retrieved from *www.qualitymetric.com/demos/TP_Launch.aspx?SID=52461*.
Hindrances to Asthma Treatment and Control • Intermittent nature of symptoms • Role of denial • Poor perception of asthma severity by patient	Discussion with patient and caregiver about possible hindrances.
Environmental and Trigger Control • Identifications of possible triggers and possible preventive measures • Avoidance of allergens and other triggers • Need to maintain good hydration	*Environmental Management* (National Jewish Health). Retrieved from *www.nationaljewish.org/healthinfo/conditions/asthma/lifestyle-management/environmental*. *Pollen Count Report* (sign up for daily notification about a particular area) (American Academy of Asthma Allergy and Immunology). Retrieved from *www.aaaai.org/nab*. Trigger diary kept by patient.
Medications Types (include mechanism of action) • β_2-Agonists • Corticosteroids • Methylxanthines • Anti-IgE • Leukotriene modifiers • Combination drugs Establishing medication schedule Use of preventive and maintenance agents (e.g., antiinflammatory agents)	*Asthma: Treatment* (National Jewish Health). Available at *www.nationaljewish.org/healthinfo/conditions/asthma/treatment*. Asthma Action Plan (see Table 29-12). Write out medication list and schedule.

Teaching Topic	Resources

Cigarette smoke has several direct effects on the respiratory tract (Table 29-16). The irritating effect of the smoke causes hyperplasia of cells, including goblet cells, thereby increasing the production of mucus. Hyperplasia reduces airway diameter and increases the difficulty in clearing secretions. Smoking reduces the ciliary activity and may cause actual loss of cilia. Smoking also produces abnormal dilation of the distal air space with destruction of alveolar walls. Many cells develop large, atypical nuclei, which are considered a precancerous condition. Smoking causes chronic, enhanced inflammation of various parts of the lung with structural changes and repair (called remodeling). The reasons for the inflammatory response are not clearly understood, but may be genetically determined, since patients who have never smoked can develop COPD.

Cigarette smoking causes oxidative stress, as well as an imbalance between proteases that break down connective tissue in the lung and antiproteases that protect the lungs.[16] These changes resulting from cigarette smoking increase with more severe disease and even persist with smoking cessation. (See Chapter 11 for more detail about cigarette smoking.)

Passive smoking is the exposure of nonsmokers to cigarette smoke, also known as *environmental tobacco smoke* (ETS) or secondhand smoke. In adults, involuntary smoke exposure is associated with decreased pulmonary function, increased respiratory symptoms, and severe lower respiratory tract infections (e.g., pneumonia). ETS is also associated with increased risk for lung cancer and nasal sinus cancer.

Occupational Chemicals and Dusts. If a person has intense or prolonged exposure to various dusts, vapors, irritants, or fumes in the workplace, symptoms of lung impairment consistent with COPD can develop. If a person has occupational exposure and smokes, the risk of COPD increases.[16]

Air Pollution. High levels of urban air pollution are harmful to people with existing lung disease. However, the effect of outdoor air pollution as a risk factor for the development of COPD is unclear. Another risk factor for COPD development is coal and other biomass fuels that are used for indoor heating and cooking. Many people who have never smoked are at significant risk for developing COPD because of cooking with these fuels in poorly ventilated areas.[16]

Infection. Infections are a risk factor for developing COPD. Severe recurring respiratory tract infections in childhood have been associated with reduced lung function and increased respiratory symptoms in adulthood. It is unclear whether the development of COPD can be related to recurrent infections in adults. People who smoke and also have human immunodeficiency virus (HIV) have an accelerated development of COPD. Tuberculosis is also a risk factor for COPD development.

Genetics. The fact that a relatively small percentage of smokers get COPD strongly suggests that genetic factors influence which smokers get the disease. Because of the genetic-environmental interaction, two people may have the same smoking history, but only one develops COPD. To date, one genetic factor has been clearly identified (see next section).[16]

α_1-Antitrypsin (AAT) Deficiency. **α_1-Antitrypsin (AAT) deficiency** is an autosomal recessive disorder that may affect the lungs or liver. AAT deficiency is a genetic risk factor for COPD. Approximately 3% of all people diagnosed with COPD may have undetected AAT deficiency. AAT is a serum protein produced by the liver and normally found in the lungs. The main function of AAT, an α_1-protease inhibitor, is to protect normal lung tissue from attack by proteases during inflammation related to cigarette smoking and infections. Severe AAT deficiency leads to premature bullous emphysema in the lungs found on x-ray. Smoking greatly exacerbates the disease process in these patients.[22]

Genetic Link

AAT deficiency is an autosomal recessive disorder (see Figs. 13-4 and 13-5 and the Genetics in Clinical Practice box). The

TABLE 29-16 EFFECTS OF TOBACCO SMOKE ON RESPIRATORY SYSTEM

Area of Defect	Acute Effects	Long-Term Effects

Elastin and collagen fibers	↑ Destruction by proteases ↓ Function of antiproteases (α_1-antitrypsin) ↓ Synthesis and repair of elastin	Emphysema

GENETICS IN CLINICAL PRACTICE

α_1-Antitrypsin (AAT) Deficiency

Genetic Basis
- Autosomal recessive disorder.
- Mutations in *SERPINA1* gene (located on chromosome 14) cause AAT deficiency.
- Gene provides instructions for the liver to make the protein AAT, which protects the lungs and liver from powerful proteolytic enzymes.
- Without enough functional AAT, proteolytic enzymes destroy alveoli and cause lung disease.

Incidence
- Occurs in 1 in 1700 to 3500 live births in the United States.
- People of northern European descent most affected.

Genetic Testing
- DNA testing is available.
- Screening of siblings is useful.
- Serum assay is available to measure the amount of AAT.

Clinical Implications
- AAT deficiency can cause lung and liver disease.
- Onset of disease is between ages 20 and 40 yr.
- Treatment includes AAT replacement (Prolastin).
- Disease predisposes to early-onset emphysema.

severity of AAT deficiency depends on which forms of the gene are inherited. The most common abnormal genes are the S and Z alleles. The normal genotype is MM. The most common genotype associated with AAT disease is ZZ (also referred to as PI-ZZ). Other variations include MZ (slightly increased risk of poor lung function) and SZ (higher risk of lung and liver problems in smokers). Some individuals with MZ and SZ genotypes may never seek health care because they have minimal manifestations of the disorder.[22]

Although 100,000 people in the United States are suspected of having the ZZ phenotype, fewer than 10% have been detected. Clues to AAT deficiencies are the onset of symptoms often occurring by age 40, minimal to no tobacco use, and family history of emphysema and/or liver disease.[23] Chronic liver disease as an infant or adult with increased liver enzyme levels may also be seen. Individuals with this type of emphysema are primarily of northern European origin.

A simple blood test can determine low levels of AAT. Those with borderline or low levels can then be genetically tested.

IV-administered AAT (e.g., Prolastin-C) augmentation therapy is used for people with AAT deficiency. The infusions are usually administered weekly. Its effectiveness in slowing the progression of the disease and the results of this treatment continue to be evaluated.

Aging. Although aging is often considered a risk factor for COPD, the evidence is unclear. Does the aging process lead to COPD, or is COPD a result of the cumulative exposures that occur over a long life?[16] Normal aging results in loss of elastic recoil, stiffening of the chest wall, gas exchange alteration, and decrease in exercise tolerance. As people age, the lungs gradually lose their elastic recoil. Thoracic cage changes result from osteoporosis and calcification of the costal cartilages. The thoracic cage becomes stiff and rigid, and the ribs are less mobile. The shape of the rib cage gradually changes because of the increased residual volume (RV), causing it to expand and become rounded. Decreased chest compliance and elastic recoil of the lungs caused by aging affect the mechanical aspects of ventilation and increase the work of breathing.[24]

As one ages, the number of functional alveoli decreases as peripheral airways lose supporting tissues. The surface area for gas exchange decreases, and the PaO_2 decreases. Changes in the elasticity of the lungs reduce the ventilatory reserve.[24] These changes are similar to those seen in the patient with emphysema.

Pathophysiology

COPD is characterized by chronic inflammation of the airways, lung parenchyma (respiratory bronchioles and alveoli), and pulmonary blood vessels (Fig. 29-8). The pathogenesis of COPD is complex and involves many mechanisms. The defining feature of COPD is not fully reversible airflow limitation during forced exhalation. This is caused by loss of elastic recoil and airflow obstruction caused by mucus hypersecretion, mucosal edema, and bronchospasm.

In COPD various processes occur such as airflow limitation, air trapping, gas exchange abnormalities, and mucus hyperse-

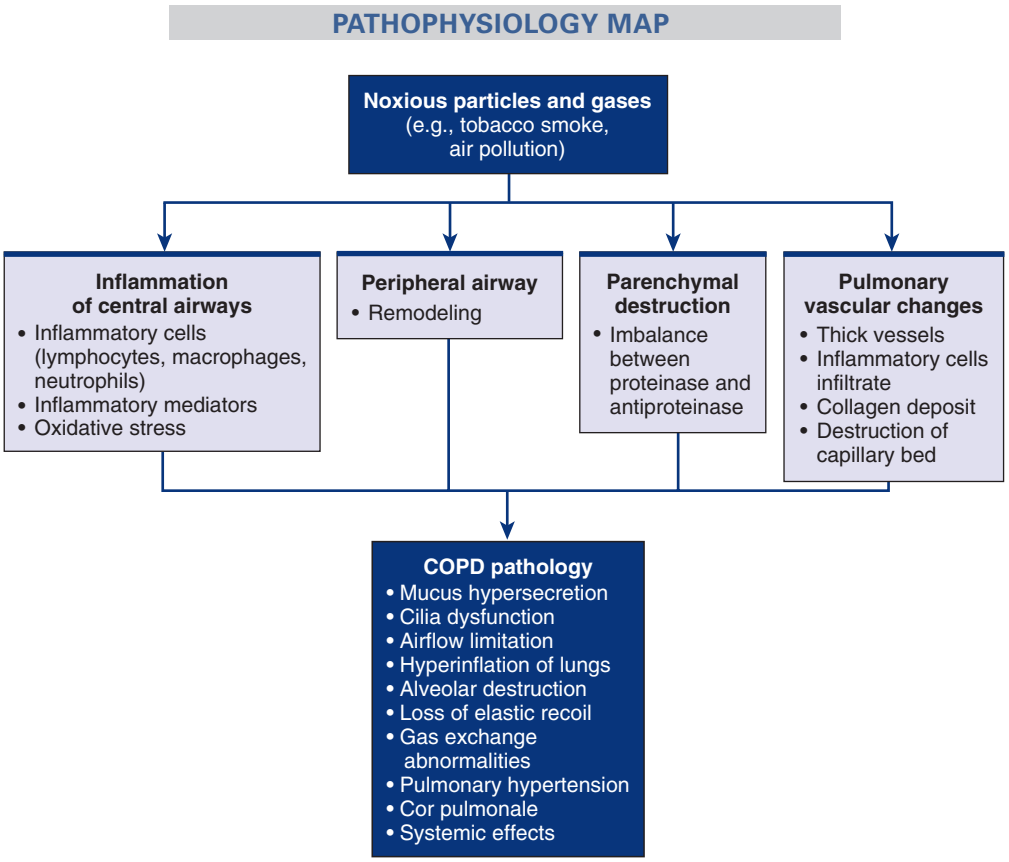

FIG. 29-8 Pathophysiology of chronic obstructive pulmonary disease *(COPD)*.

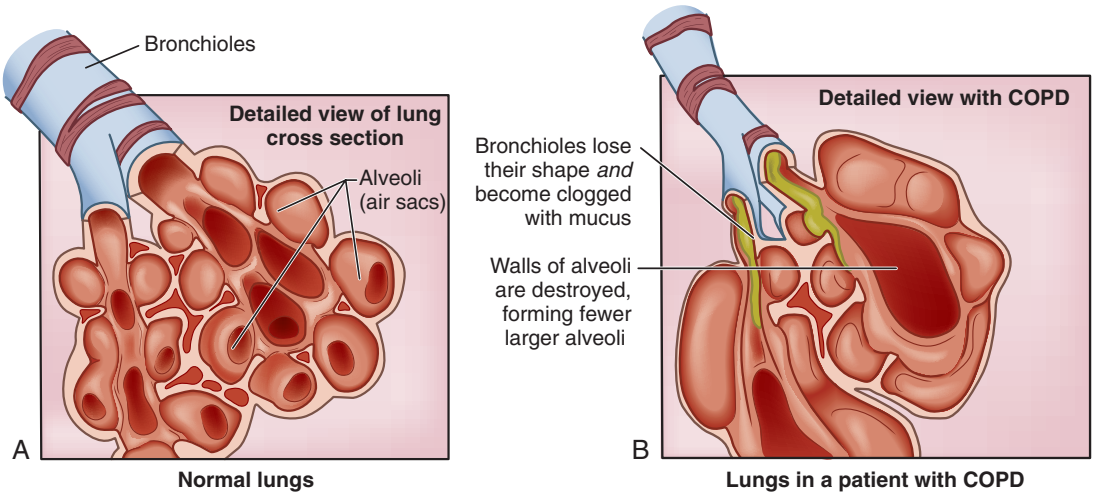

FIG. 29-9 **A,** Normal lungs showing bronchioles and alveoli. **B,** Changes in the bronchioles and alveoli in the lungs of a patient with chronic obstructive pulmonary disease *(COPD)*.

cretion. In severe disease, pulmonary hypertension and systemic manifestations occur (see Fig. 29-8). COPD has an uneven distribution of pathologic changes, with severely destroyed lung areas existing together with areas of relatively normal lung.

The inflammatory process starts with inhalation of noxious particles and gases (e.g., cigarette smoke), but is magnified in the person with COPD. The abnormal inflammatory process causes tissue destruction and disrupts the normal defense mechanisms and repair process of the lung. The mechanisms for the enhanced inflammatory response are not clearly understood, but may be genetically determined.[16]

The predominant inflammatory cells in COPD are neutrophils, macrophages, and lymphocytes. This pattern of inflammatory cells is different from that in asthma. (In asthma the inflammatory cells are eosinophils, mast cells, neutrophils, lymphocytes, and macrophages.) These inflammatory cells attract other inflammatory mediators (e.g., leukotrienes) and proinflammatory cytokines (e.g., tumor necrosis factor). The end result of the inflammatory process is structural changes in the lungs.[16]

The inflammatory process may also be magnified by oxidants, which are produced by cigarette smoke and other inhaled particles and released from the inflammatory cells. The oxidants adversely affect the lungs as they inactivate antiproteases (which prevent the natural destruction of the lungs), stimulate mucus secretion, and increase fluid in the lungs.

After the inhalation of oxidants in tobacco or air pollution, the activity of proteases (which break down the connective tissue of the lungs) increases and the antiproteases (which protect against the breakdown) are inhibited. Therefore the natural balance of protease/antiprotease is tipped in favor of destruction of the alveoli and loss of the lungs' elastic recoil.[16,24]

Inability to expire air is a main characteristic of COPD. The primary site of the airflow limitation is in the smaller airways. As the peripheral airways become obstructed, air is progressively trapped during expiration. The volume of residual air becomes greatly increased in severe disease as alveolar attachments to small airways (similar to rubber bands) are destroyed. The residual air, combined with the loss of elastic recoil, makes passive expiration of air difficult. As air is trapped in the lungs, the chest hyperexpands and becomes barrel shaped, since the respiratory muscles are not able to function effectively. The functional residual capacity is increased. The patient is now trying to breathe in when the lungs are in an "overinflated" state; thus the patient appears dyspneic and exercise capacity is limited.

Gas exchange abnormalities result in hypoxemia and hypercapnia (increased CO_2) as the disease worsens. As the air trapping increases, walls of alveoli are destroyed (Fig. 29-9), and bullae (large air spaces in the parenchyma) and blebs (air spaces adjacent to pleurae) can form.

Bullae and blebs are not effective in gas exchange, since they do not contain the capillary bed that normally surrounds each alveolus. Therefore a significant ventilation-perfusion (V/Q) mismatch and hypoxemia result. Peripheral airway obstruction also results in V/Q imbalance and, combined with the respiratory muscle impairment, can lead to CO_2 retention, particularly in severe disease.

Excess mucus production, resulting in a chronic productive cough, is a feature of individuals with predominant chronic bronchitis. However, not all COPD patients have sputum production. Excess mucus production is a result of an increased number of mucus-secreting goblet cells and enlarged submucosal glands. In addition, dysfunction of cilia leads to chronic cough and sputum production. Some of the inflammatory mediators also stimulate mucus production.

Pulmonary vascular changes resulting in mild to moderate pulmonary hypertension may occur late in the course of COPD. The small pulmonary arteries vasoconstrict due to hypoxia. As the disease advances, the structure of the pulmonary arteries changes, resulting in thickening of the vascular smooth muscle. Because of the loss of alveolar walls and the capillaries surrounding them, pressure in the pulmonary circulation increases.

Typically, the patient does not have difficulty with hypoxemia at rest until late in the disease. However, hypoxemia may develop during exercise, and the patient may benefit from supplemental O_2. Pulmonary hypertension may progress and lead to hypertrophy of the right ventricle of the heart **(cor pulmonale).** The right ventricle dilates and may eventually lead to right-sided heart failure.[25]

In addition to lung disease, COPD is a systemic disease. Chronic inflammation is an underlying etiology for these systemic effects. Cardiovascular diseases commonly exist in COPD (smoking is a primary risk factor for both of them). Other common systemic diseases include cachexia (skeletal muscle wasting), osteoporosis, diabetes, and metabolic syndrome, which cannot be readily related to smoking.[16,26]

Clinical Manifestations

Clinical manifestations of COPD typically develop slowly, but COPD should be considered in all patients over age 40 with 10 or more pack-years of cigarette smoking.[21] A diagnosis of COPD should be considered in any patient who has symptoms of cough, sputum production, or dyspnea and/or a history of exposure to risk factors for the disease.

A chronic intermittent cough, which is often the first symptom to develop, may later be present every day as the disease progresses. The cough is often dismissed by patients as they expect it with smoking or environmental exposures. The cough may be unproductive of mucus. However, significant airflow limitation may exist without sputum or cough.[16] Typically dyspnea is progressive, usually occurs with exertion, and is present every day.

Patients may complain of not being able to take a deep breath, heaviness in the chest, gasping, increased effort to breathe, and air hunger. Patients usually ignore the symptoms and rationalize that "I'm getting older" and "I'm out of shape." They change behaviors to avoid dyspnea, such as taking the elevator. Gradually the dyspnea interferes with daily activities, such as carrying grocery bags. They cannot walk as fast as their partner or peers. However, as symptoms worsen and interfere with daily activity or they have their first COPD exacerbation, patients usually seek medical care.

In late stages of COPD, dyspnea may be present at rest. As more alveoli become overdistended, increasing amounts of air are trapped. This causes a flattened diaphragm, and the patient must breathe from partially inflated lungs. Effective abdominal breathing is decreased because of the flattened diaphragm from the overinflated lungs. The person becomes more of a chest breather, relying on the intercostal and accessory muscles. However, chest breathing is not efficient.

Wheezing and chest tightness may be present, but may vary by time of the day or from day to day, especially in patients with more severe disease. Wheezes may arise from the laryngeal area, or wheezes may not be present on auscultation. Chest tightness, which often follows activity, may feel similar to muscular contraction.

The person with advanced COPD frequently experiences fatigue, weight loss, and anorexia. Even with adequate caloric intake, the patient still loses weight. Fatigue is a highly prevalent symptom that affects the patient's activities of daily living. Paroxysms of coughing may be so severe the patient faints or fractures a rib.

During physical examination a prolonged expiratory respiratory phase, wheezes, or decreased breath sounds are noted in all lung fields. The patient may need to breathe louder than normal for auscultated breath sounds to be heard. The anteroposterior diameter of the chest is increased ("barrel chest") from the chronic air trapping. The patient may sit upright with arms supported on a fixed surface such as an overbed table *(tripod position)*. The patient may naturally purse lips on expiration (pursed-lip breathing) and use accessory muscles, such as those in the neck, to aid with inspiration. Edema in the ankles may be the only clue to right-sided heart involvement (cor pulmonale).

Over time, hypoxemia (PaO_2 less than 60 mm Hg or O_2 saturation less than 88%) may develop with hypercapnia ($PaCO_2$ over 45 mm Hg). The bluish red color of the skin results from polycythemia and cyanosis. Polycythemia develops as a result of increased production of red blood cells as the body attempts to compensate for chronic hypoxemia. Hemoglobin concentrations may reach 20 g/dL (200 g/L) or more. However, the person may also have lowered hemoglobin and hematocrit because of chronic anemia.

Clinically it is common for a person to have a combination of emphysema and chronic bronchitis, often with one condition predominating. It is sometimes difficult to distinguish COPD from asthma, especially if the individual has a history of cigarette smoking. However, some clinical features are different (see Table 29-3).

Classification of COPD. COPD should be considered in any person with a chronic cough and dyspnea who has smoked cigarettes or been exposed to environmental or occupational pollutants. The diagnosis is confirmed by spirometry.

COPD can be classified as mild, moderate, severe, and very severe (Table 29-17). An FEV_1/FVC ratio of less than 70% establishes the diagnosis of COPD, and the severity of obstruction (as indicated by FEV_1) determines the stage of COPD. The management of COPD is based on the patient's symptoms, classification, and exacerbation history.

Complications

Cor Pulmonale. *Cor pulmonale* results from pulmonary hypertension, which is caused by diseases affecting the lungs or pulmonary blood vessels (Fig. 29-10). In North America 50% of the cases of cor pulmonale are due to COPD. Cor pulmonale is a late manifestation of COPD, yet not all patients with COPD develop cor pulmonale. Once the patient develops cor pulmonale, the prognosis worsens.[27]

In COPD, pulmonary hypertension is caused primarily by constriction of the pulmonary vessels in response to alveolar hypoxia, with acidosis further potentiating the vasoconstriction. Chronic alveolar hypoxia causes vascular remodeling. Chronic hypoxia also stimulates erythropoiesis, which causes polycythemia. This results in increased viscosity of the blood. An anatomic reduction of the pulmonary vascular bed, as seen in emphysema with bullae, may occur. These patients have increased pulmonary vascular resistance and thus develop pulmonary hypertension.

TABLE 29-17 CLASSIFICATION OF COPD SEVERITY*

The following classification is based on postbronchodilator FEV_1.

Classification	Level of Severity	FEV_1 Results
GOLD 1	Mild	FEV_1 ≥80% predicted
GOLD 2	Moderate	FEV_1 50%-80% predicted
GOLD 3	Severe	FEV_1 30%-50% predicted
GOLD 4	Very severe	FEV_1 <30% predicted

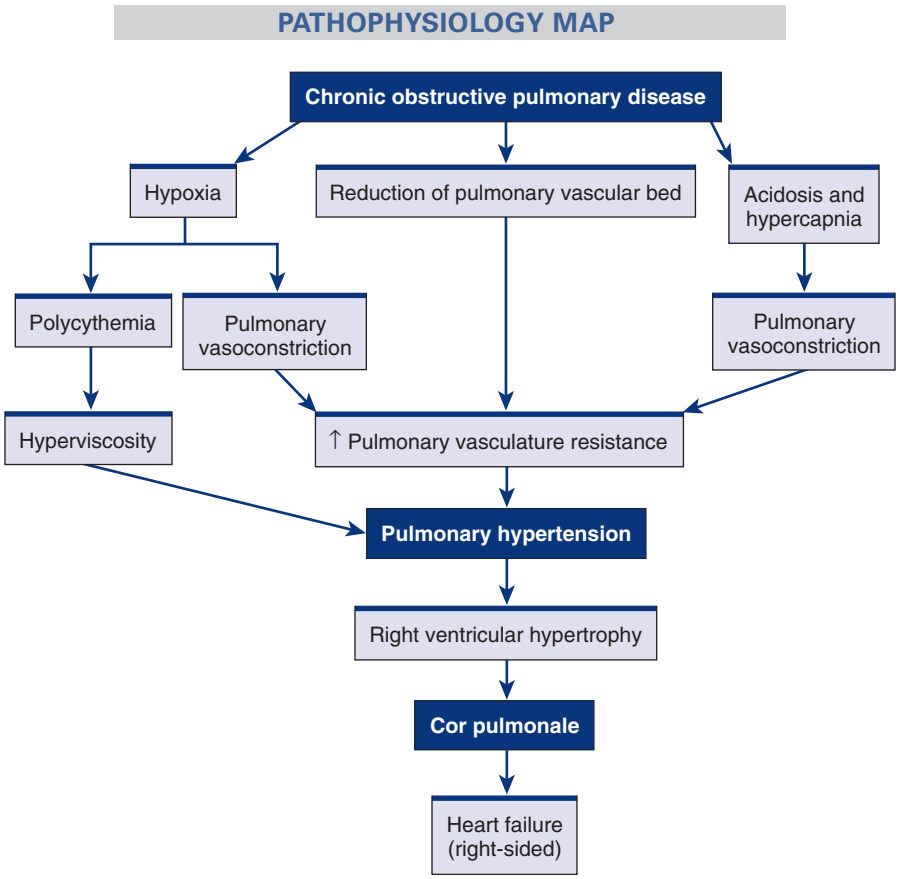

FIG. 29-10 Mechanisms involved in the pathophysiology of pulmonary hypertension and cor pulmonale secondary to chronic obstructive pulmonary disease.

Normally the right ventricle and pulmonary circulatory system are low-pressure systems compared with the left ventricle and systemic circulation. When pulmonary hypertension develops, the pressures on the right side of the heart must increase to push blood into the lungs. Eventually, right-sided heart failure develops.

Dyspnea is the most common symptom of chronic cor pulmonale. Lung sounds are normal, or crackles may be heard in the bases of the lungs bilaterally. Heart sound changes occur but are usually masked by the underlying lung disease. Other manifestations of right-sided heart failure may develop, including distended neck veins (jugular venous distention), hepatomegaly with right upper quadrant tenderness, peripheral edema, and weight gain.

ECG changes indicating right ventricular hypertrophy may be seen in severe cases. Typically the patient has large pulmonary vessels on chest x-ray and increased pressure on a right-sided heart cardiac catheterization. Echocardiogram may reflect right-sided heart enlargement. B-type natriuretic peptide (BNP) levels, which are used to diagnose heart failure, may be elevated in cor pulmonale secondary to the stretching of the right ventricle. Normally BNP levels are used to distinguish cardiac from respiratory causes of dyspnea, but in cor pulmonale the cause of the heart failure is the lung disease.[27]

Treatment of cor pulmonale is initially targeted at managing the COPD (e.g., bronchodilation). Continuous low-flow, long-term O_2 therapy (for more than 15 hr/day) improves survival.[28] Diuretics are generally used, similar to their use with chronic heart failure. (Cor pulmonale is also discussed in Chapter 28.)

COPD Exacerbations. According to the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines, a *COPD exacerbation* is an acute event in the natural course of the disease. The primary causes of exacerbations are bacterial or viral infections.[16,29] Exacerbations are signaled by an acute change in the patient's usual dyspnea, cough, and/or sputum (i.e., something different from the usual daily patterns). Exacerbations of COPD are typical and increase in frequency (average one or two a year) as the disease progresses. It may take several weeks for a patient to recover from an exacerbation.

Assess patients for the classic signs of exacerbation such as an increase in dyspnea, sputum volume, or sputum purulence. They may also have nonspecific complaints of malaise, insomnia, fatigue, depression, confusion, decreased exercise tolerance, increased wheezing, or fever without other causes.[30]

As the severity of COPD increases, exacerbations of COPD are associated with poorer outcomes. Exacerbations may be treated at home or in the hospital, depending on the severity. The severity is determined by the patient's medical history before the exacerbation, the presence of other diseases, symptoms, ABGs, and other laboratory tests. Typically in the later stages of COPD the patient has a low-normal pH, high-normal or above-normal $PaCO_2$, and high-normal bicarbonate (HCO_3^-). This indicates compensated respiratory acidosis as the patient has chronically retained CO_2 and the kidneys have conserved HCO_3^- to increase the pH to within the normal range (see Table 29-3).

Carefully assess the patient's ABGs for any movement toward respiratory acidosis and further hypoxemia, indicating respira-

tory failure. Also assess the patient's medical history for the stage of COPD as noted by the level of FEV_1. Assess for new symptoms or worsening of usual symptoms. Determine the number of previous exacerbations per year and if treatment occurred in the home or hospital. The presence of other co-morbid conditions complicates the exacerbation. In addition, the current treatment affects its management. Be alert for signs of severity such as use of accessory muscles, central cyanosis, edema in the lower extremities, unstable BP, right-sided heart failure, and altered alertness. These manifestations affect whether the patient is treated as an inpatient or outpatient.

Short-acting bronchodilators, oral systemic corticosteroids, and antibiotics are the typical therapies for exacerbations. SABAs with or without short-acting anticholinergics are preferred for those who are breathless. Drug administration via MDI or nebulizer works equally well, although sicker patients often prefer the nebulizer. Antibiotic use remains somewhat controversial. However, the presence of green or purulent sputum (as opposed to white sputum) is one of the best ways to determine if antibiotics are needed.[16,29]

Therapies used to treat exacerbations of COPD in the hospital are similar to home management, except supplemental O_2 therapy titrated by ABG measurement may be used. Attempts are made to use noninvasive mechanical methods (e.g., continuous positive airway pressure [CPAP] to support ventilation rather than invasive ventilatory support [e.g., intubation and mechanical ventilation]). Teach the patient and the caregiver early recognition of the three cardinal symptoms of exacerbations (increase in dyspnea, sputum volume, or sputum purulence) to promote early treatment and thus prevent hospitalization and possible respiratory failure.

Acute Respiratory Failure. Patients with severe COPD who have exacerbations are at risk for respiratory failure. Frequently, COPD patients wait too long to contact their health care provider when they first develop symptoms suggestive of exacerbation. Discontinuing bronchodilator or corticosteroid medication may also precipitate respiratory failure.

Cardioselective β-adrenergic blockers (e.g., atenolol, metoprolol) can be safely used. Chronic treatment with β-blockers may improve survival and reduce the risk of exacerbations of COPD.[16,31]

Indiscriminate use of sedatives, benzodiazepines, and opioids, especially in the preoperative or postoperative patient who retains CO_2, may suppress the ventilatory drive and lead to respiratory failure. The person with COPD who retains CO_2 is usually treated with low-flow rates of O_2 with careful monitoring of ABGs to avoid hypercapnia. It is vital to provide adequate O_2 while assessing the ABGs, rather than risk not providing O_2 because of the fear of CO_2 narcosis (discussed on p. 592).

In patients with COPD, surgery or severe, painful illness involving the chest or abdominal organs may lead to splinting and ineffective ventilation and respiratory failure. To prevent postoperative pulmonary complications, careful preoperative screening, which includes PFTs and ABG assessment, is important in the patient with a heavy smoking history and/or COPD. (Respiratory failure is discussed in Chapter 68.)

Depression and Anxiety. Patients with COPD experience many losses as the disease progresses. Because many patients with COPD experience depression and anxiety, assess for both. Ask patients if they "feel down or blue" most of the time. Do they appear anxious about being able to control their breathlessness or know what to do if they have an exacerbation? Are they exhibiting concern over more difficulty in self-care activities such as bathing? How is the family coping with the patient's disease?

Help the patient with muscle relaxation exercises that can reduce anxiety (see Chapter 7). In addition, teach patients about the treatment and disease, which can give them a sense of control of their disease and complex treatment regimens. It is important to include the patient's caregiver in the teaching so he or she can help the patient cope physically and emotionally.

A consultation with a mental health specialist may be needed for proper screening and diagnosis of depression or other mental health problems. Cognitive and behavioral therapy along with COPD teaching may improve the quality of life. Medications may be used to treat both depression and anxiety. Buspirone (BuSpar), which is used to treat anxiety, has few if any respiratory depression effects. Benzodiazepines should be avoided because they may depress the respiratory drive and may be habit forming. When the patient becomes anxious because of dyspnea, the use of pursed-lip breathing (see Table 29-13) and short-acting bronchodilators may be appropriate.

Diagnostic Studies

Spirometry is required to confirm the diagnosis in individuals suspected of having COPD. Spirometry confirms the presence of airflow obstruction and determines the severity of COPD. The patient is given a short-acting bronchodilator, and post-bronchodilator values are compared with a normal reference value.

A diagnosis of COPD is made when the FEV_1/FVC ratio is less than 70% along with the appropriate symptoms. The value of FEV_1 provides a guideline for the degree of severity of COPD. FEV_1 can be expressed as a percentage compared with a normal reference value (percent predicted). The lower the FEV_1, the sicker the patient.

In addition to spirometry, other diagnostic studies are performed (Table 29-18). Chest x-rays are not diagnostic but may show a flat diaphragm because of the hyperinflated lungs. Computed tomography (CT) scans are not routinely used to diagnose COPD. However, in individuals with predominant emphysema, enlarged air spaces in the apices may be seen on the CT scan.

Other tests may be used to assess the response to therapy, disease severity, and quality of life. Two validated questionnaires are the COPD Assessment Test (CAT) and modified Medical Research Council (mMRC) Dyspnea Scale. The CAT (see eTable 29-3 on the website for this chapter) measures the daily impact of COPD on a person's life and can help the health care team make better management decisions.[32] This test is found online in more than 50 languages with scoring and easy to understand guidelines *(www.catestonline.org)*. The mMRC measures the patient's level of dyspnea (see eTable 29-4).

Patients often have exercise-induced hypoxemia, and thus a 6-minute walk test should be done by a physical or respiratory therapist, with pulse oximetry readings taken when the patient is walking and at rest. If values of O_2 saturation are 88% or lower when at rest and the patient is breathing room air, he or she qualifies for supplemental O_2.[16] Later in the disease the findings presented in Table 29-3 may be present.

A history and physical examination are extremely important in a diagnostic workup.

The BODE index can be used to assess not only the risk of death from COPD, but also the pulmonary and systemic mani-

Collaborative Therapy

- Cessation of cigarette smoking
- Treatment of exacerbations
- Drug therapies (see Tables 29-7 and 29-19)
- Airway clearance techniques
- Breathing exercises and retraining
- Hydration of 3 L/day (if not contraindicated)
- Patient and caregiver teaching
- Influenza immunization yearly
- Pneumovax immunization
- Long-term O_2 (if indicated)
- Progressive plan of exercise, especially walking and upper body strengthening
- Pulmonary rehabilitation program
- Nutritional supplementation if low BMI
- Surgery
  - Lung volume reduction
  - Lung transplantation

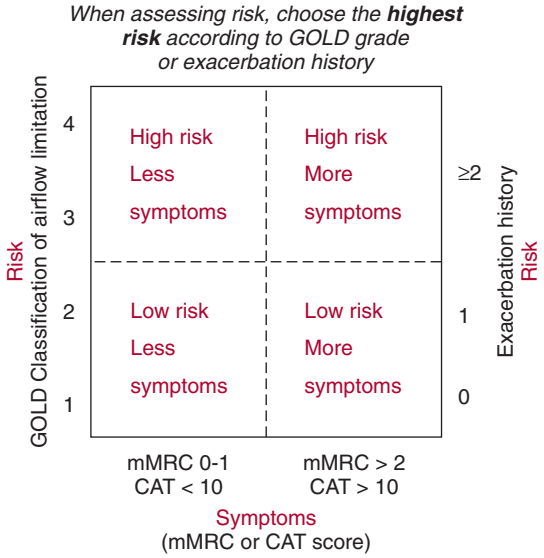

FIG. 29-11 Rubric for chronic obstructive pulmonary disease *(COPD)* showing the association between symptoms, spirometric classification, and future risk of exacerbations. The following factors are considered in the rubric: (1) current level of patient's symptoms as measured by one of two validated questionnaires (modified Medical Research Council *[mMRC]* Dyspnea Scale [see eTable 29-4] or the COPD Assessment Test *[CAT]* [see eTable 29-3]); (2) severity of the disease as measured by the FEV_1; (3) exacerbation risk as reflected in the spirometric classification or patient's history of exacerbations; and (4) presence of co-morbidities. Source: Global Initiative for Chronic Obstructive Lung Disease: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease (updated 2013). Retrieved from *www.goldcopd.org*.

festations (see *www.qxmd.com/calculate-online/respirology/bode-index*).

ABGs are usually assessed in the severe stages (FEV_1 less than 50%) and monitored in patients hospitalized with acute exacerbations. In the later stages of COPD, typical findings are low PaO_2, elevated $PaCO_2$, decreased or low-normal pH, and increased HCO_3^- levels. In early stages, there may be a normal or only slightly decreased PaO_2 and a normal $PaCO_2$. An ECG may be normal or show signs of right ventricular failure. An echocardiogram or multigated acquisition (MUGA) (cardiac blood pool) scan (see Table 32-6) can be used to evaluate right- and left-sided ventricular function. Sputum for culture and sensitivity may be obtained if the patient is hospitalized for an acute exacerbation and has not responded to empiric therapy with antibiotics.

Collaborative Care

Two major evidence-based references related to the care of COPD patients are (1) GOLD *(www.goldcopd.org)* and (2) clinical guidelines from the American College of Physicians.[15,16] Most patients are treated as outpatients. They are hospitalized for exacerbations and potential complications when respiratory failure, pneumonia, and cor pulmonale occur.

The GOLD guidelines present a rubric for assessing and diagnosing COPD (Fig. 29-11). You may be a part of the health care team that administers the mMRC or CAT and inquires about exacerbations. This information is used to detect COPD patients who are at risk for problems.[16]

Evaluate the patient's exposure to environmental or occupational irritants, and determine ways to control or avoid them. For example, teach the patient to avoid aerosol hair sprays and smoke-filled rooms. The patient with COPD is extremely susceptible to pulmonary infections. The patient with COPD and anyone who smokes should receive an influenza virus vaccine yearly. The pneumococcal vaccine (Pneumovax) is recommended for all smokers ages 19 or older and all patients with COPD.[21,33] (The guidelines for Pneumovax are presented in Table 28-5.)

Exacerbations of COPD should be treated as soon as possible, especially if the patient is in the severe stages. Some patients are given a prescription for antibiotics and are instructed to begin taking them when the first symptoms or signs of an exacerbation occur.[34]

Smoking Cessation. Cessation of cigarette smoking in any person with COPD at any level of severity is the most important intervention that can impact the natural history of COPD.[16] After a person discontinues smoking, the accelerated decline in pulmonary function found with smoking slows to almost nonsmoking levels.[21,29] Thus the sooner the smoker stops, the less pulmonary function is lost and the sooner the symptoms decrease, especially cough and sputum production. (Smoking cessation techniques are discussed in Chapter 11 and in Tables 11-4 to 11-6.)

Drug Therapy. Medications for COPD can reduce symptoms, increase exercise capacity, improve overall health, and reduce the number and severity of exacerbations. Bronchodilator drug therapy relaxes smooth muscles in the airway and improves the ventilation of the lungs, thus reducing the degree of breathlessness. Patients with COPD do not respond as dra-

TABLE 29-19 DRUG THERAPY

Medication Guidelines for Stable COPD

The treatment guidelines are based on the FEV_1 results.

FEV_1 Results	Treatment Guidelines*
FEV_1 60%-80% predicted (with respiratory symptoms)	Treatment with inhaled bronchodilators may be used.
FEV_1 <60% predicted (with respiratory symptoms)	Treat with inhaled bronchodilators: anticholinergics or long-acting β_2–agonist OR Monotherapy with long-acting inhaled anticholinergics or long-acting β_2-agonist OR Combination therapy with long-acting inhaled anticholinergics, long-acting β_2-agonist, or inhaled corticosteroids

*NOTE: Occasional use of short-acting inhaled bronchodilator for acute symptoms are not addressed in these recommendations.
Source: Qaseem A, Wilt T, Weinberger S, et al: Diagnosis and management of stable chronic obstructive pulmonary disease: a clinical practice guideline update from the American College of Physicians, American College of Chest Physicians, American Thoracic Society, and European Respiratory Society, *Ann Intern Med* 155:179, 2011.
FEV_1, Forced expiratory volume in 1 sec.

matically to bronchodilator therapy as those with asthma. However, bronchodilator therapy reduces dyspnea and increases FEV_1. The inhaled route of medication is preferred and given on a PRN or regular basis.

Patients commonly do not properly administer inhaled medications. Therefore it is important for you to demonstrate and talk with patients about inhaler use. Give the patient clear, readable instructions.[10]

Medications are given in a stepwise fashion according to the level of airflow obstruction determined from spirometry (FEV_1) and symptoms (see Fig. 29-11). Medications are stepped up but usually not stepped down, as in asthma, because in COPD continual symptoms are probably present (Table 29-19).

Bronchodilator medications commonly used are β_2-adrenergic agonists; anticholinergic agents; and, to a much lesser extent, methylxanthines (see Table 29-7). The choice of a bronchodilator depends on the patient's response. These medications are given on a PRN or scheduled basis. When the patient has mild COPD or fewer symptoms, a short-acting bronchodilator is used.[21] Albuterol or ipratropium may be used as single agents, but combining bronchodilators improves their effect and decreases the risk of adverse effects.[29] Albuterol and ipratropium can be nebulized together (DuoNeb) or delivered by inhalation spray (Combivent Respimat).

In the moderate stage of COPD (FEV_1 less than 60%), a long-acting bronchodilator may be used (see Tables 29-7 and 29-19). A short-acting bronchodilator may still be used PRN as a "rescue" for dyspnea. Salmeterol and formoterol are widely used LABAs, and they can be used in COPD as monotherapy (unlike drug therapy for asthma).[21] Indacaterol (Arcapta Neohaler) is the newest LABA with a duration of action of 24 hours, and thus it can be used just once a day.[16] Tiotropium (Spiriva), a long-acting anticholinergic, is used once a day.

The addition of an ICS to long-acting bronchodilator therapy is often prescribed in COPD patients with FEV_1 of less than 60%. Examples of combinations of ICSs with LABAs are fluticasone/salmeterol (Advair) and budesonide/formoterol (Symbicort). Inhaled long-acting anticholinergics, LABAs, or ICSs all reduce COPD exacerbations. However, in COPD, unlike asthma, ICSs are not used as monotherapy because of the concerns about side effects. Some patients are on triple therapy with Advair and tiotropium.[21] Oral corticosteroids should not be used for long-term therapy in COPD, but are effective for short-term use to treat exacerbations.

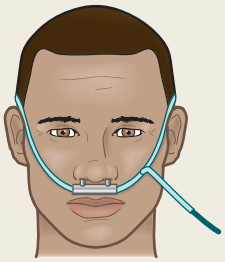
The use of long-acting theophylline in the treatment of COPD is controversial because it interacts with many drugs. A low dose of theophylline with an ICS may benefit a few patients with COPD who do not respond to other inhaled medications.

Roflumilast (Daliresp) is an oral medication used to decrease the frequency of exacerbations in severe COPD. This drug is a phosphodiesterase inhibitor, which is an antiinflammatory drug that suppresses the release of cytokines and other inflammatory mediators, and inhibits the production of reactive oxygen radicals.[21,35]

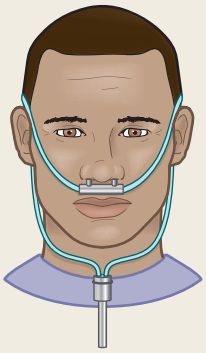
New drug delivery devices are becoming available at a rapid pace. One example is Respimat, which is an easy-to-use handheld device that provides a high deposition of drug to the lungs and low mouth and throat deposition. Respimat simplifies coordination between activation of the medication and inhalation without propellant, and it is independent of inspiratory flow. It also has a dose indicator. Combivent Respimat (ipratropium and albuterol) inhalation aerosol is now available.[36]

Oxygen Therapy. O_2 therapy is frequently used in the treatment of COPD and other problems associated with hypoxemia. Long-term continuous (more than 15 hr/day) O_2 therapy (LTOT) increases survival and improves exercise capacity and mental status in hypoxemic patients.[15,21]

Oxygen is a colorless, odorless, tasteless gas that constitutes 21% of the atmosphere. Administering supplemental O_2 increases the partial pressure of O_2 (PO_2) in inspired air. Used clinically, it is considered a drug. For reimbursement purposes, Medicare pays for oxygen when certain clinical criteria are met (i.e., the patient's O_2 saturation is 88% or less, and PaO_2 is 55 mm Hg or less).



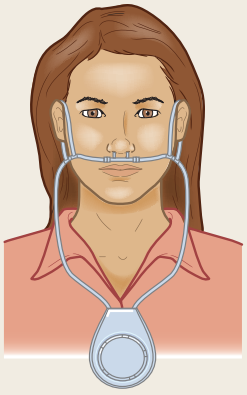
Indications for Use. Goals for O_2 therapy are to keep the SaO_2 greater than 90% during rest, sleep, and exertion, or the PaO_2 greater than 60 mm Hg. O_2 is usually administered to treat hypoxemia caused by a variety of problems such as (1) respiratory disorders (e.g., COPD, pulmonary hypertension, cor pulmonale, pneumonia, lung cancer, pulmonary emboli); (2) cardiovascular disorders (e.g., myocardial infarction, dysrhythmias, angina pectoris, and cardiogenic shock); and (3) central nervous system disorders (e.g., overdose of opioids, head injury, sleep disorders [sleep apnea]).



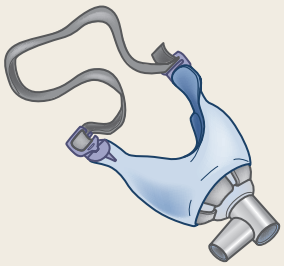
Methods of Administration. The goal of O_2 administration is to supply the patient with adequate O_2 to maximize the oxygen-carrying ability of the blood. There are various methods of O_2 administration (Table 29-20 and Fig. 29-12). The method selected depends on factors such as the fraction of inspired O_2 (FIO_2) required by the patient and delivered by the device, the patient's mobility, humidification required, patient cooperation, comfort, cost, and financial resources.

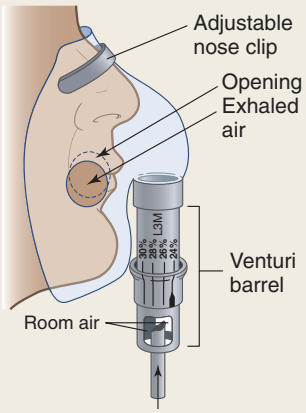
O_2 delivery systems are classified as low- or high-flow systems. Most methods of O_2 administration are low-flow devices that deliver O_2 in concentrations that vary with the person's respiratory pattern. In contrast, the Venturi mask is a high-flow device that delivers fixed concentrations of O_2 (e.g., 24%, 28%) independent of the patient's respiratory pattern.

TABLE 29-20 METHODS OF OXYGEN ADMINISTRATION



Description	Nursing Interventions
Low-Flow Delivery Devices	
Nasal Cannula	
• Most commonly used device. • O_2 delivered via plastic nasal prongs. • Safe and simple method that allows some freedom of movement. Patient can eat, talk, or cough while wearing device. • Useful for a patient requiring low O_2 concentrations. • O_2 concentrations of 24% (at 1 L/min) to 44% (at 6 L/min) can be obtained.	• Stabilize nasal cannula when caring for a restless patient. • Amount of O_2 inhaled depends on room air and patient's breathing pattern. • Most patients with COPD can tolerate 2 L/min via cannula. • Assess patient's nares and ears for skin breakdown. May need to pad cannula where it sits on ears. • If flow rates are >5 L/min, nasal membranes may dry and may cause pain in frontal sinuses.
Simple Face Mask	
• Covers patient's nose and mouth. • Used only for short periods, especially when transporting patients. • Longer use is typically not tolerated because of tight seal and heat generated around nose and mouth from mask. • O_2 concentrations of 35%-50% can be achieved with flow rates of 6-12 L/min. • Mask provides adequate humidification of inspired air.	• Wash and dry under mask q2hr. • Mask must fit snugly. • Nasal cannula may be provided while patient is eating. • Watch for pressure necrosis at top of ears from elastic straps if patient wears for a longer time. (Gauze or other padding may alleviate this problem.)
Partial and Non-Rebreather Masks	
• Useful for short-term (24 hr) therapy for patients needing higher O_2 concentrations (60%-90% at 10-15 L/min). • O_2 flows into reservoir bag and mask during inhalation. • This bag allows patient to rebreathe about first third of exhaled air (rich in O_2) in conjunction with flowing O_2. • Vents remain open on partial mask only. Some facilities prefer this over non-rebreather as a safety issue.	• O_2 flow rate must be sufficient to keep bag from collapsing during inspiration to avoid CO_2 buildup. • If deflation occurs, increase liter flow to keep bag inflated. • Mask should fit snugly. • With non-rebreather masks, make sure valves are open during expiration and closed during inhalation to prevent drastic decrease in FIO_2. • Monitor patient closely, since more advanced interventions may be required such as CPAP, BiPAP, or intubation with mechanical ventilation.
Oxygen-Conserving Cannula	
• Generally indicated for long-term O_2 therapy at home vs. during hospitalization (e.g., pulmonary fibrosis, pulmonary hypertension). • May be "moustache" (Oxymizer) or "pendant" type. • Cannula has a built-in reservoir that ↑ O_2 concentration and allows patient to use lower flow, usually 30%-50%, which increases comfort, lowers cost, and can be increased with activities. • Can deliver up to 8 L/min O_2.	• May cause necrosis over tops of ears. Can be padded. • Cannula cannot be cleaned. Manufacturer recommends changing cannula every week. • It is more expensive than standard cannulas and requires evaluation with ABGs and oximetry to determine correct flow for patient. • Cannula is highly visible.





Pendant-type O_2-conserving cannula.

TABLE 29-20 METHODS OF OXYGEN ADMINISTRATION—cont'd

Description	Nursing Interventions	
High-Flow Delivery Devices		
Tracheostomy Collar		
• Collar attaches to neck with elastic strap and can deliver high humidity and O_2 via tracheostomy. • O_2 concentration is lost into atmosphere because collar does not fit tightly. • Venturi device can be attached to flow meter and thus can deliver exact amounts of O_2 via collar.	• Secretions collect inside collar and around tracheostomy. Remove collar and clean at least q4hr to prevent aspiration of fluid and infection. • Because condensation occurs in tubing, periodically drain distally to tracheostomy.	
Tracheostomy T Bar		
• Almost identical to tracheostomy collar, but it has a vent and a T connector that allow an inline catheter (e.g., Ballard catheter) to be connected for suctioning. • Tight fit allows better O_2 and humidity delivery than tracheostomy collar.	• Empty as necessary. • Because T bars disconnect easily, monitor closely. • T bar may pull on a patient's tracheostomy tube, causing irritation and potential tissue damage. Monitor this closely. • See tracheostomy collar above.	
Venturi Mask		
• Mask can deliver precise, high-flow rates of O_2. • Lightweight plastic, cone-shaped device is fitted to face. • Masks are available for delivery of 24%, 28%, 31%, 35%, 40%, and 50% O_2. • Method is especially helpful for administering low, constant O_2 concentrations to patients with COPD. • Adaptors can be applied to increase humidification.	• Entrainment device on mask must be changed to deliver higher concentrations of O_2. • Air entrainment ports must not be occluded. • Mask is uncomfortable. Remove when patient eats. • Patient can talk but voice may be muffled. • See other applicable nursing interventions under simple face mask above.	

ABGs, Arterial blood gases; *BiPAP,* biphasic positive airway pressure; *CPAP,* continuous positive airway pressure; *FIO_2,* fraction of inspired O_2.

FIG. 29-12 Golfer uses Helios liquid portable O_2 system.

Mechanical ventilators are another example of a high-flow O_2 delivery system. Because room air is mixed with O_2, in low-flow systems the percentage of O_2 delivered to the patient is not as precise as with high-flow systems.

Humidification and Nebulization. O_2 obtained from cylinders or wall systems is dry. Dry O_2 has an irritating effect on mucous membranes and dries secretions. Therefore it is important that a high liter flow of O_2, delivering more than 35% to 50% O_2, be humidified, either by humidification or nebulization. A common device used for humidification when the patient has a cannula or a mask is a bubble-through humidifier. It is a small plastic jar filled with sterile distilled water that is attached to the O_2 source by means of a flow meter. O_2 passes into the jar, bubbles through the water, and then goes through tubing to the patient's cannula or mask. The purpose of the bubble-through humidifier is to restore the humidity conditions of room air. However, the need for bubble-through humidifiers at flow rates between 1 and 4 L/minute is based on the patient's comfort.

Another means of administering humidified O_2 is via a nebulizer. It delivers particulate water mist (aerosols) with nearly 100% humidity. The humidity can be increased by heating the

water, which increases the gas's ability to hold moisture. Humidified (100%) gas is required when the upper airway is bypassed in acute care. However, patients with established tracheostomies do not always require 100% humidity. When nebulizers are used, large tubing should be employed to connect the device to a face mask or T bar. If small tubing is used, condensation can occlude the flow of O_2. Vapotherm Precision Flow can deliver high flows (up to 40 L/minute) of warm humidified gas (air/O_2) with precise percentages to the patient through a nasal cannula, and it is noninvasive.[37]

Complications

Combustion. O_2 supports combustion and increases the rate of burning, so it is important to prohibit smoking in the area in which O_2 is being used. A "No Smoking" sign should be prominently displayed on the patient's door. Also caution the patient against smoking cigarettes with an O_2 cannula in place.

Carbon Dioxide Narcosis. The chemoreceptors in the respiratory center that control the drive to breathe respond to CO_2 and O_2. Normally, CO_2 accumulation is the major stimulant of the respiratory center. Over time some COPD patients develop a tolerance for high CO_2 levels (the respiratory center loses its sensitivity to the elevated CO_2 levels). Theoretically, for these individuals the "drive" to breathe is hypoxemia. Thus there has been concern regarding the dangers of administering O_2 to COPD patients and reducing their drive to breathe. However, the "hypoxic drive" is complex and involves other factors, including ventilation and perfusion. In addition, not all patients with COPD retain CO_2.

The key concern is not providing adequate oxygen to these patients, since this is much more detrimental because it may lead to hypoxia. It is much easier to reverse high CO_2 than low O_2. Although O_2 administration should be titrated to the lowest effective dose, many patients who have end-stage COPD require high flow rates and higher concentrations for survival. They may exhibit higher than normal levels of CO_2 in their blood, but this is not a major concern. What is important is careful, ongoing assessment when providing O_2 to these patients, monitoring both the physical and cognitive effects of O_2 levels.

It is critical to start O_2 at low flow rates until ABGs can be obtained. ABGs are used as a guide to determine what FIO_2 level is sufficient and can be tolerated. Assess the patient's mental status and vital signs before starting O_2 therapy and frequently thereafter.

Oxygen Toxicity. Pulmonary **O_2 toxicity** may result from prolonged exposure to a high level of O_2 (PaO_2). High concentrations of oxygen can result in a severe inflammatory response because of oxygen radicals and damage to alveolar-capillary membranes resulting in severe pulmonary edema, shunting of blood, and hypoxemia. These individuals develop acute respiratory distress syndrome (ARDS) (see Chapter 68). Fortunately, O_2 toxicity is relatively rare.

Prevention of O_2 toxicity is important for the patient who is receiving O_2. The amount of O_2 administered should be just enough to maintain the PaO_2 within a normal or acceptable range for the patient. Monitor ABGs frequently to evaluate the effectiveness of therapy and to guide the tapering of supplemental O_2. A safe limit of O_2 concentrations has not yet been established. All levels above 50% and O_2 used for longer than 24 hours should be considered potentially toxic. Levels of 40% and below used for short periods may be regarded as relatively nontoxic and probably will not result in significant O_2 toxicity.

DELEGATION DECISIONS

Oxygen Administration

All members of the health care team should be alert to possible problems with gas exchange in patients who are receiving oxygenation. Patients who are hypoxemic should be cared for by the registered nurse (RN) until they consistently have O_2 saturations ≥90%.

Role of Registered Nurse (RN)

- Assess need for adjustments in O_2 flow rate.
- Evaluate response to O_2 therapy.
- Monitor patient for signs of adverse effects of O_2 therapy.
- In many cases, choose the optimal O_2 delivery device (e.g., a nasal cannula or simple face mask).
- Teach patient and caregivers about home O_2 use.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- For stable patients, adjust O_2 flow rate depending on desired O_2 saturation level.

Role of Unlicensed Assistive Personnel (UAP)

- Use pulse oximetry to measure O_2 saturation.
- Report O_2 saturation level to RN.
- Assist patient with adjustment of O_2 delivery devices (e.g., nasal cannula, face mask).
- Report to RN any change in patient level of consciousness or complaints of shortness of breath.

Absorption Atelectasis. Normally, nitrogen (which constitutes 79% of the air that is breathed) is not absorbed into the bloodstream. This prevents alveolar collapse. When high concentrations of O_2 are given, nitrogen is washed out of the alveoli and replaced with O_2. If airway obstruction occurs, the O_2 is absorbed into the bloodstream and the alveoli collapse. This process is called *absorption atelectasis.*

Infection. Infection can be a major hazard of O_2 administration. Heated nebulizers present the highest risk. The constant use of humidity supports bacterial growth, with the most common organism being *Pseudomonas aeruginosa.* Disposable equipment that operates as a closed system, such as the Ballard closed suctioning system, should be used. Each hospital has a policy on the required frequency of equipment changes based on the type of equipment used.

Chronic Oxygen Therapy at Home. Improved survival occurs in patients with COPD who receive long-term O_2 therapy (LTOT) (more than 15 hr/day) to treat hypoxemia.[16,21] The improved prognosis results from preventing progression of the disease and subsequent cor pulmonale. The benefits of LTOT include improved mental acuity, sleep, and exercise tolerance; decreased hematocrit; and reduced pulmonary hypertension.

Some patients fear becoming "addicted" to O_2 and are reluctant to use it. Tell them that it is not "addicting" and that it needs to be used because of the positive effects on the heart, lungs, and brain. Evaluate the need for LTOT when the patient's condition has stabilized. The goal of O_2 therapy is to maintain SaO_2 greater than 90% during rest, sleep, and exertion.

Short-term home O_2 therapy (1 to 30 days) may be indicated for the patient in whom hypoxemia persists after discharge from the hospital. For example, a patient with underlying COPD who develops a serious respiratory tract infection may need continued O_2 therapy to treat hypoxemia for 4 to 6 weeks after discharge from the hospital. Measure the patient's oxygenation status by SaO_2 30 to 90 days after an acute episode to determine if the O_2 is still needed.

TABLE 29-21 HOME OXYGEN DELIVERY SYSTEMS*

- Liquid O_2
- Compressed O_2 cylinders
- Concentrator or extractor
- Portable O_2 concentrator
- O_2 conserving or pulsed devices

*Detailed descriptions of these delivery systems are presented in eTable 29-5 (available on the website for this chapter).

FIG. 29-13 A portable liquid O_2 unit can be refilled from a liquid O_2 reservoir unit.

Patients may receive O_2 only during exercise and/or sleep. Evaluate the need for O_2 during these periods with a 6-minute walk test or overnight oximetry. (Pulse oximetry is discussed in Chapter 26.)

Periodic reevaluations are necessary for the patient who is using chronic supplemental O_2. Generally, the patient should be reevaluated every 30 to 90 days during the first year of therapy and annually after that, as long as the patient remains stable.

Nasal cannulas, either regular or the O_2-conserving type (see Table 29-20), are usually used to deliver O_2 from a central source in the home. The source may be a liquid O_2 storage system, compressed O_2 in tanks, or an O_2 concentrator or extractor, depending on the patient's home environment, insurance coverage, activity level, and proximity to an O_2 supply company (Table 29-21). To increase mobility in the home, the patient can use extension tubing (up to 50 ft) without adversely affecting the O_2 flow delivery. Small, portable systems, such as liquid O_2, may be provided for the patient who remains active outside the home (see Fig. 29-12).

Home O_2 systems are usually rented from a company that sends a respiratory therapist to the patient's home (Fig. 29-13). The therapist teaches the patient and caregiver how to use the O_2 system, how to care for it, and how to recognize when the supply is running low and needs to be reordered. A patient and caregiver teaching guide for the use of O_2 at home is presented in Table 29-22.

Encourage the patient who uses home O_2 to remain active and travel normally. If travel is by automobile, arrangements can be made for O_2 to be available at the destination point. O_2 supply companies can often assist in these arrangements. If a patient wishes to travel by bus, train, or airplane, the patient should inform the appropriate people when reservations are made that O_2 will be needed for travel. If there is a potential for the patient to become hypoxic, O_2 needs for flying can be determined via a hypoxia inhalation test or through a mathematical formula. Portable oxygen concentrators are a ready source of renewable O_2 and can be available by recharging at home or with a DC (e.g., auto) power supply. These systems are widely approved by airlines for in-flight use. The patient should contact the airline to determine the particular accommodations and policies for in-flight O_2.

TABLE 29-22 PATIENT & CAREGIVER TEACHING GUIDE

Home Oxygen Use

The company that provides the prescribed O_2 therapy equipment will instruct the patient on equipment care. The following are some general instructions that you may include when teaching the patient and caregiver about the use of home O_2.

Decreasing Risk for Infection

- Brush teeth or use mouthwash several times a day.
- Wash nasal cannula (prongs) with a liquid soap and thoroughly rinse once or twice a week.
- Replace cannula every 2-4 wk.
- If you have a cold, replace the cannula after your symptoms pass.
- Always remove secretions that are coughed out.
- If you use an O_2 concentrator, every day unplug the unit and wipe down the cabinet with a damp cloth and dry it.
- Ask the company providing the equipment how often to change the filter.

Safety Issues

- Post "No Smoking" warning signs outside the home.
- O_2 will not "blow up," but it will increase the rate of burning, since it is a fuel for the fire.
- Do not allow smoking in the home, and do not smoke yourself while wearing O_2. Nasal cannulas and masks can catch fire and cause serious burns to face and airways.
- Do not use flammable liquids such as paint thinners, cleaning fluids, gasoline, kerosene, oil-based paints, or aerosol sprays while using O_2.
- Do not use blankets or fabrics that carry a static charge, such as wool or synthetics.
- Inform your electric company if you are using a concentrator. In case of a power failure, it will know the medical urgency of restoring your power.

Adapted from *www.YourLungHealth.org*.

Breathing Retraining. The patient with COPD has dyspnea with an increased respiratory rate. In addition, the accessory muscles of breathing in the neck and upper part of the chest are used excessively to promote chest wall movement. These muscles are not designed for long-term use, and as a result, the patient experiences increased fatigue.

The main types of breathing retraining exercises are (1) pursed-lip breathing and (2) diaphragmatic breathing. The purpose of **pursed-lip breathing (PLB)** is to prolong exhalation and thereby prevent bronchiolar collapse and air trapping. PLB is simple and easy to teach and learn, and it gives the patient more control over breathing, especially during exercise and periods of dyspnea[38] (see Table 29-13). Patients should be taught to use "just enough" positive pressure with the pursed lips because excessive resistance may increase the work of breathing.

Diaphragmatic (abdominal) breathing focuses on using the diaphragm instead of the accessory muscles of the chest to (1) achieve maximum inhalation and (2) slow the respiratory rate.[39] However, the use of diaphragmatic breathing in patients with COPD may increase the work of breathing and dyspnea. Patients with moderate to severe COPD with marked hyperinflation may be poor candidates for diaphragmatic breathing.[40]

PLB slows the respiratory rate and is easier to learn than diaphragmatic breathing. In the setting of extreme acute dyspnea, it is most important to focus on helping the patient slow the respiratory rate by using the principles of PLB. Other techniques that decrease breathing frequency, such as yoga, may also be used to reduce dyspnea.[40]

Airway Clearance Techniques. Many patients with COPD or other conditions (e.g., cystic fibrosis, bronchiectasis) who retain secretions require help to adequately clear their airways. Airway clearance techniques (ACTs) loosen mucus and secretions so they can be cleared by coughing. A variety of safe techniques can be used to achieve airway clearance. When ACTs are compared, it is primarily patient preference that determines which one is used.[41]

ACTs are especially beneficial in patients who have a COPD exacerbation.[42] Respiratory therapists, physical therapists, and nurses are involved in performing these techniques. ACTs are often used with other treatments. Typically the patient receives bronchodilator therapy via an inhaled device (e.g., nebulization) before ACT. Then the ACT is used, followed by effective coughing (e.g., huff coughing). ACTs include effective coughing, chest physiotherapy, airway clearance devices, and high-frequency chest ventilation.

Effective Coughing. Many patients with COPD have developed ineffective coughing patterns that do not adequately clear their airways of sputum. They also fear developing spastic coughing, resulting in increased dyspnea. Although other techniques (e.g., chest physiotherapy) are used to loosen secretions and mucus, the patient must cough effectively to bring the secretions to the central airways to expectorate them.

Huff coughing is an effective forced expiratory technique that you can easily teach the patient. Before starting, ensure that the patient is breathing deeply from the diaphragm. Place the patient's hands on the lower lateral chest wall, and then ask the patient to breathe deeply through the nose. You should feel the patient's hands move outward, which represents a breath from the diaphragm. Guidelines for effective huff coughing are presented in Table 29-23.

Chest Physiotherapy. **Chest physiotherapy (CPT)** is primarily used for patients with excessive bronchial secretions who have difficulty clearing them (e.g., cystic fibrosis, bronchiectasis). CPT consists of postural drainage, percussion, and vibration. CPT should be performed by an individual who has been properly trained.

Percussion and *vibration* are manual or mechanical techniques used to augment postural drainage. These techniques are used after the patient has assumed a postural drainage position to assist in loosening the mobilized secretions (see eFig. 29-1 on the website for this chapter). Percussion, vibration, and postural drainage assist in bringing secretions into larger, more central airways. Effective coughing (huff coughing) is then necessary to help raise these secretions.

Complications associated with improperly performed CPT include fractured ribs, bruising, hypoxemia, and discomfort.

TABLE 29-23 PATIENT & CAREGIVER TEACHING GUIDE

Effective Huff Coughing

When teaching effective huff coughing:

1. Help the patient assume a sitting position with head slightly flexed, shoulders relaxed, knees flexed, forearms supported by pillow, and, if possible, feet on the floor.

Then you should instruct the patient to:

2. Inhale slowly through the mouth while breathing deeply from the diaphragm.
3. Hold the breath for 2-3 seconds.
4. Forcefully exhale quickly as if one is fogging up a mirror with one's breath (thus creating a "huff"). (This moves the secretions to larger airways.)
5. Repeat the "huff" one or two more times while refraining from a "regular" cough.
6. Cough when mucus is felt in the breathing tubes.
7. Rest for five to ten regular breaths.
8. Repeat the huffs (three to five cycles) until you feel you have cleared mucus or you become tired.

CPT may be stressful for some patients, and some may develop hypoxemia and bronchospasms.

Postural Drainage. **Postural drainage** is the use of positioning techniques that drain secretions from specific segments of the lungs and bronchi into the trachea. The postural drainage positions used depend on the areas of lung that are involved. This is determined by patient assessment (including the patient's preference), chest x-rays, and chest auscultation. For example, some patients with left lower lobe involvement require postural drainage of only the affected region, whereas a person with cystic fibrosis may require postural drainage of all segments.

The purpose of various positions in postural drainage is to drain each segment toward the larger airways. A side-lying position can be used for the patient who cannot tolerate a head-down position. Aerosolized bronchodilators and hydration therapy are usually administered before postural drainage. The chosen postural drainage position is maintained for about 5 minutes during percussion and vibration. A common order is two to four times a day. In acute situations, postural drainage may be performed as frequently as every 4 hours. Schedule the procedure to be completed at least 1 hour before meals or 3 hours after meals.

Beds are available that can rotate and percuss in various postural drainage positions, and these are quite effective. Some positions for postural drainage (e.g., Trendelenburg) should not be performed on the patient with chest trauma, hemoptysis, heart disease, pulmonary embolus, or head injury, and in other situations where the patient's condition is not stable.

Percussion. *Percussion* is performed in the appropriate postural drainage position with the hands in a cuplike position, with the fingers and thumbs closed (Fig. 29-14). The cupped hand should create an air pocket between the patient's chest and the hand. Both hands are cupped and used in an alternating rhythmic fashion. Percussion is accomplished with flexion and extension of the wrists. If it is performed correctly, a hollow sound should be heard. The air-cushion impact facilitates the movement of thick mucus. Place a thin towel over the area to be percussed, or the patient may choose to wear a T-shirt or hospital gown.

Vibration. *Vibration* is accomplished by tensing the hand and arm muscles repeatedly and pressing mildly with the flat of

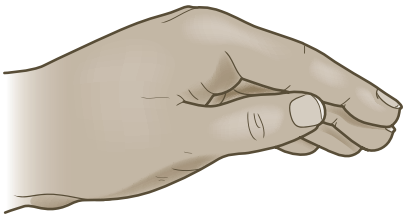


FIG. 29-14 Cupped-hand position for percussion. The hand should be cupped as though scooping up water.

FIG. 29-15 Acapella airway clearance device.

the hand on the affected area while the patient slowly exhales a deep breath. The vibrations facilitate movement of secretions to larger airways. Mild vibration is tolerated better than percussion and can be used in situations where percussion may be contraindicated. Commercial vibrators are available for hospital and home use.

Airway Clearance Devices. Various *airway clearance devices* are available to mobilize secretions, are easier to tolerate than CPT, and take less time than conventional CPT sessions. These devices include the Flutter, Acapella, and TheraPEP Therapy System. These devices use the principle of positive expiratory pressure (PEP) and may provide greater benefit to patients with COPD than other ACTs.[42]

The Flutter mucus clearance device is a hand-held device that is shaped like a small, fat pipe (see eFig. 29-2 available on the website for this chapter). It provides PEP treatment for patients with mucus-producing conditions. The Flutter has a mouthpiece, a high-density stainless steel ball, and a cone that holds the ball. When the patient exhales through the Flutter, the steel ball moves, which causes oscillations (vibrations) in the airways and loosens mucus. It helps move mucus up through the airways to the mouth where the mucus can be expectorated. The patient must be upright, and the angle at which the Flutter is held is critical. The Acapella is another small hand-held device (Fig. 29-15) that combines the benefits of both PEP therapy and airway vibrations to mobilize pulmonary secretions. It can be used in virtually any setting, since patients are free to sit, stand, or recline. The patient may also inhale through the Acapella, and nebulizers can be attached to it. This saves time because the treatment does not have to be preceded by the nebulizer.

TheraPEP Therapy System can also provide sustained PEP and can simultaneously deliver aerosols so the patient can inhale and exhale through it. TheraPEP has a mouthpiece attached to tubing connected to a small cylindric resistor and a pressure indicator. The pressure indicator provides visual feedback about the pressure that the patient needs to hold in an exhalation to receive the PEP. The therapist initially determines the pressure, and you can reinforce the treatment. (A description and photo of this system are available at *www.smiths-medical.com/catalog/bronchial-hygiene/therapep/therapep-system.html*.)

High-Frequency Chest Wall Oscillation. High-frequency chest wall oscillation uses an inflatable vest (e.g., the Vest Airway system or the SmartVest) with hoses connected to a high-frequency pulse generator. (A description and photo are available at *www.thevest.com/products*.) The pulse generator delivers air to the vest, which vibrates the chest. The high-frequency airwaves dislodge mucus from the airways, mobilize the mucus, and move it toward larger airways. The vest can be used without the aid of another person. The units weigh 23 to 30 lb and are quiet. They come in a suitcase and are portable.

Nutritional Therapy. Many COPD patients in the advanced stages are underweight with loss of muscle mass and cachexia. Weight loss is a predictor of a poor prognosis and increased frequency of COPD exacerbations. Weight gain after nutritional support can decrease the risk of mortality.

The cause of weight loss is not entirely known. To some extent, loss of muscle mass is associated with aging. (Most people with COPD are older.) If the patient is on high doses of corticosteroids, the net effect is protein catabolism and loss of muscle mass. Eating becomes an effort because of the dyspnea related to the energy expended to chew, the reduction of airflow while swallowing, and O_2 desaturation.

Decreased appetite and weight loss also occur because of the systemic inflammatory process in COPD. The inflammation results in increased metabolism, which could explain why some individuals with COPD lose weight despite adequate nutritional intake.[43] Other factors that contribute to malnutrition in COPD include altered taste caused by chronic mouth breathing, excessive sputum, fatigue, anxiety, depression, increased energy needs, numerous infections, and side effects of polypharmacy.[44]

To decrease dyspnea and conserve energy, the patient should rest for at least 30 minutes before eating and use a bronchodilator before meals. Teach the patient to avoid exercise and treatments for at least 1 hour before and after eating. If a patient has O_2 therapy prescribed, use of supplemental O_2 by nasal cannula while eating may be beneficial. Assess the patient's dentition because broken or missing teeth or loose dentures make eating more difficult. Activity such as walking or getting out of bed during the day can stimulate the appetite and promote weight gain. Sensations of bloating and early satiety when eating can be attributed to swallowing air while eating, side effects of medication (especially corticosteroids and theophylline), and the abnormal position of the diaphragm relative to the stomach in association with hyperinflation of the lungs.

Fluid intake should be at least 3 L/day unless contraindicated by other medical conditions. Fluids should be taken between meals (rather than with them) to prevent excess stomach distention and to decrease pressure on the diaphragm. Sodium restriction may be indicated if there is accompanying heart failure.

Getting the patient to eat adequate amounts of nutritionally sound foods may be difficult even though well-balanced meals are available. Give the patient or meal preparer printed information that can make mealtime easier and more nutritious (Table 29-24).

Underweight patients with COPD need extra protein and calories. They may need 25 to 45 kcal/kg body weight and more than 1.5 g of protein/kg body weight to maintain their weight.[45] The patient with excessive malnutrition may need up to 2.5 g of protein/kg of body weight to restore muscle mass.

TABLE 29-24 NUTRITIONAL THERAPY

Maximizing Food Intake in COPD

Sometimes it is difficult for patients with COPD to consume adequate amounts of nutrients. Teach the patients to make mealtimes easier and more nutritious by increasing calories and protein without increasing the amount of food eaten.

- Eat high-calorie foods first.
- Limit liquids at mealtimes.
- Rest before meals.
- Try more frequent meals and snacks.
- Increase calories by adding margarine, butter, mayonnaise, sauces, gravies, and peanut butter to foods.
- Keep favorite foods and snacks on hand.
- Try cold foods, which can make you feel less full than hot foods.
- Keep ready-prepared meals available for times when you have increased shortness of breath.
- Eat larger meals when you are not as tired.
- Avoid foods that you know cause gas (e.g., cabbage, beans, cauliflower).
- Add skim milk powder (2 tbs) to regular milk (8 oz) to add protein and calories.
- Use milk or half-and-half instead of water when making soups, cereals, instant puddings, cocoa, or canned soups.
- Add grated cheese to sauces, vegetables, soups, and casseroles.
- Choose dessert recipes that contain egg (e.g., sponge cake, angel food cake, egg custard, bread pudding, rice pudding).

Source: Grodner M, Roth S, Walkingshaw B: *Nutritional foundations and clinical applications: a nursing approach,* ed 5, St Louis, 2011, Mosby.

A diet high in calories and protein, moderate in carbohydrate, and moderate to high in fat is recommended and can be divided into five or six small meals a day.[46] High-protein, high-calorie nutritional supplements can be offered between meals. Nonprotein calories should be divided evenly between fat and carbohydrate, but avoid overfeeding the patient (see Table 29-24).

The dietitian is the best resource to determine what combination of nutrients and what supplements are best for the patient.[44] (Nutritional supplements are discussed in Chapter 40.)

Surgical Therapy for COPD. Three different surgical procedures have been used in severe COPD. One type of surgery is *lung volume reduction surgery* (LVRS). The goal of this surgery is to reduce the size of the lungs by removing the most diseased lung tissue so the remaining healthy lung tissue can perform better. The rationale for LVRS is that reducing the size of the hyperinflated emphysematous lungs results in decreased airway obstruction and increased room for the remaining normal alveoli to expand and function. The procedure reduces lung volume and improves lung and chest wall mechanics. LVRS is being explored as a therapy that can be performed via a bronchoscope (BLVR).[16]

The second surgical procedure is *bullectomy.* This procedure is used for carefully selected patients with emphysematous COPD who have large bullae (larger than 1 cm). The bullae are usually resected via thoracoscope.

The third surgical procedure is *lung transplantation,* which benefits carefully selected patients with advanced COPD. Although single-lung transplant is the most commonly used technique because of a shortage of donors, bilateral transplantation can be performed. (Lung transplantation is discussed in Chapters 14 and 28.)

A novel approach is being explored for patients with emphysema. Airway bypass is a bronchoscopic procedure currently under evaluation to determine if creating small extra-anatomic openings between the diseased lung and the distal bronchi can reduce hyperinflation. This is a minimally invasive treatment that improves pulmonary function and reduces dyspnea by enabling trapped air to exit the lungs.[47]

NURSING MANAGEMENT CHRONIC OBSTRUCTIVE PULMONARY DISEASE

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a person with COPD are presented in Table 29-25.

NURSING DIAGNOSES

The nursing diagnoses for the patient with COPD may include, but are not limited to, those presented in Nursing Care Plan 29-2.

PLANNING

The overall goals are that the patient with COPD will have (1) prevention of disease progression, (2) ability to perform ADLs and improved exercise tolerance, (3) relief from symptoms, (4) no complications related to COPD, (5) knowledge and ability to implement a long-term treatment regimen, and (6) overall improved quality of life.

NURSING IMPLEMENTATION

HEALTH PROMOTION. The incidence of COPD would decrease dramatically if people would not begin smoking or would stop smoking. (Techniques to help patients stop smoking are discussed in Chapter 11 and Tables 11-4 to 11-6.) Avoiding or controlling exposure to occupational and environmental pollutants and irritants is another preventive measure to maintain healthy lungs. (These factors are discussed in the section on nursing management of lung cancer in Chapter 28.)

Counseling the patient in smoking cessation is vital, because it is the only way to slow the progression of COPD. As health care professionals, nurses who smoke should reevaluate their own smoking behavior and its relationship to their health. Nurses and other health care providers who smoke should be aware that the odor of smoke is obvious on their clothes, and it can be offensive or tempting to patients.

Early diagnosis and treatment of respiratory tract infections and exacerbations of COPD help prevent progression of the disease. People with COPD should avoid others who are sick, practice good hand-washing techniques, take medications as prescribed, exercise regularly, and maintain a healthy weight. Influenza and pneumococcal pneumonia vaccines are recommended for patients with COPD.

Families with a history of COPD, as well as AAT deficiency, should be aware of the genetic nature of the disease. These individuals should consult a pulmonologist about regular spirometry screening even though they do not have symptoms. Genetic counseling is appropriate for the patient with AAT deficiency who is planning to have children.

ACUTE INTERVENTION. The patient with COPD requires acute intervention for complications such as exacerbations of COPD, pneumonia, cor pulmonale, and acute respiratory failure. (The nursing care for these conditions is discussed in Chapters 28 and 68.) Once the crisis in these situations has been resolved, assess the degree and severity of the underlying respiratory problem. The information obtained will help in planning the nursing care.

TABLE 29-25 NURSING ASSESSMENT

Chronic Obstructive Pulmonary Disease

Subjective Data

Important Health Information

Past health history: Long-term exposure to chemical pollutants, respiratory irritants, occupational fumes, dust; recurrent respiratory tract infections; previous hospitalizations

Medications: Use of O_2 and duration of O_2 use, bronchodilators, corticosteroids, antibiotics, anticholinergics, OTC drugs, herbs, medications purchased outside United States

Functional Health Patterns

Health perception–health management: Smoking (pack-years, including passive smoking, willingness to stop smoking, and previous attempts); family history of respiratory disease (especially α_1-antitrypsin deficiency)

Nutritional-metabolic: Anorexia, weight loss or gain

Activity-exercise: Increasing dyspnea and/or increase in sputum volume or purulence (to detect exacerbation); fatigue, ability to perform ADLs; swelling of feet; progressive dyspnea, especially on exertion; ability to walk up one flight of stairs without stopping; wheezing; recurrent cough; sputum production (especially in the morning); orthopnea

Elimination: Constipation, gas, bloating

Sleep-rest: Insomnia; sitting up position for sleeping, paroxysmal nocturnal dyspnea

Cognitive-perceptual: Headache, chest or abdominal soreness

Coping–stress tolerance: Anxiety, depression

Objective Data

General

Debilitation, restlessness, assumption of upright position

Integumentary

Cyanosis (bronchitis), pallor or ruddy color, poor skin turgor, thin skin, digital clubbing, easy bruising; peripheral edema (cor pulmonale)

Respiratory

Rapid, shallow breathing; inability to speak; prolonged expiratory phase; pursed-lip breathing; wheezing; rhonchi, crackles, diminished or bronchial breath sounds; ↓ chest excursion and diaphragm movement; use of accessory muscles; hyperresonant or dull chest sounds on percussion

Cardiovascular

Tachycardia, dysrhythmias, jugular venous distention, distant heart tones, right-sided S_3 (cor pulmonale), edema (especially in feet)

Gastrointestinal

Ascites, hepatomegaly (cor pulmonale)

Musculoskeletal

Muscle atrophy, ↑ anteroposterior diameter (barrel chest)

Possible Diagnostic Findings

Abnormal ABGs (compensated respiratory acidosis, ↓ PaO_2 or SaO_2, ↑ $PaCO_2$), polycythemia, pulmonary function tests showing expiratory airflow obstruction (e.g., low FEV_1, low FEV_1/FVC, large RV), chest x-ray showing flattened diaphragm and hyperinflation or infiltrates

ABGs, Arterial blood gases; *FEV_1,* forced expiratory volume in 1 sec; *FVC,* forced vital capacity; *RV,* residual volume.

AMBULATORY AND HOME CARE. By far the most important aspect in the long-term care of the patient with COPD is teaching. (A patient and caregiver teaching guide is presented in Table 29-26.)

Pulmonary Rehabilitation. Pulmonary rehabilitation (PR) is an evidence-based intervention that includes many disciplines working together to individualize treatment of the symptomatic COPD patient. PR is designed to reduce symptoms and improve quality of life. PR is an effective intervention to improve exercise capacity and decrease hospitalizations, anxiety, and depression.[48,49] PR should no longer be viewed as a "last ditch" effort for patients with severe COPD.

PR can be done in an inpatient or outpatient setting or in the home. Components of PR vary, but usually include exercise training, smoking cessation, nutrition counseling, and education. A mandatory component of any PR program is exercise that focuses on the muscles used in ambulation, but upper limb exercises may be included also. Smoking cessation is critical to the patient's success. Some rehabilitation programs do not accept patients who are current smokers and not committed to quitting. Physical therapists or nurses who have experience in pulmonary care are often responsible for the management of pulmonary rehabilitation centers. A large part of your role is to teach patients self-management of their disease.

The minimum length of an effective program is 6 weeks with many insurance plans paying for it, but the longer the program, the more effective the results. Other important topics include health promotion, psychologic counseling, and vocational rehabilitation. One benefit of group PR appears to be the development of social relationships and support from peers and health care providers that boost patient's' self-confidence, coping, and motivation for self-care.[50]

PR groups may be inaccessible to many because of cost, disability, transportation, or geographic location. One alternative program uses the Internet to deliver daily motivational messages that are linked with individualized walking goals and feedback related to pedometer use.[51] Another program uses telehealth for homebound older adults with COPD with daily objective measures of health (e.g., weight, O_2 saturation). This information is received centrally by a nurse who calls back the patient for further evaluation if parameters are abnormal.[52]

Activity Considerations. Exercise training leads to energy conservation, which is an important component in COPD rehabilitation. The patient with severe COPD typically uses upper thoracic and neck muscles to breathe rather than the diaphragm. Thus the patient has difficulty performing upper-extremity

INFORMATICS IN PRACTICE

Texting for Chronic Obstructive Pulmonary Disease (COPD) Patients

- Sometimes patients with COPD or those requiring O_2 therapy experience difficulty speaking because of shortness of breath.
- Encourage your patient to use typed messages displayed on a monitor to communicate.
- Texting and instant messaging family and friends are good alternatives to having phone conversations.

NURSING CARE PLAN 29-2

Patient With Chronic Obstructive Pulmonary Disease

NURSING DIAGNOSIS **Ineffective breathing pattern** *related to* alveolar hypoventilation, anxiety, chest wall alterations, and hyperventilation *as evidenced by* assumption of three-point position, dyspnea, increased anteroposterior diameter of chest, nasal flaring, orthopnea, prolonged expiration, pursed-lip breathing, use of accessory muscles to breathe

PATIENT GOALS
1. Returns to baseline respiratory function
2. Demonstrates an effective rate, rhythm, and depth of respirations

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Respiratory Status: Ventilation	***Ventilation Assistance***
• Respiratory rate _____ • Respiratory rhythm _____ • Depth of inspiration _____ • Pulmonary function tests _____ **Measurement Scale** 1 = Severe deviation from normal range 2 = Substantial deviation from normal range 3 = Moderate deviation from normal range 4 = Mild deviation from normal range 5 = No deviation from normal range	• Monitor respiratory and oxygenation status *to assess need for intervention.* • Auscultate breath sounds, noting areas of decreased or absent ventilation and presence of adventitious sounds *to obtain ongoing data on patient's response to therapy.* • Encourage slow, deep breathing; turning; and coughing *to promote effective breathing techniques and secretion mobilization.* • Administer medications (e.g., bronchodilators and inhalers) that promote airway patency and gas exchange. • Position to minimize respiratory efforts (e.g., elevate head of the bed and provide overbed table for patient to lean on) *to save energy for breathing.* • Monitor for respiratory muscle fatigue *to determine a need for ventilatory assistance.* • Initiate a program of respiratory muscle strength and/or endurance training *to establish effective breathing patterns and techniques.*
• Accessory muscle use _____ • Pursed-lip breathing _____ • Orthopnea _____ • Impaired expiration _____ **Measurement Scale** 1 = Severe 2 = Substantial 3 = Moderate 4 = Mild 5 = None	

NURSING DIAGNOSIS **Ineffective airway clearance** *related to* expiratory airflow obstruction, ineffective cough, decreased airway humidity, and tenacious secretions *as evidenced by* ineffective or absent cough, presence of abnormal breath sounds, or absence of breath sounds

PATIENT GOALS
1. Maintains clear airway by effectively coughing
2. Experiences clear breath sounds

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Respiratory Status: Airway Patency	***Cough Enhancement***
• Adventitious breath sounds _____ • Anxiety _____ • Gasping _____ • Choking _____ **Measurement Scale** 1 = Severe 2 = Substantial 3 = Moderate 4 = Mild 5 = None	• Assist patient to sitting position with head slightly flexed, shoulders relaxed, and knees flexed *to allow for adequate chest expansion.* • Instruct patient to inhale deeply, bend forward slightly, and perform three or four huffs (against an open glottis) *to prevent airway collapse during exhalation.*† • Instruct patient to inhale deeply several times, exhale slowly, and cough at the end of exhalation *to loosen secretions before coughing.* • Instruct the patient to follow coughing with several maximal inhalation breaths *to reoxygenate the lungs.* ***Airway Management*** • Encourage slow, deep breathing; turning; and coughing *to mobilize pulmonary secretions.* • Position patient *to maximize ventilation potential.* • Regulate fluid intake to optimize fluid balance *to liquefy secretions for easier expectoration.* • Perform endotracheal or nasotracheal suctioning as appropriate *to clear the airway.* • Administer bronchodilators and use airway clearance devices *to facilitate clearance of retained secretions and increase ease of breathing.*

NURSING DIAGNOSIS **Impaired gas exchange** *related to* alveolar hypoventilation *as evidenced by* headache on awakening, $PaCO_2$ ≥45 mm Hg, PaO_2 <60 mm Hg, or SaO_2 <90% at rest

PATIENT GOALS
1. Returns to baseline respiratory function
2. $PaCO_2$ and PaO_2 return to levels normal for patient

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Respiratory Status: Gas Exchange	***Oxygen Therapy***
• PaO_2 _____ • $PaCO_2$ _____ • Arterial pH _____ • Chest x-ray findings _____ **Measurement Scale** 1 = Severe deviation from normal range 2 = Substantial deviation from normal range 3 = Moderate deviation from normal range 4 = Mild deviation from normal range 5 = No deviation from normal range	• Administer supplemental O_2 as ordered. • Set up O_2 equipment and administer through a heated, humidified system to provide moist O_2. • Periodically check O_2 delivery device *to ensure that the prescribed concentration is being delivered.* • Monitor the effectiveness of O_2 therapy (e.g., pulse oximetry, ABGs) *to evaluate patient response to therapy.* • Observe for signs of O_2-induced hypoventilation *because this occurs with CO_2 narcosis.* • Instruct patient and family about use of O_2 at home *to promote safe long-term O_2 therapy.*

*Nursing diagnoses listed in order of priority.
†Guidelines for effective huff coughing are presented in Table 29-23.

TABLE 29-26 PATIENT & CAREGIVER TEACHING GUIDE

Chronic Obstructive Pulmonary Disease

Include the following information in the teaching plan to assist the patient and caregiver to improve quality of life through teaching and promotion of lifestyle practices that support successful living with chronic obstructive pulmonary disease (COPD).

Teaching Topic	Resources
Overall Guide	*Patient Guide: What You Can Do About a Lung Disease Called COPD* (Global Initiative for Lung Disease). Retrieved from *www.goldcopd.org/uploads/users/files/GOLD_Patient_RevJan10.pdf*. (Also available in other languages.)
What Is COPD?	
• Basic anatomy and physiology of lung • Basic pathophysiology of COPD • Signs and symptoms of COPD, exacerbation, cold, flu, pneumonia • Tests to assess breathing	*COPD Statement: Patient Education Section* (American Thoracic Society [ATS]). Retrieved from *www.thoracic.org*. (Also available in Spanish.) *How Lungs Work* (American Lung Association [ALA]). Available under "Your Lungs" at *www.lung.org/your-lungs*.
Breathing and Airway Clearance Exercises	
• Pursed-lip breathing • Airway clearance technique—huff cough	See Table 29-13. See Table 29-23.
Energy Conservation Techniques	
• Daily activities (e.g., waking up, bathing, grooming, shopping, traveling)	Consult with physical therapist and occupational therapist. *COPD: Lifestyle Management* (National Jewish Health). Retrieved from *www.nationaljewish.org/healthinfo/conditions/copd-chronic-obstructive-pulmonary-disease/lifestyle-management*.
Medications	
Types (include mechanism of action and types of devices) • Methylxanthines • β_2-Adrenergic agonists • Corticosteroids • Anticholinergics • Antibiotics • Other medications Establishing medication schedule	*COPD Statement: Patient Education Section: Medications and Other Treatments OR Patient Information Series: Medicines to Treat COPD* (ATS). Retrieved from *www.thoracic.org*. OR *COPD Medicines* (ALA). Retrieved from *www.lungusa.org*. OR *COPD Medications* (National Jewish Health). Search "COPD medications." Also has link to medication chart to take to provider. Retrieved from *www.nationaljewish.org/healthinfo*.
Correct Use of Inhalers, Spacer, and Nebulizer	See Figs. 29-5 to 29-7. See Tables 29-8 to 29-10. See Table 29-15 for links to videos on medication devices.
Home Oxygen	
• Explanation of rationale for use • Guide for home O_2 use and equipment	*Oxygen Therapy* (National Jewish Health). Retrieved from *www.nationaljewish.org/healthinfo/medications/lung-diseases/treatments/oxygen-therapy*. *Traveling With Oxygen* (American College of Chest Physicians). Retrieved from *www.chestnet.org/accp/patient-guides/traveling-oxygen*.
Psychosocial/Emotional Issues	
Concerns about interpersonal relationships • Dependency • Intimacy Problems with emotions • Depression, anxiety, panic Treatment decisions • Support and rehabilitation groups End-of-life issues	Open discussion (sharing with patient, significant other, and family). *Living With COPD: Get Social Support* (ALA help line, Better Breathers Club, and printed materials). Retrieved from *www.lung.org/lung-disease/copd/living-with-copd/get-social-support.html*. *Questions About Pulmonary Rehabilitation* (ATS). Retrieved from *patients.thoracic.org/materials/index.php*. (Available in English and Spanish.)
COPD Management Plan	
• Focus on self-management • Need to report changes • Cause of flare-ups or exacerbation • Recognition of signs and symptoms of respiratory infection, heart failure • Reduce risk factors, especially smoking cessation • Exercise program of walking and arm strengthening • Yearly follow-up	Nurse and patient develop and write up COPD management plan that meets individual needs. *COPD Management Tools* (ALA). Retrieved from *www.lung.org/lung-disease/copd/living-with-copd/copd-management-tools.html*.
Healthy Nutrition	
• Strategies to lose weight (if overweight) • Strategies to gain weight (if underweight)	Consultation with dietitian. See Table 29-24. *Nutrition* (ALA). Retrieved from *www.lung.org/lung-disease/copd/living-with-copd/nutrition.html*.

activities, particularly those that require raising the arm above the head. Exercise training of the upper extremities may improve muscle function and help to reduce dyspnea.

Frequently the patient has already adapted alternative energy-saving practices for ADLs. Alternative methods of hair care, shaving, showering, and reaching may need to be explored. An occupational therapist may help with ideas in these areas. Assuming a tripod posture (elbows supported on a table, chest in fixed position) and placing a mirror on the table while using an electric razor or hair dryer conserve much more energy than when the patient stands in front of a mirror to shave or blow-dry hair.

If the patient uses home O_2 therapy, O_2 should be used during activities of hygiene because these are energy consuming. Encourage the patient to make a schedule and plan daily and weekly activities to leave plenty of time for rest periods. The patient should also try to sit as much as possible when performing activities. Another energy-saving tip is to exhale when

pushing, pulling, or exerting effort during an activity and inhale during rest.

Regular physical exercise is important for patients with COPD. To ensure long-term adherence, the exercise must be individualized and easy to perform. Walking or other endurance exercises (e.g., cycling) combined with strength training are likely the best interventions to strengthen muscles and improve the patient's endurance. Teach the patient coordinated walking with slow, pursed-lip breathing—breathing in through the nose while taking one step, then breathing out through pursed lips while taking two to four steps.

When patients are home, the adherence to exercise may wane. A simple but effective way to sustain optimal exercise intensity with positive outcomes (i.e., no exacerbations) in home settings is to use a metronome. The level of exercise intensity is established on a treadmill by the appropriate health care provider using a metronome. The patient then uses the clip-on metronome to maintain the rate and intensity of walking (instead of trying to walk a certain amount of time).[48]

At times patients may need rest periods and sit or lean against an object such as a tree or post. The patient may need to ambulate using O_2. Walk with the patient, giving verbal reminders when necessary regarding breathing (inhalation and exhalation) and steps. Walking with the patient helps decrease anxiety and helps maintain a slow pace. It also enables you to observe the patient's actions and physiologic responses to the activity. Many patients with moderate or severe COPD are anxious and fearful of walking or performing exercise. These patients and their caregivers require support while they build the confidence they need to walk or to perform daily exercises.

In many situations PR programs are not an option, and patients are advised to exercise on their own. If possible, arrange a one-time consult with the physical therapist to outline an exercise program for the patient that can be followed at home and that you can reinforce in the outpatient setting. Encourage the patient to walk 15 to 20 minutes a day at least three times a week with gradual increases. Severely disabled patients can begin at a slow pace by walking for 2 to 5 minutes three times a day and slowly building up to 20 minutes a day, if possible.

Some patients benefit from using their β_2-adrenergic agonist approximately 10 minutes before exercise. Parameters that may be monitored in the patient with mild COPD are resting pulse and pulse rate after walking. Pulse rate after walking should not exceed 75% to 80% of the maximum heart rate (maximum heart rate is age in years subtracted from 220). In some patients, exercise is limited by dyspnea and the limitation in breathing, rather than increased heart rate. Thus it is better to use the patient's perceived sense of dyspnea as an indication of exercise tolerance.

Tell the patient that shortness of breath will probably increase during exercise (as it does for a healthy individual) but that the activity is not being overdone if this increased shortness of breath returns to baseline within 5 minutes after cessation of exercise. Instruct the patient to wait 5 minutes after completion of exercise before using the β_2-adrenergic agonist to allow a chance to recover. During this time, slow, pursed-lip breathing should be used. If it takes longer than 5 minutes to return to baseline, the patient most likely has overdone it and should proceed at a slower pace during the next exercise period. The patient may benefit from keeping a diary or log of the exercise program. The diary can help provide a realistic evaluation of the patient's progress. In addition, the diary can help motivate the patient and add to the patient's sense of accomplishment. Stationary cycling can also be used either alone or with walking. Cycles and treadmills are particularly good when weather prevents walking outside.

Fatigue, sleep disturbances, and dyspnea are common complaints of patients with COPD. Of these symptoms, dyspnea appears to be the only one that affects the patient's ability to carry out daily activities. Therefore you and other health team members should focus your interventions on improving dyspnea, which would then improve the patient's functional performance. Nutritional counseling (discussed previously) is integral to a PR program. Teaching is an important component of PR and should include information on self-management and prevention and treatment of exacerbations (see Table 29-26).

Sexuality and Sexual Activity. Modifying but not abstaining from sexual activity can also contribute to a healthy psychologic well-being. Most patients with COPD are older. Assess and reflect on your own attitudes and feelings about sexuality, sexual functioning, and aging before exploring sexual issues with the older COPD patient. First assess the patient's concerns related to sexuality and functioning. Ask open-ended questions to determine if the patient wants to discuss any of these concerns. You could ask, "How has your breathing problem affected how you see yourself as a woman or man?" Another question could be, "How does your shortness of breath affect your desire for intimacy with your partner?" These types of questions give the person an opening to discuss concerns. Much of the sexual performance issues experienced by the patient with COPD are changes related to aging, and if you are aware of these changes, you can teach the patient the "normalcy" of the changes.

Dyspnea, the predominant symptom in COPD, should not be a major problem with success in sexual functioning, except for those patients in severe stages. If the patient can walk up two flights of stairs or walk briskly, he or she likely has sufficient energy for sexual activity. Erectile dysfunction can occur with COPD as with many chronic diseases. Using an inhaled bronchodilator before sexual activity can help ventilation. The patient with COPD may also find these suggestions helpful: (1) plan sexual activity during the part of the day when breathing is best, which is usually late morning or early afternoon (plus older men often achieve an erection more easily in the morning); (2) use slow pursed-lip breathing; (3) refrain from sexual activity after eating or drinking alcohol; (4) choose less stressful positions during intercourse (missionary position for men is the worst); (5) use O_2 if prescribed; and (6) understand that cigarettes can increase male impotence. Often the patient has coexisting cardiac disease and should obtain advice from a health care provider related to appropriate levels of activity. These aspects of sexual activity require open communication between partners regarding their needs and expectations and the changes that may be necessary as the result of a chronic disease (e.g., changes in body image, role reversal).[53,54]

Sleep. Adequate sleep is extremely important to maintain quality of life and productivity. Patients with COPD have an increased prevalence of sleep disorders. The hyperinflation of the lungs and the reduction in ventilation can result in severe drops in O_2 saturation (down to 60% or less) during sleep. This leads to a strain on the heart. In addition, hypercapnia may develop with more frequent awakening. The net result is sleeping poorly and awakening unrefreshed and fatigued.

Current tobacco use, depression, and anxiety are all common in COPD and lead to more trouble sleeping. β_2-Agonists may

ETHICAL/LEGAL DILEMMAS

Advance Directives

Situation

L.H., a 79-year-old man with COPD, is in respiratory failure when he is admitted to the hospital. He is placed on a ventilator and responds occasionally by opening his eyes. His advance directives (ADs) were drawn up 5 years ago, and copies were given to his wife and health care provider at that time. The patient's wife brings the documents to the intensive care unit and tells you that the hospital must stop treating her husband and allow him to die as he requested. However, the patient's oldest son is threatening the hospital with a lawsuit if the staff does not provide full care to his father.

Ethical/Legal Points for Consideration

- A Living Will, one form of AD, permits individuals to state their own preferences and refusals should the individual become terminally ill or be in a situation where there is no hope of recovery, and the person is not able to speak for himself or herself.*
- The Durable Power Attorney for Health Care, another form of AD, permits individuals to identify a proxy to make health care decisions in the event the individual is incapacitated.
- AD laws vary from state to state concerning the need for witnesses and who the proxy is.
- Some families are deeply divided about decisions for their loved ones, and conflicts often arise when money and property are involved.
- Health care providers are obligated to follow the patient's ADs when a patient is no longer able to speak for himself or herself.
- In your scope of nursing practice, you need to (1) be informed about the decision-making laws and regulations in your state, (2) make AD documents available to patients, (3) teach patients and their families about ADs, (4) determine if all involved health care providers are aware of the existence of ADs, (5) assist the patient and the family in communicating with the health care providers when a "no code" order is requested, and (6) assist the conflicted family in obtaining appropriate counseling whenever necessary.

Discussion Questions

1. What should you do next with the information provided by L.H.'s wife?
2. How should you address the needs of each member of this family in L.H.'s plan of care?
3. What resources can you use to facilitate decision making in this situation?

*Advance directives are listed in Table 10-6.

cause restlessness and insomnia. Many patients with COPD have postnasal drip or nasal congestion that may cause coughing and wheezing at night. Nasal saline sprays or rinses before sleep and in the morning may help. If the patient is prescribed O_2 therapy, using it at night will decrease insomnia. If the patient is a restless sleeper, snores, stops breathing while asleep, and has a tendency to fall asleep during the day, the patient may need to be tested for sleep apnea[55] (see Chapter 8).

Psychosocial Considerations. Healthy coping is a challenge for the COPD patient and the family. People with COPD frequently have to deal with many lifestyle changes that may involve decreased ability to care for themselves, decreased energy for social activities, and loss or change in a job.

When a patient with COPD is first diagnosed or has complications that require hospitalization, expect a variety of emotional responses. Emotions frequently encountered include guilt, loneliness from social isolation, denial, and frustration from increased dependence. Guilt may result from the knowledge that the disease was caused largely by cigarette smoking. Many patients struggle with depression and anxiety. It is important to convey a sense of understanding and caring to the patient. The patient with COPD may benefit from stress management techniques (e.g., massage, muscle relaxation) and referral to a therapist[16] (see Chapter 7). Support groups at local American Lung Association chapters (such as the Better Breathers Club), hospitals, and clinics can also be helpful.

Patients frequently ask whether moving to a warmer or drier climate will help. In general, such a move is not significantly beneficial. Discourage moves to places with an elevation of 4000 ft or more because of the lower partial pressure of O_2 found in the air at higher elevations. A disadvantage of moving may be that a person leaves a job, friends, and familiar environment, which could be psychologically stressful. Any advantage gained from a different climate may be outweighed by the psychologic effects of the move.

Patients need to know that symptoms can be managed, but COPD cannot be cured. End-of-life issues and advance directives are important topics for discussion in the terminal stages of COPD. However, this may be difficult for the patient and family to consider because of the uncertainty of the disease. (Palliative care and end-of-life care are discussed in Chapter 10.)

EVALUATION

The expected outcomes for the patient with COPD are presented in Nursing Care Plan 29-2.

CYSTIC FIBROSIS

Cystic fibrosis (CF) is an autosomal recessive, multisystem disease characterized by altered transport of sodium and chloride ions in and out of epithelial cells. This defect primarily affects the lungs, gastrointestinal tract (pancreas and biliary tract), and reproductive tract.[56]

CF was first described in 1938 when autopsies of young children revealed multiple cysts in the pancreas, so the disease was called "cystic fibrosis of the pancreas."[57] Once advances in care allowed children to live into later childhood, the lung disease became the more significant problem.

Approximately 30,000 children and adults in the United States have CF. About 10 million (about 1 in every 31) Americans are carriers of the CF gene but do not have the disease. Of the CF patients in the Cystic Fibrosis Patient Registry, more than 48% are 18 years of age or older. The first signs and symptoms typically occur in children, but some patients are not diagnosed until they are adults; some live to over 80 years old. The severity and progression of the disease vary. With early diagnosis and improvements in therapy, the prognosis of patients with CF has significantly improved. The median predicted survival was 16 years in 1970, but has increased to more than 37 years.[58] Nurses who work in adult care settings increasingly manage patients with CF.

Etiology and Pathophysiology

Genetic Link

CF is an autosomal recessive disorder (see Figs. 13-4 and 13-5 and the Genetics in Clinical Practice box). The CF gene is located on chromosome 7 and produces a protein called CF transmembrane regulator (CFTR). The CFTR protein localizes to the epithelial surface of the airways, gastrointestinal tract, and ducts of the liver, pancreas, and sweat glands. CFTR regulates sodium and chloride channels. Mutations in the *CFTR*

GENETICS IN CLINICAL PRACTICE

Cystic Fibrosis (CF)

Genetic Basis

- Autosomal recessive disorder.
- Caused by mutations in CF transmembrane regulator *(CFTR)* gene on chromosome 7.
- Many different mutations of *CFTR* gene have been identified.
- *CFTR* gene provides instructions for making protein that controls the channel that transports sodium and chloride.
- Mutations in the *CFTR* gene disrupt the function of the channels, preventing them from regulating the flow of sodium, chloride, and water across cell membranes.

Incidence

- In the United States 1 in 3000 white births.
- Less common in other ethnic populations (1 in 17,000 African Americans and 1 in 31,000 Asian Americans).
- One in 20-25 whites are carriers of the gene.
- If both parents carry the affected gene, there is a 25% chance each offspring will have the disease (see Figs. 13-4 and 13-5).

Genetic Testing

- Blood-based DNA testing is available for disease and carrier states.
- All 50 states have passed legislation requiring that all newborns be screened for CF.
- Testing is usually done in children if CF is suspected or if parents are possible carriers.
- In parents who are known carriers, amniocentesis or chorionic villus sampling in pregnant women may be useful for prenatal testing.

Clinical Implications

- CF is the most common autosomal recessive disease in whites.
- CF has a wide range of clinical expression of disease.
- CF requires long-term medical management.
- Advances in medical care have improved life expectancy.
- Most people who have a child with CF are not aware of a family history of disease.
- CF screening should be offered to all individuals of reproductive age regardless of family history.

gene alter this protein in such a way that the channels are blocked. As a result, cells that line the passageways of the lungs, pancreas, intestines, and other organs produce secretions that are low in sodium chloride content (thus low in water content), making mucus abnormally thick and sticky (Fig. 29-16). This mucus fills (plugs up) the glands in these organs and causes the glands to atrophy, ultimately resulting in organ failure. The high concentrations of sodium and chloride in the sweat of the patient with CF result from decreased chloride reabsorption in the sweat duct.[59]

In the respiratory system, both the upper and lower respiratory tracts can be affected. Upper respiratory tract manifestations may include chronic sinusitis and nasal polyposis. The hallmark of respiratory involvement in CF is its effect on the airways. The disease progresses from being a disease of the small airways *(chronic bronchiolitis)* to involvement of the larger airways, and finally causes destruction of lung tissue. The mucus becomes dehydrated and tenacious due to the defect in the chloride secretion and excess sodium absorption. Cilia motility is decreased, thus allowing mucus to adhere to the airways. The bronchioles become obstructed with thick mucus, leading to air trapping and hyperinflation of the lungs.

CF is characterized by chronic airway infection that cannot be eradicated. Organisms commonly cultured from the sputum

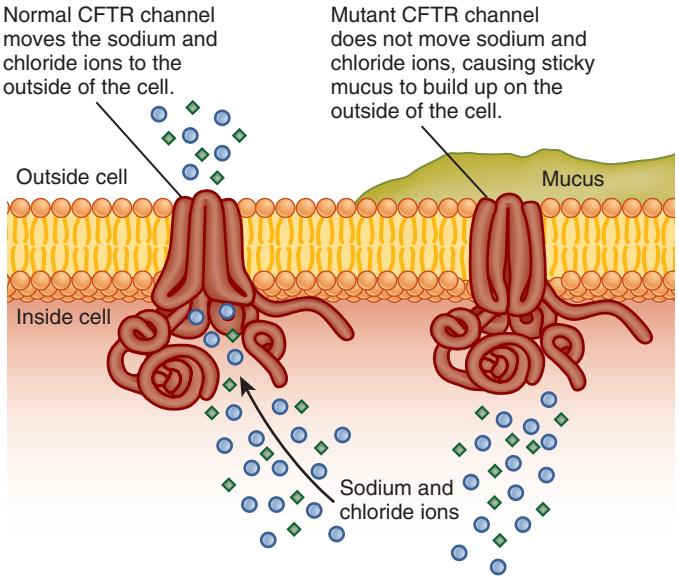

FIG. 29-16 People with cystic fibrosis inherit a defective gene on chromosome 7 called cystic fibrosis transmembrane regulator *(CFTR).* The protein produced by this gene normally helps sodium and chloride move in and out of cells. If the protein does not work correctly, then the movement of sodium and chloride is blocked and an abnormally thick sticky mucus is produced on the outside of the cell.

of a patient with CF are *Staphylococcus aureus, Haemophilus influenzae,* and *Pseudomonas aeruginosa,* and less commonly but more seriously, *Burkholderia cepacia. Pseudomonas* is by far the most common organism. Antibiotic resistance often develops. Pulmonary inflammation may precede the chronic infection and can cause a decrease in respiratory function. Inflammatory mediators (e.g., interleukins, oxidants, proteases released by neutrophils) are increased and contribute to the progression of lung disease.

Lung disorders that initially occur are chronic bronchiolitis and bronchitis. However, after months or years, changes in the bronchial walls lead to bronchiectasis (Fig. 29-17). Over a long period, pulmonary vascular remodeling occurs because of local hypoxia and arteriolar vasoconstriction; pulmonary hypertension and cor pulmonale result in the later phases of the disease. Blebs and large cysts in the lung are also severe manifestations of lung destruction, and pneumothorax may develop. Other pulmonary complications include hemoptysis caused by erosion of enlarged pulmonary arteries. Hemoptysis may range from scant streaking to major bleeding, which can sometimes be fatal.

The sweat glands of CF patients secrete normal volumes of sweat, but sodium chloride cannot be absorbed from sweat as it moves through the sweat duct. Therefore four times the normal amount of sodium and chloride is excreted in sweat. This abnormality usually does not affect the person's general health, but it is the main diagnostic test for CF (explained later in the diagnostic studies section).

Pancreatic insufficiency is caused primarily by mucous plugging of the pancreatic exocrine ducts, which results in atrophy of the gland and progressive fibrotic cyst formation. The pancreas's exocrine function may be completely lost. Because of the exocrine dysfunction, pancreatic enzymes such as lipase, amylase, and the proteases (trypsin, chemotrypsin) are not made in sufficient amounts to allow for absorption of nutrients.

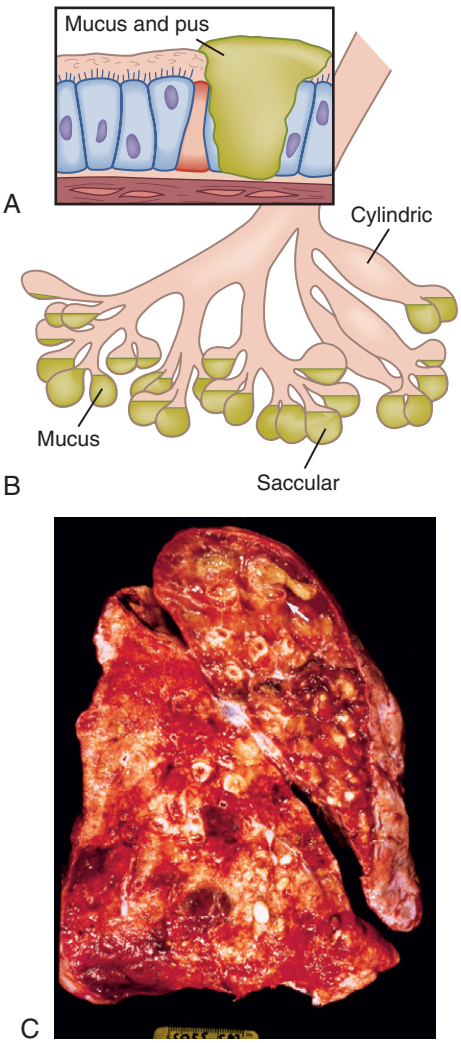

FIG. 29-17 Pathologic changes in bronchiectasis. **A,** Longitudinal section of bronchial wall where chronic infection has caused damage. **B,** Collection of purulent material in dilated bronchioles, leading to persistent infection. **C,** Bronchiectasis in a patient with cystic fibrosis who underwent lung transplantation. Cut surfaces of lung show markedly distended peripheral bronchi filled with mucopurulent secretions.

Malabsorption of fat, protein, and fat-soluble vitamins (A, D, E, and K) occurs. Fat malabsorption results in steatorrhea, and protein malabsorption results in failure to grow and gain weight.

CF-related diabetes mellitus (CFRD) is thought to be related to destruction of islet cells in the pancreas.[58] CFRD is a unique type of diabetes with characteristics of both type 1 and type 2 diabetes. The pancreas in people with CF produces insulin, but too late to fully respond to carbohydrate intake.

Other common disorders that develop in CF include osteopenia and osteoporosis. These disorders are related to malnutrition, malabsorption of vitamin D, insufficient testosterone levels, chronically elevated inflammatory cytokines, and the direct effect of the *CFTR* mutation on the development of bone.

Individuals with CF often have other gastrointestinal problems, including abdominal pain, which may be caused by conditions such as GERD. The liver and gallbladder can be damaged by mucus deposits. The liver enzymes may become chronically elevated, with cirrhosis developing over time. Gallstones, pancreatitis, and portal hypertension can also occur.[56] Distal intestinal obstruction syndrome (DIOS) results from intermittent obstruction commonly occurring in the terminal ileum. It is usually caused by thickened, dehydrated stool and mucus. The patient may appear to have a small bowel obstruction. DIOS develops because of chronic malabsorption related to exocrine dysfunction, nonadherence to enzyme supplementation, dehydration, swallowing of mucus, and use of opioids.

Clinical Manifestations

The clinical manifestations of CF vary depending on the severity of the disease. Carriers are not affected by the mutation. The disease severity may vary greatly, both within families and among different families.

The median age of diagnosis of CF is 5 months of age.[58] An initial finding of meconium ileus in the newborn infant prompts the diagnosis in 20% of people with CF. Other signs that suggest a CF diagnosis are acute or persistent respiratory symptoms (wheezing, coughing, frequent pneumonia), failure to thrive or malnutrition, steatorrhea (large, oily, frequent bowel movements), and family history. Without treatment, a large, protuberant abdomen may develop with an emaciated appearance of the extremities. A diagnosis may also be prompted by findings of bronchiectasis.

One of the most common symptoms of CF in the adult is frequent cough. With time, the cough becomes persistent and produces viscous, purulent, often yellow or greenish sputum. Although the most common bacteria in the airways in childhood is *S. aureus*, as the patient ages, the prevalence of *Pseudomonas* organisms increases. Other respiratory problems are recurring lung infections such as bronchiolitis, bronchitis, and pneumonia. As the disease progresses, periods of clinical stability are interrupted by exacerbations characterized by increased cough, weight loss, increased sputum, and decreased pulmonary function. Over time the exacerbations become more frequent, bronchiectasis worsens, and the recovery of lost lung function is less complete, which may ultimately lead to respiratory failure.

If the patient with CF develops DIOS, he or she may have right lower quadrant pain (the area of the ileocecal valve), loss of appetite, nausea, emesis, and often a palpable mass. Insufficient pancreatic enzyme release causes the typical pattern of protein and fat malabsorption with a person being thin with a low body mass index (BMI) and frequent, bulky, foul-smelling stools.

Both males and females have delayed puberty. Nearly all men with CF have reproductive issues because their vas deferens fails to develop in utero, so there is no transport of sperm from storage in the testes to the penile urethra. However, they make sperm normally, and with assisted reproductive technology are capable of fathering a child.

Some women with CF have difficulty conceiving; the cervical mucus is thought to be thickened. During exacerbations, menstrual irregularities and secondary amenorrhea are common. A majority of women with CF are able to become pregnant. Most pregnancies result in viable infants with mothers who are able to breastfeed normally.[60]

Complications

Complications in CF include CFRD, bone disease, sinus disease, and liver disease. Pneumothorax, a relatively uncommon but serious complication, is caused by the formation of bullae and blebs. A small amount of blood in sputum is common in the

CF patient because of chronic lung infection. Massive hemoptysis, which is relatively uncommon, can be life threatening.[58] With advanced lung disease, digital clubbing occurs. Respiratory failure and cor pulmonale caused by pulmonary hypertension are late complications of CF.

Diagnostic Studies

The diagnostic criteria for CF include a combination of clinical presentation, family history, laboratory testing, and genetic testing. The sweat chloride test is considered the gold standard for the diagnosis of CF. However, the diagnosis is not clear-cut in all individuals, especially in adults. The sweat chloride test is performed with the pilocarpine iontophoresis method. Pilocarpine is placed on the skin and carried by a small electric current to stimulate sweat production. This part of the process takes about 5 minutes, and the patient feels a slight tingling or warmth. The sweat is collected on filter paper or gauze and then analyzed for sweat chloride concentrations. The test takes approximately 1 hour. Sweat chloride values above 60 mmol/L are considered positive for the diagnosis of CF. Usually a second sweat chloride test is obtained at the same time (one test in each arm) to confirm the diagnosis.

A genetic test is often used if the results from a sweat chloride test are unclear. A blood sample or cells taken inside the cheek (buccal smear) are sent to a laboratory that specializes in genetic testing. Most laboratories test for only the most common mutations of the CF gene. Because more than 1700 mutations cause CF, screening for all mutations is difficult and is performed in a specialty laboratory.

Collaborative Care

A multidisciplinary team should be involved in the care of a patient with CF. The Cystic Fibrosis Foundation provides funding for and accredits more than 100 CF care centers nationwide. The high quality of specialized care available throughout the care center network has led to the improved length and quality of life for people with CF. These care centers offer the best care, treatments, and support for those with CF (see *www.cff.org/LivingWithCF/CareCenterNetwork/CFFoundation-accreditedCareCenters*). The teams at these care centers include a nurse, physician, respiratory therapist, physical therapist, dietitian, social worker, and often a nurse practitioner.

Management of pulmonary problems in CF aims at relieving airway obstruction and controlling infection. Drainage of thick bronchial mucus is assisted by aerosol and nebulization treatments of medications used to dilate the airways, liquefy mucus, and facilitate clearance. The abnormal viscosity of CF secretions is increased by concentrated deoxyribonucleic acid (DNA) from neutrophils involved in chronic infection. Agents that degrade the DNA in CF sputum (e.g., dornase alfa [Pulmozyme]) increase airflow and reduce the number of acute pulmonary exacerbations. Inhaled hypertonic saline (7%) is effective in clearing mucus and also decreases the frequency of exacerbations. Hypertonic saline is safe, but some patients require concomitant bronchodilators to avoid bronchospasm. Bronchodilators (e.g., β_2-adrenergic agonists) may be used to control bronchospasm, but the long-term benefit is not proven.

Airway clearance techniques are critical, since the normal ciliary motion in CF airways is impaired. CPT (including postural drainage with percussion and vibration) and high-frequency chest wall oscillation loosen mucus. Clearance is achieved by the specialized expiratory techniques aimed at using airflow to remove the loosened secretions. Examples of clearance techniques and devices are PEP devices (e.g., Flutter device [see eFig. 29-2], Acapella [see Fig. 29-15]), breathing exercises (autogenic drainage [see *http://hospitals.unm.edu/cf/autogenic_drainage.shtml*]), pursed-lip breathing (see Table 29-13), and huff coughing (see Table 29-23). Individuals with CF may prefer a certain technique or device that works well for them in a daily routine. No clear evidence exists that any of the airway clearance techniques are superior to the others (see Table 29-18). (Airway clearance techniques are discussed on p. 594.)

More than 95% of patients with CF die of complications from lung infection.[60] Standard treatment of infections includes antibiotics for exacerbations and may include chronic suppressive therapy in conjunction with airway clearance. The use of antibiotics should be carefully guided by sputum culture results. Early intervention with antibiotics is useful, and long courses of antibiotics are the usual treatment. Prolonged high-dose therapy may be necessary because many drugs are abnormally metabolized and rapidly excreted in the patient with CF. There is no evidence to support the chronic use of oral antibiotics in adults with CF.

Most patients have *Pseudomonas* infection, which can be difficult to treat because over time the organism develops resistance to antibiotics. It also has the ability to form a biofilm that must be penetrated to kill the organism. One commonly used antibiotic to treat patients who are chronically infected with *Pseudomonas* organisms is aerosolized tobramycin (TOBI) given every other month, every day, twice a day. This treatment regimen increases lung function and decreases the frequency of exacerbations. Oral agents commonly used for mild exacerbations (i.e., increased cough and sputum) are oral antibiotics such as a semisynthetic penicillin or trimethoprim/sulfamethoxazole (to treat *S. aureus*) or oral quinolones, especially ciprofloxacin (Cipro) (to treat *P. aeruginosa*). The quinolones are used judiciously because of the rapid development of resistant strains. More severe exacerbations require a 2- to 4-week course of IV antimicrobial therapy. Azithromycin, used chronically (longer than 6 months), decreases the frequency of pulmonary exacerbations in CF, especially in those infected with *Pseudomonas*. The effectiveness of this drug is probably related to its antiinflammatory effect.[61]

If home support and resources are adequate, the CF patient and caregiver may choose to continue IV antibiotic therapy at home.[62] The usual treatment is two antibiotics with different mechanisms of action (e.g., cephalosporin and an aminoglycoside). The patient with cor pulmonale or hypoxemia may require home O_2 therapy. (O_2 therapy is discussed on p. 589.) Patients with a large pneumothorax require chest tube drainage, perhaps repeatedly. Sclerosing of the pleural space or partial pleural stripping and pleural abrasion performed surgically may be indicated for recurrent episodes of pneumothorax. With massive hemoptysis, bronchial artery embolization is performed. CF has become a leading indication for lung transplantation.[58] (Lung transplants are discussed in Chapter 28.)

The management of pancreatic insufficiency includes pancreatic enzyme replacement of lipase, protease, and amylase (e.g., pancrelipase [Pancreaze, Creon, Ultresa, Viokase, Zenpep]) administered before each meal and snack. Adequate intake of fat, calories, protein, and vitamins is important. Fat-soluble vitamins (A, D, E, and K) must be supplemented, since they are malabsorbed. Use of caloric supplements improves nutritional

status. Added dietary salt is indicated whenever sweating is excessive, such as during hot weather, when fever is present, or from intense physical activity. Hyperglycemia may require insulin treatment.

If the patient develops DIOS with complete bowel obstruction, gastric decompression may be needed. This complication is most often managed medically. If DIOS does not resolve with medical treatment, surgery may be needed to prevent the development of ischemic bowel. Partial and uncomplicated episodes of DIOS are treated with ingestion of a balanced polyethylene glycol (PEG) electrolyte solution (MiraLax, GoLYTELY) used to hydrate bowel contents. In addition, water-soluble contrast enemas may be used.[50] Careful monitoring of bowel habits and patterns is essential for CF patients.

Ivacaftor (Kalydeco) is used to treat patients who have a specific *G551D* mutation in the *CFTR* gene. About 4% of those with CF, or roughly 1200 people, have the *G551D* mutation. Ivacaftor is effective only in patients with CF who have this mutation. It is not effective in patients with CF who have two copies of the *F508* mutation in the *CFTR* gene, which is the most common mutation that results in CF. If a patient's mutation status is not known, a CF mutation test should be done to determine whether the *G551D* mutation is present. Ivacaftor, rather than treating the effects of the basic chloride ion channel defect (e.g., pancreatic insufficiency), targets the function of the gene itself, assisting this mutation to open the chloride channel. This drug proves that it is possible to alter the function of a mutation. Further research is ongoing to develop a drug that targets a more common mutation.[63]

Aerobic exercise is effective in clearing the airways. Important needs to consider when planning an aerobic exercise program for the patient with CF are (1) meeting increased nutritional demands of exercise, (2) observing for dehydration, and (3) drinking large amounts of fluid and replacing salt losses.

There is a higher incidence of depression among individuals with CF than their unaffected peers. CF imposes a significant burden on the individual and family. Issues related to fertility, decreased life expectancy, costs of health care, and career choices may lead to depression.[58]

NURSING MANAGEMENT CYSTIC FIBROSIS

NURSING ASSESSMENT

Subjective and objective data that should be obtained from the patient with CF are presented in Table 29-27.

NURSING DIAGNOSES

Nursing diagnoses for the patient with CF may include, but are not limited to, the following:

- Ineffective airway clearance *related to* abundant, thick bronchial mucus, weakness, and fatigue
- Ineffective breathing pattern *related to* bronchoconstriction, anxiety, and airway obstruction
- Impaired gas exchange *related to* recurring lung infections
- Imbalanced nutrition: less than body requirements *related to* dietary intolerances, intestinal gas, and altered pancreatic enzyme production
- Ineffective coping *related to* multiple life stressors such as decreased life expectancy, cost of treatment, and limitation on career choices

TABLE 29-27 NURSING ASSESSMENT

Cystic Fibrosis

Subjective Data

Important Health Information

Past health history: Recurrent respiratory and sinus infections, persistent cough with excessive sputum production

Medications: Use of and compliance with bronchodilators, antibiotics, herbs

Functional Health Patterns

Health perception–health maintenance: Family history of cystic fibrosis; diagnosis of cystic fibrosis in childhood, genetic testing in offspring

Nutritional-metabolic: Dietary intolerances, voracious appetite, weight loss, heartburn

Elimination: Intestinal gas; large, frequent bowel movements, constipation

Activity-exercise: Fatigue, ↓ exercise tolerance, amount and type of exercise; dyspnea, cough, excessive mucus or sputum production, coughing up blood, airway clearance techniques

Cognitive-perceptual: Abdominal pain

Sexuality-reproductive: Delayed menarche, menstrual irregularities, problems conceiving or fathering a child

Coping–stress tolerance: Anxiety, depression, problems adapting to diagnosis

Objective Data

General

Restlessness; failure to thrive

Integumentary

Cyanosis (circumoral, nail bed), digital clubbing; salty skin

Eyes

Scleral icterus

Respiratory

Sinus difficulties; persistent runny nose; diminished breath sounds, sputum (thick, white or green, tenacious), hemoptysis, ↑ work of breathing, use of accessory muscles of respiration, barrel chest

Cardiovascular

Tachycardia

Gastrointestinal

Protuberant abdomen; abdominal distention; foul, fatty stools

Possible Diagnostic Findings

Abnormal ABGs and pulmonary function tests; abnormal sweat chloride test, chest x-ray, fecal fat analysis

ABGs, Arterial blood gases.

PLANNING

The overall goals are that the patient with CF will have (1) adequate airway clearance, (2) reduced risk factors associated with respiratory infections, (3) adequate nutritional support to maintain appropriate BMI, (4) ability to perform ADLs, (5) recognition and treatment of complications related to CF, and (6) active participation in planning and implementing a therapeutic regimen.

NURSING IMPLEMENTATION

Assist young adults in gaining independence by helping them assume responsibility for their care and for their vocational or school goals. An important issue to discuss is sexuality. Delayed or irregular menstruation is not uncommon. There may be

delayed development of secondary sex characteristics such as breasts in girls. The person with CF may use the illness to avoid certain events or relationships. Other crises and life transitions that must be dealt with in the young adult include building confidence and self-respect on the basis of achievements, persevering with employment goals, developing motivation to achieve, learning to cope with the treatment program, and adjusting to the need for dependence if health fails. Disclosing the CF diagnosis to friends, potential spouses, or employers may pose emotional and financial challenges.

The issue of marrying and having children is difficult. Genetic counseling may be an appropriate suggestion for the couple considering having children. Another concern is the uncertainty surrounding the shortened life span of the parent with CF. In addition, the parent's ability to care for the child must be taken into consideration.

Acute intervention for the patient with CF includes relief of bronchoconstriction, airway obstruction, and airflow limitation. Interventions include aggressive CPT, antibiotics, and O_2 therapy in severe disease. Good nutrition is important. Advances in long-term vascular access (e.g., implanted ports) and inhaled antibiotics have made administration of medication much easier. This has also eased the transition for treatment at home.

The family and the person with CF have a great financial and emotional burden. The cost of drugs, special equipment, and health care is often a financial hardship. Because most CF patients now live to childbearing age, family planning and genetic counseling are important. The burden of living with a chronic disease at a young age can be emotionally overwhelming. Community resources are often available to help the family. In addition, the Cystic Fibrosis Foundation can be of assistance. As the person continues toward and into adulthood, you and other skilled health professionals should be available to help the patient and the family cope with complications resulting from the disease.

BRONCHIECTASIS

Etiology and Pathophysiology

Bronchiectasis is characterized by permanent, abnormal dilation of medium-sized bronchi that is a result of inflammatory changes that destroy elastic and muscular structures supporting the bronchial wall. Infection is the primary reason for the continuing cycle of inflammation, airway damage, and remodeling. Bronchiectasis can follow a single episode of severe pneumonia, with a wide variety of infectious agents initiating the condition. Airways can become colonized with microorganisms (e.g., *Pseudomonas* species), which cause the bronchial walls to weaken, and pockets of infection begin to form (see Fig. 29-17).

When the walls of the bronchial system are injured, the mucociliary mechanism is damaged, allowing bacteria and mucus to accumulate within the pockets. Stasis of thickened mucus occurs due to impaired clearance of mucus by the cilia. This results in a reduced ability to clear mucus from the lungs and decreased expiratory airflow. Thus bronchiectasis is classified as an obstructive lung disease. Large connections (anastomoses) develop between the blood vessels in the lungs, and hemoptysis is often the result.[59]

A variety of pathophysiologic processes can result in bronchiectasis.[64] CF is the main cause of bronchiectasis in children. In adults the main cause is bacterial infections of the lungs that are either not treated or receive delayed treatment. Other causes of bronchiectasis are obstruction of an airway with mucus plugs or generalized impairment of pulmonary defenses. A number of systemic diseases such as inflammatory bowel disease, rheumatoid arthritis, or immune disorders (e.g., acquired immunodeficiency syndrome [AIDS]) may be associated with bronchiectasis.[25]

Clinical Manifestations

The hallmark of bronchiectasis is persistent cough with consistent production of thick, tenacious, purulent sputum. However, some patients with severe disease and upper lobe involvement may have no sputum production and little cough. Recurrent infections injure blood vessels, and hemoptysis occurs. In severe cases it may be life threatening. The other manifestations of bronchiectasis are pleuritic chest pain, dyspnea, wheezing, clubbing of digits, weight loss, and anemia. On auscultation of the lungs, a variety of adventitious sounds can be heard (e.g., crackles, wheezes, rhonchi).[65,66]

Diagnostic Studies

An individual with a chronic productive cough with copious purulent sputum (which may be blood streaked) should be suspected of having bronchiectasis. Chest x-rays may show some nonspecific abnormalities. A high-resolution CT (HRCT) scan of the chest is the preferred method for diagnosing bronchiectasis.

Sputum may provide additional information regarding the severity of impairment and the presence of active infection. Patients are frequently found to have *H. influenzae, Streptococcus pneumoniae, S. aureus,* or *P. aeruginosa,* with the latter leading to more frequent exacerbations and rapid decline in lung function. PFTs usually show an obstructive pattern, including a decrease in FEV_1 and FEV_1/FVC.[65,66]

Collaborative Care

Bronchiectasis is difficult to treat. Therapy is aimed at treating acute flare-ups and preventing a decline in lung function. Antibiotics are the mainstay of treatment and are often given empirically, but attempts are made to culture the sputum. Long-term suppressive therapy with antibiotics is reserved for those patients who have symptoms that recur a few days after stopping antibiotics. Antibiotics may be given orally, IV, or inhaled. Inhaled tobramycin is effective in treating patients with *P. aeruginosa.*

Concurrent bronchodilator therapy with LABAs, SABAs, or anticholinergics is given to prevent bronchospasm and stimulate mucociliary clearance. Hyperosmolar agents (e.g., hypertonic saline) may be given via a nebulizer to liquefy secretions. In addition, oral and inhaled corticosteroids may be used.

Maintaining good hydration is important to liquefy secretions. CPT and other airway clearance techniques are important to facilitate expectoration of sputum. Teach the patient to reduce exposure to excessive air pollutants and irritants, avoid cigarette smoking, and obtain pneumococcal and influenza vaccinations.

Surgical resection of parts of the lungs, which was common in the past, has largely been replaced by more effective supportive and antibiotic therapy. For selected patients who are disabled in spite of maximal therapy, lung transplantation is an option. Massive hemoptysis may require surgical resection or embolization of the bronchial artery.[66]

NURSING MANAGEMENT
BRONCHIECTASIS

Early detection and treatment of lower respiratory tract infections helps prevent complications such as bronchiectasis. Any obstructing lesion or foreign body should be removed promptly.

An important nursing goal is to promote drainage and removal of mucus. Various airway clearance techniques can be effectively used to facilitate secretion removal. CPT with postural drainage is widely used.

Administration of the prescribed medications is important. The patient needs to understand the importance of taking the prescribed regimen of drugs to obtain maximum effectiveness. Rest is important to prevent overexertion.

If hemoptysis occurs, patients should be given explicit instructions on when they should contact the health care provider. Some patients may periodically expectorate a "spot" of blood that is usual for them. In the acute care setting, if the patient has hemoptysis, contact the health care provider immediately, elevate the head of the bed, and place the patient in a side-lying position with the suspected bleeding side down.

Good nutrition is important and may be difficult to maintain because the patient is often anorexic. Oral hygiene to cleanse the mouth and remove dried sputum crusts may improve the patient's appetite. Offer foods that are appealing, since they may increase the patient's desire to eat.

Adequate hydration to help liquefy secretions and thus make it easier to remove them is extremely important. Unless there are contraindications, instruct the patient to drink at least 3 L of fluid daily. To accomplish this, advise the patient to increase fluid consumption by increasing intake by one glass per day until the goal is reached. Generally, the patient should be counseled to use low-sodium fluids to avoid systemic fluid retention.

Direct hydration of the respiratory system may also prove beneficial in the expectoration of secretions. Often nebulized hypertonic saline may be ordered for a more aggressive effect. At home, a steamy shower can prove effective. Expensive equipment that requires frequent cleaning is usually unnecessary. Teach the patient and caregiver to recognize significant clinical manifestations to report to the health care provider. These manifestations include increased sputum production, bloody sputum, increasing dyspnea, fever, chills, and chest pain.

CASE STUDY

Chronic Obstructive Pulmonary Disease

iStockphoto/Thinkstock

Patient Profile

H.M. is a 68-year-old white, married, female, retired traffic police officer. She has been in the hospital for 3 days with a COPD exacerbation and will be discharged tomorrow.

Subjective Data

- Before admission had 7 days of exceptional shortness of breath and increased volume of sputum, which turned greenish
- Had increased Ventolin HFA use at home to five or six times a day for dyspnea
- Had jitters and racing heart
- Had three or four bouts of bronchitis in the past year that she treated at home
- Thirty pack-year history of smoking; smokes half a pack per day now to "clear out lungs" in the morning
- Eats a regular diet but "gets full fast"
- Cannot climb one flight of stairs without stopping; walks down the flat driveway 10 yards without difficulty
- Awakens two or three times per night coughing and short of breath

Objective Data

Physical Examination

- Weight 129 lb, height 5 ft 8 in, BMI 20 kg/m^2
- BP 136/76 mm Hg, pulse 86, respiratory rate 28
- Increased anteroposterior diameter of chest (barrel shaped)
- Slight use of accessory (neck) muscles with breathing
- Distant breath sounds with occasional rhonchi
- No peripheral edema

Diagnostic Studies

- Last PFT: decreased FEV_1 (48%) and FEV_1/FVC (62%)
- ABGs on admission: pH 7.34, $PaCO_2$ 49 mm Hg, HCO_3^- 27 mEq/L, PaO_2 70 mm Hg
- WBC: 14,000/µL on admission
- Chest x-ray: hyperinflation, flat diaphragm, no sign of pneumonia

Collaborative Care

- GOLD 3 (severe) COPD with acute exacerbation
- O_2 2 L via nasal catheter while in hospital
- Prednisone 30 mg daily PO for 3 days, 20 mg for 3 days, 10 mg for 10 days
- Azithromycin 250 mg PO: take two tablets day 1, then take one tablet days 2 through 4
- Ipratropium HFA MDI 2 puffs four times a day
- At discharge: Advair Diskus 250/50 one inhalation q12hr

Discussion Questions

1. What classic manifestations indicate the patient had a COPD exacerbation?
2. What are some likely causes of her COPD?
3. What symptoms indicate the overuse of inhalers, and which drug would cause the symptoms described?
4. What is the only way H.M. can halt the progression of her lung disease?
5. Why would H.M. "feel full fast" when eating? What could you do to minimize this issue?
6. Interpret the ABGs. What pattern do you see?
7. ***Priority Decision:*** What are nursing priorities for discharge planning and teaching?
8. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
9. ***Evidence-Based Practice:*** H.M.'s son has been trying to convince his mother to quit smoking for many years without success. He asks you to tell his mother the results of her PFTs to convince her it is time to quit. Will this approach work?

evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient is concerned that he may have asthma. Of the symptoms that he relates to the nurse, which ones suggest asthma or risk factors for asthma *(select all that apply)*?
   - **a.** Allergic rhinitis
   - **b.** Prolonged inhalation
   - **c.** History of skin allergies
   - **d.** Cough, especially at night
   - **e.** Gastric reflux or heartburn
2. In evaluating an asthmatic patient's knowledge of self-care, the nurse recognizes that additional instruction is needed when the patient says,
   - **a.** "I use my corticosteroid inhaler when I feel short of breath."
   - **b.** "I get a flu shot every year and see my health care provider if I have an upper respiratory tract infection."
   - **c.** "I use my inhaler before I visit my aunt who has a cat, but I only visit for a few minutes because of my allergies."
   - **d.** "I walk 30 minutes every day but sometimes I have to use my bronchodilator inhaler before walking to prevent me from getting short of breath."
3. A plan of care for the patient with COPD could include *(select all that apply)*
   - **a.** exercise such as walking.
   - **b.** high flow rate of O_2 administration.
   - **c.** low-dose chronic oral corticosteroid therapy.
   - **d.** use of peak flow meter to monitor the progression of COPD.
   - **e.** breathing exercises such as pursed-lip breathing that focus on exhalation.
4. The effects of cigarette smoking on the respiratory system include
   - **a.** hypertrophy of capillaries causing hemoptysis.
   - **b.** hyperplasia of goblet cells and increased production of mucus.
   - **c.** increased proliferation of cilia and decreased clearance of mucus.
   - **d.** proliferation of alveolar macrophages to decrease the risk for infection.
5. The major advantage of a Venturi mask is that it can
   - **a.** deliver up to 80% O_2.
   - **b.** provide continuous 100% humidity.
   - **c.** deliver a precise concentration of O_2.
   - **d.** be used while a patient eats and sleeps.
6. Which guideline would be a part of teaching patients how to use a metered-dose inhaler (MDI)?
   - **a.** After activating the MDI, breathe in as quickly as you can.
   - **b.** Estimate the amount of remaining medicine in the MDI by floating the canister in water.
   - **c.** Disassemble the plastic canister from the inhaler and rinse both pieces under running water every week.
   - **d.** To determine how long the canister will last, divide the total number of puffs in the canister by the puffs needed per day.
7. Which treatments in CF would the nurse expect to implement in the management plan of patients with CF *(select all that apply)*?
   - **a.** Sperm banking
   - **b.** IV corticosteroids on a chronic basis
   - **c.** Airway clearance techniques (e.g., Acapella)
   - **d.** GoLYTELY given PRN for severe constipation
   - **e.** Inhaled tobramycin to combat *Pseudomonas* infection
8. A patient who has bronchiectasis asks the nurse, "What conditions would warrant a call to the clinic?"
   - **a.** Blood clots in the sputum
   - **b.** Sticky sputum on a hot day
   - **c.** Increased shortness of breath after eating a large meal
   - **d.** Production of large amounts of sputum on a daily basis

1. a, c, d, e, 2. a, 3. a, e, 4. b, 5. c, 6. d, 7. a, c, d, e, 8. a

CASE STUDY

Managing Multiple Patients

Introduction

You are assigned to care for the following four patients on a medical-surgical unit. You are sharing one unlicensed assistive personnel (UAP) assigned with another RN.

Patients

Kevin Peterson/ Photodisc/Thinkstock

F.T. is a 70-year-old man admitted yesterday with left-lower lobe pneumonia. He is receiving oxygen at 2 L/min via nasal cannula and IV antibiotics. His last pulse oximetry reading was 92%.

iStockphoto/Thinkstock

M.R. is a 60-year-old man who is 4 days postoperative following a total laryngectomy with tracheostomy for treatment of laryngeal cancer. He is receiving intermittent tube feeding via a percutaneous gastrostomy (PEG) tube and last received pain medication 4 hours ago.

iStockphoto/Thinkstock

J.H. is a 52-year-old man admitted with right lower lobe pneumonia. A bronchoscopy with biopsy done on admission revealed small cell lung carcinoma. He is intermittently confused and anxious with rapid, shallow respirations. He is currently considering his treatment options.

iStockphoto/Thinkstock

H.M. is a 68-year-old white woman admitted 3 days ago with a COPD exacerbation who is anticipating discharge later today. She is on oral prednisone and had been given a new inhaler to use. She will also be started on home oxygen.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale for your decision.
2. ***Delegation Decision:*** Which morning tasks can you delegate to the UAP *(select all that apply)?*
   - a. Take a pulse oximetry reading on F.T.
   - b. Assess M.R.'s pain level and show him how to administer his tube feeding.
   - c. Assist H.M. with AM care and gather belongings in anticipation of discharge.
   - d. Teach F.T. how to use the incentive spirometer and titrate oxygen to obtain pulse oximetry >95%.
   - e. Provide coffee and emotional support for J.H.'s family as they await a family meeting with the physician.
3. ***Priority and Delegation Decision:*** While you are assessing J.H., the UAP tells you that H.M. is complaining of chest pain and worsening shortness of breath. M.R. is also requesting pain medication. What should you do first?
   - a. Ask the UAP to get H.M.'s vital signs while you give M.R. pain medication.
   - b. Ask the UAP to increase H.M.'s oxygen to 4L/minute while you assess M.R.'s pain.
   - c. Ask the UAP to obtain a stat 12-lead ECG on H.M. while you perform a focused assessment.
   - d. Ask the UAP to have another RN give M.R. his pain medication while you go directly to H.M.'s room.

Case Study Progression

After assessing H.M., you notify her health care provider. A stat 12-lead ECG is obtained and a blood sample is drawn to check cardiac enzymes. H.M.'s chest pain is not relieved by sublingual nitroglycerin. You then administer 4 mg IV morphine. H.M. states that her pain is "a little better" but continues to complain of dyspnea. The 12-lead ECG and cardiac enzyme results are all within normal limits.

4. Because of H.M.'s reduced mobility, you recognize that she is at risk for pulmonary emboli and anticipate the health care provider will order which tests to determine the cause of her current symptoms?
   - a. BNP and echocardiogram
   - b. D-dimer and spiral CT scan
   - c. CBC and abdominal flat-plate
   - d. Serum electrolytes and renal ultrasound
5. While the charge nurse accompanies H.M. to radiology, you turn your attention back to your remaining three patients. Prior to administering M.R.'s 8 AM tube feeding, you aspirate 300 mL of gastric contents from his PEG tube. Which action should you take next?
   - a. Discard the aspirated contents and administer the tube feeding as ordered.
   - b. Replace the aspirated contents and administer half of ordered tube feeding volume.
   - c. Discard the aspirated contents and withhold the next two scheduled tube feedings.
   - d. Replace the aspirated contents and notify the health care provider prior to administering any further tube feedings.
6. When preparing F.T.'s AM medications, you note that he is scheduled to receive the following antibiotics at 8 AM: levofloxacin (Levaquin) 750 mg in 150 mL normal saline over 90 minutes (give once every 24 hours) and cefazolin (Kefzol) 1 g in 100 mL normal saline over 30 minutes (give q8hr). He has only one IV site. Which action is most appropriate?
   - a. Obtain a second peripheral IV site.
   - b. Call the health care provider to change the administration times.
   - c. Check with pharmacy to see if they can be mixed together in the same IV bag.
   - d. Administer the cefazolin first because it takes the least amount of time to infuse.
7. ***Management Decision:*** J.H.'s son calls you on the telephone to inquire about his father's current condition and long-term prognosis. Which initial response would be most appropriate?
   - a. Ask the person calling what the code word is to identify themselves as family.
   - b. Tell the caller that you are not allowed to discuss any information over the telephone.
   - c. Ask J.H. what the physician has explained to him in order to clarify his current understanding of the situation.
   - d. Empathize with J.H.'s son's need to know his father's prognosis while acknowledging that no one really knows.

LEARNING OUTCOMES

1. Describe the structures and functions of the hematologic system.
2. Differentiate among the different types of blood cells and their functions.
3. Explain the process of hemostasis.
4. Link the age-related changes in the hematologic system to differences in findings of hematologic studies.
5. Select the significant subjective and objective assessment data related to the hematologic system that should be obtained from a patient.
6. Describe the components of a physical assessment of the hematologic system.
7. Differentiate normal from common abnormal findings of a physical assessment of the hematologic system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the hematologic system.

Hematology is the study of blood and blood-forming tissues. This includes bone marrow, blood, spleen, and lymph system. A basic knowledge of hematology is useful in clinical settings to evaluate the patient's ability to transport oxygen and carbon dioxide, maintain intravascular volume, coagulate blood, and combat infections. Assessment of the hematologic system is based on the patient's health history, physical examination, and results of diagnostic studies.

STRUCTURES AND FUNCTIONS OF HEMATOLOGIC SYSTEM

Bone Marrow

Blood cell production **(hematopoiesis)** occurs within the bone marrow. *Bone marrow* is the soft material that fills the central core of bones. Although there are two types of bone marrow (yellow [adipose] and red [hematopoietic]), it is the red marrow that actively produces blood cells. In the adult the red marrow is found primarily in the flat and irregular bones, such as the ends of long bones, pelvic bones, vertebrae, sacrum, sternum, ribs, flat cranial bones, and scapulae.

All three types of blood cells (red blood cells [RBCs], white blood cells [WBCs], and platelets) develop from a common hematopoietic stem cell within the bone marrow. The hematopoietic *stem cell* is best described as an immature blood cell that is able to self-renew and to differentiate into hematopoietic progenitor cells. As the cells mature and differentiate, several different types of blood cells are formed (Fig. 30-1). The marrow responds to increased demands for various types of blood cells by increasing production via a negative feedback

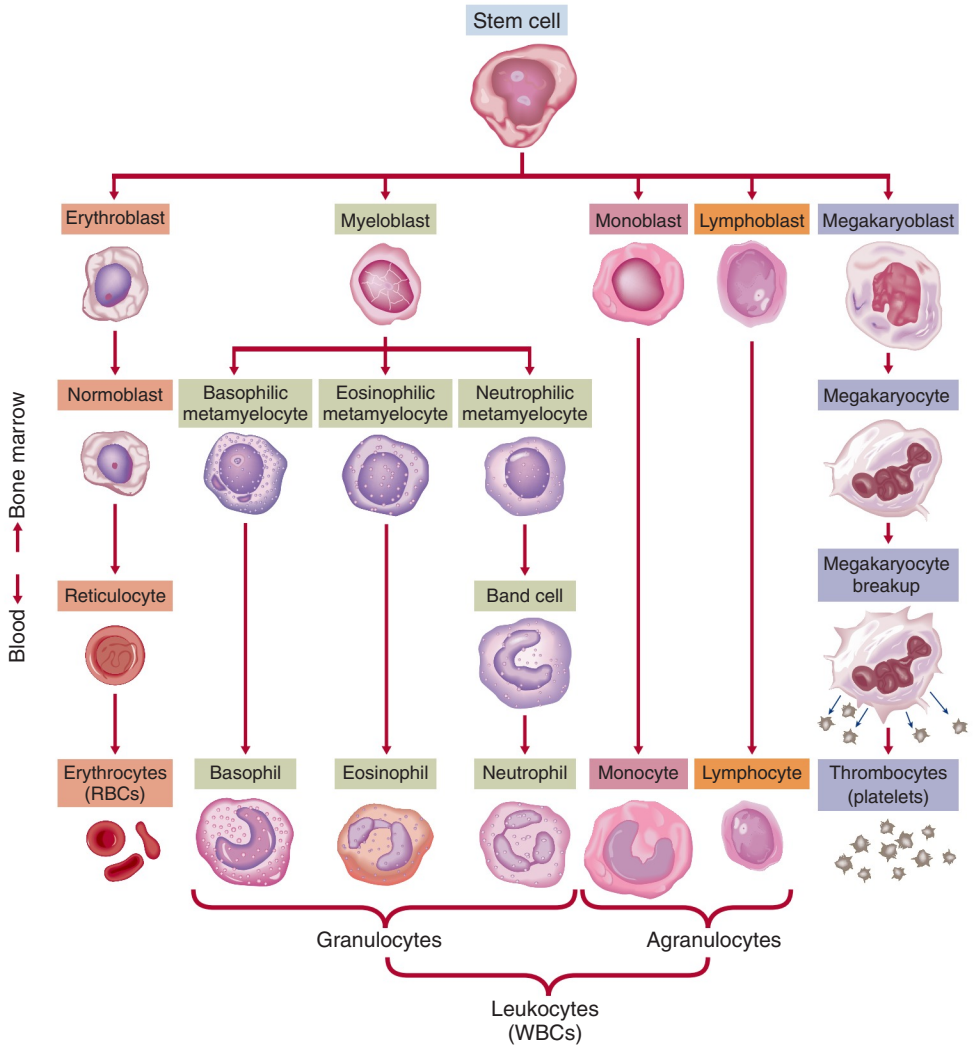

FIG. 30-1 Development of blood cells. *RBCs*, Red blood cells; *WBCs*, white blood cells.

system. The bone marrow is stimulated by various factors or cytokines (e.g., erythropoietin, granulocyte colony-stimulating factor [G-CSF], stem cell factor, thrombopoietin) that cause differentiation of the stem cells into one of the committed hematopoietic cells (e.g., RBC). For example, when tissue hypoxia occurs, erythropoietin is secreted by the kidney and liver. It circulates to the bone marrow and causes differentiation of proerythroblasts in the bone marrow.[1]

Blood

Blood is a type of connective tissue that performs three major functions: transportation, regulation, and protection (Table 30-1). Blood has two major components: plasma and blood cells. In an adult weighing between 150 and 180 lb, the volume of blood is usually between 4.7 and 5.5 L (5 to 6 quarts).

Plasma. Approximately 55% of blood is plasma (Fig. 30-2). Plasma is composed primarily of water, but it also contains proteins, electrolytes, gases, nutrients (e.g., glucose, amino acids, lipids), and waste. The term *serum* refers to plasma minus its clotting factors. Plasma proteins include albumin, globulin, and clotting factors (mostly fibrinogen). Most plasma proteins are produced by the liver, except for antibodies (immunoglobulins), which are produced by plasma cells. Albumin is a protein that helps maintain oncotic pressure in the blood.[1]

TABLE 30-1 FUNCTIONS OF BLOOD

Function	Examples
Transportation	• O_2 from lungs to cells • Nutrients from gastrointestinal tract to cells • Hormones from endocrine glands to tissues and cells • Metabolic waste products (e.g., CO_2, NH_3, urea) from cells to lungs, liver, and kidneys
Regulation	• Fluid and electrolyte balance • Acid-base balance • Body temperature • Maintaining intravascular oncotic pressure
Protection	• Maintaining homeostasis of blood coagulation • Combating invasion of pathogens and other foreign substances

Blood Cells. About 45% of the blood (see Fig. 30-2) is composed of formed elements, or blood cells. The three types of blood cells are *erythrocytes* (RBCs), *leukocytes* (WBCs), and *thrombocytes* (platelets). The primary function of erythrocytes is oxygen transportation, whereas the leukocytes are involved in protecting the body from infection. Platelets promote blood coagulation.

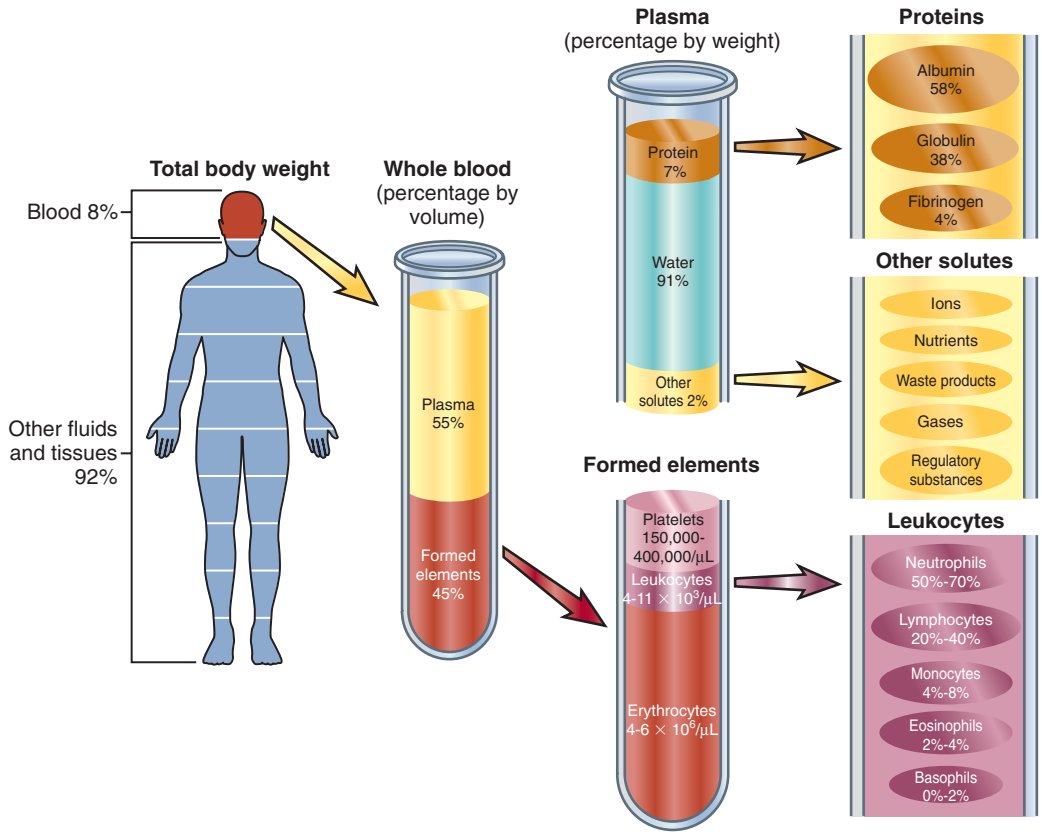

FIG. 30-2 Approximate values for the components of blood in the adult. Normally, 45% of the blood is composed of blood cells and 55% is composed of plasma.

Erythrocytes. The primary functions of RBCs include transport of gases (both oxygen and carbon dioxide) and assistance in maintaining acid-base balance. RBCs are flexible cells with a unique biconcave shape. Flexibility enables the cell to alter its shape so that it can easily pass through tiny capillaries. The cell membrane is thin to facilitate diffusion of gases.

Erythrocytes are primarily composed of a large molecule called hemoglobin. *Hemoglobin,* a complex protein-iron compound composed of heme (an iron compound) and globin (a simple protein), binds with oxygen and carbon dioxide. As RBCs circulate through the capillaries surrounding alveoli within the lung, oxygen attaches to the iron on the hemoglobin. The oxygen-bound hemoglobin is referred to as *oxyhemoglobin* and is responsible for giving arterial blood its bright red appearance. As RBCs flow to body tissues, oxygen detaches from the hemoglobin and diffuses from the capillary into tissue cells. Carbon dioxide diffuses from tissue cells into the capillary, attaches to the globin portion of hemoglobin, and is transported to the lungs for removal. Hemoglobin also acts as a buffer and plays a role in maintaining acid-base balance. This buffering function is described further in Chapter 17.

Erythropoiesis (the process of RBC production) is regulated by cellular oxygen requirements and general metabolic activity. Erythropoiesis is stimulated by hypoxia and controlled by *erythropoietin,* a glycoprotein growth factor synthesized and released primarily by the kidney. Erythropoietin stimulates the bone marrow to increase erythrocyte production. Normally the bone marrow releases 3×10^9 RBC/kg of body weight/day. The normal life span of an erythrocyte is about 120 days. Erythropoiesis is also influenced by the availability of nutrients. Many essential nutrients are necessary for erythropoiesis, including protein, iron, folate (folic acid), cobalamin (vitamin B_{12}), riboflavin (vitamin B_2), pyridoxine (vitamin B_6), pantothenic acid, niacin, ascorbic acid, and vitamin E.[1] Erythrocyte production is also affected by endocrine hormones, such as thyroxine, corticosteroids, and testosterone. For example, hypothyroidism is often associated with anemia.[2]

Several distinct cell types evolve during erythrocyte maturation (see Fig. 30-1). The **reticulocyte** is an immature erythrocyte. The reticulocyte count measures the rate at which new RBCs appear in the circulation. Reticulocytes can develop into mature RBCs within 48 hours of release into the circulation. Therefore assessing the number of reticulocytes is a useful means of evaluating the rate and adequacy of erythrocyte production.

Hemolysis (destruction of RBCs) by monocytes and macrophages removes abnormal, defective, damaged, and old RBCs from circulation. Hemolysis normally occurs in the bone marrow, liver, and spleen. Because one of the components of RBCs is bilirubin, hemolysis of these cells results in increased bilirubin to be processed by the body. When hemolysis occurs via normal mechanisms, the liver is able to conjugate and excrete all bilirubin that is released (see Fig. 31-2).

Leukocytes. *Leukocytes* (WBCs) appear white when separated from blood. Like the RBCs, leukocytes originate from stem cells within the bone marrow (see Fig. 30-1). There are different types of leukocytes, each with a different function. Leukocytes containing granules within the cytoplasm are called *granulocytes* (also known as polymorphonuclear leukocytes). Granulocytes include three types: neutrophils, basophils, and eosinophils. Leukocytes that do not have granules within the cytoplasm are called *agranulocytes* and include lymphocytes and monocytes.

Lymphocytes and monocytes are also referred to as mononuclear cells because they have only one discrete nucleus. Leukocytes have a widely variable life span. Granulocytes may live only for hours, yet some T lymphocytes may live for years.

Granulocytes. The primary function of the granulocytes is *phagocytosis,* a process by which WBCs ingest or engulf any unwanted organism and then digest and kill it. They are able to migrate through vessel walls and to the sites where they are needed. The *neutrophil* is the most common type of granulocyte, accounting for 50% to 70% of all WBCs. Neutrophils are the primary phagocytic cells involved in acute inflammatory responses. Once they engulf the pathogen, they die in 1 to 2 days.[1] Neutrophil production and maturation are stimulated by hematopoietic growth factors (e.g., G-CSF and granulocyte-macrophage colony-stimulating factor [GM-CSF])[1] (see Table 14-3).

A mature neutrophil is called a *segmented neutrophil,* or "seg" or "polysegmented neutrophil," because the nucleus is segmented into two to five lobes connected by strands. An immature neutrophil is called a *band* (for the band appearance of the nucleus). Although band cells are sometimes found in the peripheral circulation of normal people and are capable of phagocytosis, the mature neutrophil is much more effective. An increase in neutrophils in the blood is a common diagnostic indicator of infection and tissue injury.

Eosinophils account for only 2% to 4% of all WBCs. They have a similar but reduced ability for phagocytosis. One of their primary functions is to engulf antigen-antibody complexes formed during an allergic response. An elevated level of eosinophils is also seen in some neoplastic disorders, such as Hodgkin's lymphoma, and in various skin diseases and connective tissue disorders.[3] Eosinophils are also able to defend against parasitic infections.

Basophils make up less than 2% of all leukocytes. These cells have cytoplasmic granules that contain chemical mediators, such as heparin and histamine. If a basophil is stimulated by an antigen or by tissue injury, it responds by releasing substances within the granules. This is part of the response seen in allergic and inflammatory reactions. *Mast cells* are similar to basophils, but they reside in connective tissues and play a central role in inflammation, permeability of blood vessels, and smooth muscle contraction.

Lymphocytes. Lymphocytes, one of the agranular leukocytes, constitute 20% to 40% of the WBCs. Lymphocytes form the basis of the cellular and humoral immune responses (see Chapter 14). Two lymphocyte subtypes are B cells and T cells. Although T cell precursors originate in the bone marrow, these cells migrate to the thymus gland for further differentiation into T cells. *Natural killer (NK) cells* are lymphocytes that do not require prior exposure to antigens to kill virus-infected cells and activate T cells and phagocytes. Most lymphocytes transiently circulate in the blood and also reside in lymphoid tissues. (Details of lymphocyte function are presented in Chapter 14.)

Monocytes. Monocytes, the other type of agranular leukocytes, account for approximately 4% to 8% of the total WBCs. Monocytes are potent phagocytic cells that ingest small or large masses of matter, such as bacteria, dead cells, tissue debris, and old or defective RBCs. These cells are only present in the blood for a short time before they migrate into the tissues and become macrophages (see Chapter 13). In addition to macrophages that have differentiated from monocytes, tissues also contain resident macrophages. These resident macrophages are given special names (e.g., Kupffer cells in the liver, osteoclasts in the bone, alveolar macrophages in the lung). These macrophages protect the body from pathogens at these entry points and are more phagocytic than monocytes. Macrophages also interact with lymphocytes to facilitate the humoral and cellular immune responses (see Chapter 14).

Thrombocytes. The primary function of thrombocytes, or *platelets,* is to initiate the clotting process by producing an initial platelet plug in the early phases of the process. Platelets must be available in sufficient numbers and must be structurally and metabolically sound for blood clotting to occur. Platelets maintain capillary integrity by working as "plugs" to close any openings in the capillary wall. At the site of any capillary damage, platelet activation is initiated. Increasing numbers of platelets accumulate to form an initial platelet plug that is stabilized with clotting factors. Platelets are also important in the process of clot shrinkage and retraction.

Platelets, like other blood cells, originate from stem cells within the bone marrow (see Fig. 30-1). The stem cell undergoes differentiation by transforming into a *megakaryocyte,* which fragments into platelets. About one third of the platelets in the body reside in the spleen.

Platelet production is partly regulated by *thrombopoietin,* a growth factor that acts on bone marrow to stimulate platelet production. It is produced in the liver, kidneys, smooth muscle, and bone marrow. Typically, platelets have a life span of only 8 to 11 days.

Normal Iron Metabolism

Iron is obtained from food and dietary supplements. Approximately 1 mg of every 10 to 20 mg of iron ingested is absorbed in the duodenum and upper jejunum. Therefore only 5% to 10% of ingested iron is absorbed. About two thirds of total body iron is bound to heme in erythrocytes (hemoglobin) and muscle cells (myoglobin).

The other one third of iron is stored as ferritin and hemosiderin (degraded form of ferritin) in the bone marrow, spleen, liver, and macrophages (Fig. 30-3).When the stored iron is not replaced, hemoglobin production is reduced.

Transferrin, which is synthesized in the liver, serves as a carrier plasma protein for iron. The degree to which transferrin is saturated with iron is a reliable indicator of the iron supply for developing RBCs.

As part of normal iron metabolism, iron is recycled after macrophages in the liver and spleen phagocytize, or ingest and destroy, old and damaged RBCs. Iron binds to transferrin in the plasma or is stored as ferritin or hemosiderin (see Fig. 30-3). Only about 3% is lost daily in urine, sweat, bile, and epithelial cells in the gastrointestinal (GI) tract. Therefore there is normally very little iron loss except from blood loss.

Normal Clotting Mechanisms

Hemostasis is a term used to describe the arrest of bleeding. This process is important in minimizing blood loss when various body structures are injured. Four components contribute to normal hemostasis: vascular response, platelet plug formation, the development of the fibrin clot on the platelet plug by plasma clotting factors, and the ultimate lysis of the clot.

Vascular Response. When a blood vessel is injured, an immediate local vasoconstrictive response occurs. Vasoconstriction reduces the leakage of blood from the vessel not only by restricting the vessel size but also by pressing the endothelial surfaces together. The latter reaction enhances vessel wall stickiness and maintains closure of the vessel even after vasocon-

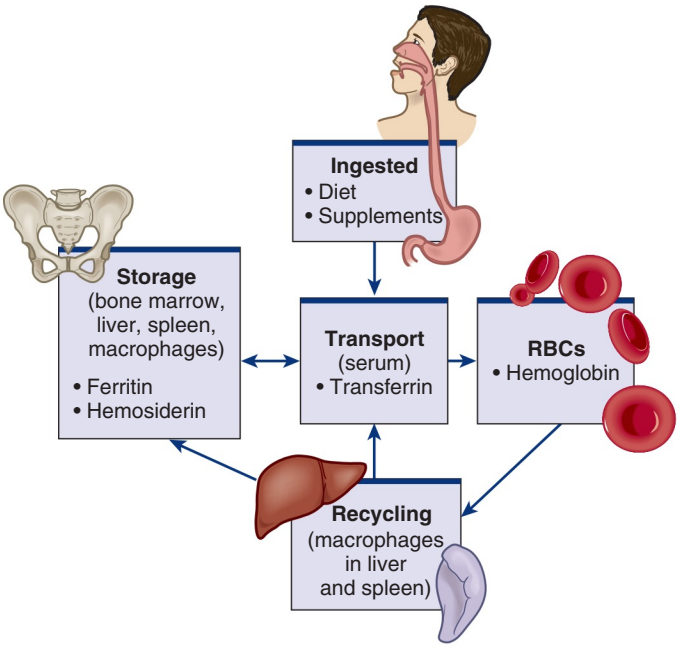

FIG. 30-3 Normal iron metabolism. Iron is ingested in the diet or from supplements. Macrophages break down ingested red blood cells *(RBCs)*. Iron is returned to blood bound to transferrin or stored as ferritin or hemosiderin.

striction subsides. Vascular spasm may last for 20 to 30 minutes, allowing time for the platelet response and plasma clotting factors to be activated. The platelet response and plasma clotting factors are triggered by endothelial injury and the release of substances such as tissue factor (TF).[1]

Platelet Plug Formation. Platelets are activated when they are exposed to interstitial collagen from an injured blood vessel. Platelets stick to one another and form clumps. The stickiness is termed *adhesiveness,* and the formation of clumps is termed *aggregation* or *agglutination.* This interaction causes the platelets to release substances such as platelet factor 3 and serotonin, which facilitate coagulation. At the same time, platelets release adenosine diphosphate, which increases platelet adhesiveness and aggregation, thereby enhancing the formation of a platelet plug. In addition, von Willebrand factor (vWF) is important in forming an adhesive bridge between platelets and vascular subendothelial structures. It is synthesized in endothelial cells and megakaryocytes and acts as a carrier for factor VIII.

In addition to their independent contribution to clotting, platelets also facilitate the reactions of the plasma clotting factors. As Fig. 30-4 shows, platelet lipoproteins stimulate necessary conversions in the clotting process.

Plasma Clotting Factors. The formation of a visible fibrin clot on the platelet plug is the conclusion of a complex series of reactions involving different clotting (coagulation) factors. The plasma clotting factors are labeled with both names and Roman

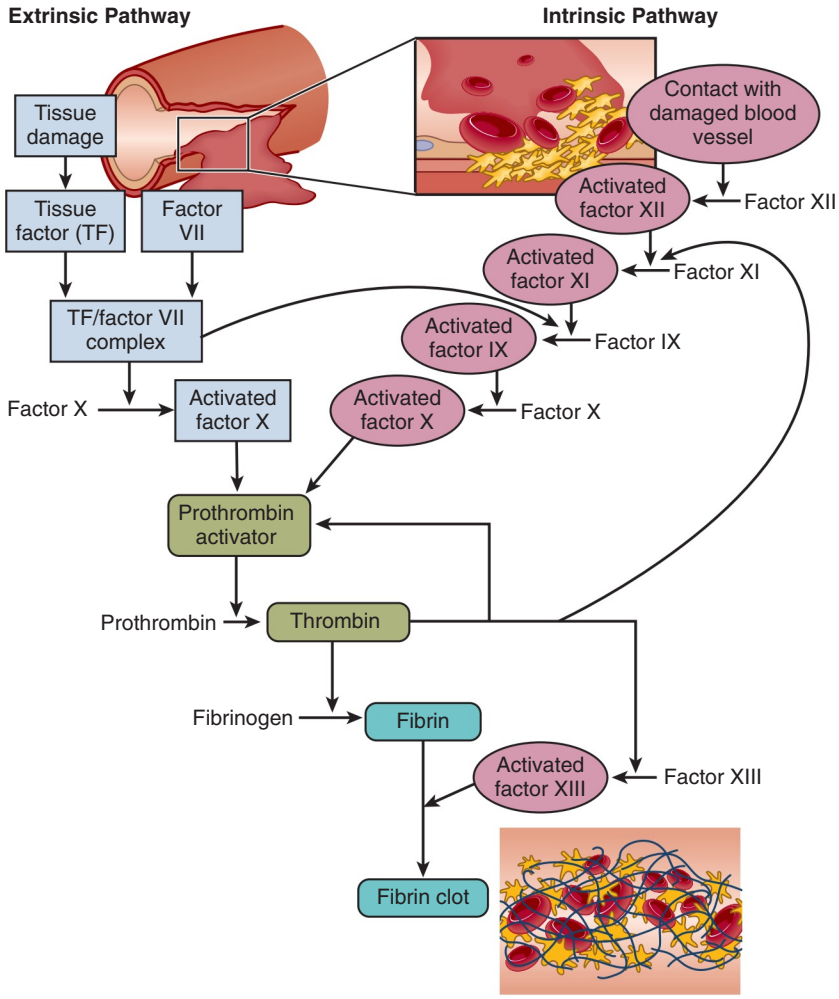

FIG. 30-4 Coagulation mechanism showing steps in the intrinsic pathway and extrinsic pathway as they would occur in the test tube.

TABLE 30-2 COAGULATION FACTORS

Coagulation Factor		Action
I	Fibrinogen	Source of fibrin to form a clot. Made in liver.
II	Prothrombin	Converted to thrombin, which then activates fibrinogen into fibrin.
III	Tissue factor, tissue thromboplastin	Released from damaged endothelial cells and activates the extrinsic pathway by reacting with factor VII.
IV	Calcium	Required cofactor at several points in the coagulation cascade.
V	Labile factor, proaccelerin	Binds with factor X to activate prothrombin.
VI		Not in use (now obsolete).
VII	Stable factor, proconvertin	Forms a complex with factor III and activates factors IX and X.
VIII	Antihemophilic factor	Works with factor IX and calcium to activate factor X.
IX	Christmas factor, plasma thromboplastin component	Together with factor VIII, activates factor X.
X	Stuart-Prower factor, Stuart factor	Activates conversion of factor II (prothrombin) to thrombin.
XI	Plasma thromboplastin antecedent	Activates factor IX when calcium is present.
XII	Hageman factor	Activates factor XI, which starts the intrinsic pathway.
XIII	Fibrin-stabilizing factor	Cross-links fibrin strands and stabilizes fibrin clot.

numerals (Table 30-2). Plasma proteins circulate in inactive forms until stimulated to initiate clotting through one of two pathways, intrinsic or extrinsic (see Fig. 30-4). The *intrinsic pathway* is activated by collagen exposure from endothelial injury when the blood vessel is damaged. The *extrinsic pathway* is initiated when tissue factor or tissue thromboplastin is released extravascularly from injured tissues.

Regardless of whether clotting is initiated by substances internal or external to the blood vessel, coagulation ultimately follows the same final common pathway of the clotting cascade. Thrombin, in the common pathway, is the most powerful enzyme in the coagulation process (see Fig. 30-4). It converts fibrinogen to fibrin, which is an essential component of a blood clot.

Lysis of Clot. Just as some blood elements foster coagulation *(procoagulants),* others interfere with clotting *(anticoagulants).* This counter mechanism to blood clotting serves to keep blood in its fluid state. Anticoagulation may be achieved by antithrombin activity, vessel and platelet activity, and fibrinolysis. As the name implies, antithrombins keep blood in a fluid state by antagonizing thrombin, a powerful coagulant. Endogenous heparin, antithrombin III, protein C, and protein S are examples of anticoagulants.

The second means of maintaining blood in its fluid form is **fibrinolysis,** a process resulting in the dissolution of the fibrin clot. The fibrinolytic system is initiated when plasminogen is activated to plasmin (Fig. 30-5). Thrombin is one of the substances that can activate the conversion of plasminogen to plasmin, thereby promoting fibrinolysis. The plasmin attacks either fibrin or fibrinogen by splitting the molecules into smaller elements known as *fibrin split products* (FSPs) or *fibrin degradation products* (FDPs). (More information about FSPs can be found in Table 30-7 later in this chapter and in the discussion of disseminated intravascular coagulation in Chapter 31.)

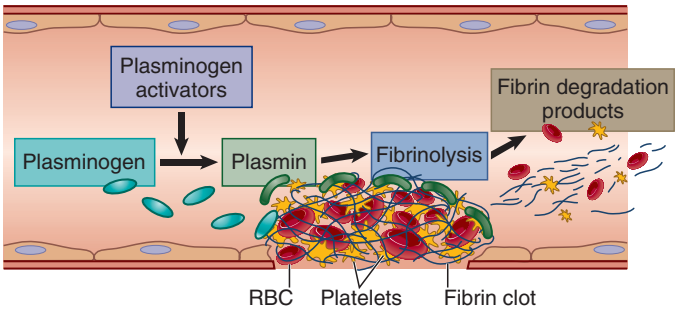

FIG. 30-5 Fibrinolytic system.

If fibrinolysis is excessive, the patient is predisposed to bleeding. In such a situation, bleeding results from the destruction of fibrin in platelet plugs or from the anticoagulation effects of increased FSPs. Increased FSPs lead to impaired platelet aggregation, reduced prothrombin, and an inability to stabilize fibrin.

Spleen

Another component of the hematologic system is the spleen, which is located in the upper left quadrant of the abdomen. The spleen has four major functions: hematopoietic, filtration, immunologic, and storage. *Hematopoietic function* is manifested by the spleen's ability to produce RBCs during fetal development. The *filtration function* is demonstrated by the spleen's ability to remove old and defective RBCs from the circulation by the mononuclear phagocyte system. Filtration also involves the reuse of iron. The spleen is able to catabolize hemoglobin released by hemolysis and return the iron component of the hemoglobin to the bone marrow for reuse. The spleen also plays an important role in filtering circulating bacteria, especially encapsulated organisms such as gram-positive cocci. The *immunologic function* is demonstrated by the spleen's rich supply of lymphocytes, monocytes, and stored immunoglobulins. The *storage function* is reflected in its role as a storage site for RBCs and platelets. More than 300 mL of blood can be stored. About one third of platelets are stored in the spleen. A person who has had a splenectomy has higher circulating levels of platelets than a person who still has his or her spleen.

Lymph System

The lymph system, consisting of lymph fluid, lymphatic capillaries, ducts, and lymph nodes, carries fluid from the interstitial spaces to the blood. It is by means of the lymph that proteins and fat from the gastrointestinal (GI) tract and certain hormones are able to return to the circulatory system. The lymph system also returns excess interstitial fluid to the blood, which is important in preventing edema.

Lymph fluid is pale yellow interstitial fluid that has diffused through lymphatic capillary walls. It circulates through a special vasculature, much as blood moves through blood vessels. The formation of lymph fluid increases when interstitial fluid increases, thereby forcing more fluid into the lymph system. When too much interstitial fluid develops or when something interferes with the reabsorption of lymph, lymphedema develops. Lymphedema that may occur as a complication of mastectomy or lumpectomy with dissection of axillary nodes is often caused by the obstruction of lymph flow from the removal of lymph nodes.

The lymphatic capillaries are thin-walled vessels that have an irregular diameter. They are somewhat larger than blood capil-

laries and do not contain valves. (eFig. 30-1 shows the lymph drainage throughout the body and is available on the website for this chapter.)

The *lymph nodes,* which are also a part of the lymphatic system, are round, oval, or bean shaped and vary in size according to their location. Structurally, the nodes are small clumps of lymphatic tissue and are found in groups along lymph vessels at various sites. More than 200 lymph nodes are found throughout the body, with the greatest number being in the abdomen surrounding the GI tract. Lymph nodes are situated both superficially and deep. The superficial nodes can be palpated, but evaluation of the deep nodes requires radiologic examination.[4] A primary function of lymph nodes is filtration of pathogens and foreign particles that are carried by lymph to the nodes.

Liver

The liver functions as a filter. It also produces all the procoagulants that are essential to hemostasis and blood coagulation. Additionally, it stores iron that is in excess of tissue needs, which can occur with frequent blood transfusions or diseases that cause iron overload. *Hepcidin*, produced by the liver, is a key regulator of iron balance. The synthesis of hepcidin is stimulated by iron overload or inflammation. Hepcidin reduces the release of stored iron from enterocytes (in the intestines) and macrophages.[5] Thus when iron is deficient, hepatocytes produce less hepcidin. Other functions of the liver are described in Chapters 39 and 44.

GERONTOLOGIC CONSIDERATIONS

HEMATOLOGIC SYSTEM

Physiologic aging is a gradual process that involves cell loss and organ atrophy. Aging leads to a decrease in bone marrow mass and cellularity and an increase in bone marrow fat.[6] However, peripheral blood cell concentrations in healthy older adults are similar to those of younger adults.[7] Although the older adult is still capable of maintaining adequate blood cell levels, the reserve capacity leaves the older adult more vulnerable to possible problems with clotting, transporting oxygen, and fighting infection, especially during periods of increased demand. This results in a diminished ability of an older adult to compensate for an acute or chronic illness.[6,7]

Hemoglobin levels begin to decrease in both men and women after middle age, with the low-normal levels seen in most older people. Total serum iron, total iron-binding capacity, and intestinal iron absorption are all decreased in older adults. Iron deficiency is usually responsible for the low hemoglobin levels. Healthy older patients are not able to produce reticulocytes in response to hemorrhage or hypoxemia as well as younger adults.[1]

The RBC plasma membranes are more fragile in the older person. This may account for a slight increase in mean corpuscular volume (MCV) and a slight decrease in mean corpuscular hemoglobin concentration (MCHC) of RBCs in some older individuals. It is essential to assess for signs of disease processes such as GI bleeding before concluding that decreased hemoglobin levels are caused solely by aging. Thus iron-deficiency anemia is a diagnosis that should be made after other causes have been ruled out.

The total WBC count and differential are generally not affected by aging. However, decreases in humoral antibody response and T cell function may occur.[6,8] During an infection, the older adult may have only a minimal elevation in the total WBC count. These laboratory findings suggest a diminished bone marrow reserve of granulocytes in older adults and reflect the possible impaired stimulation of hematopoiesis. The number of platelets is unaffected by the aging process, but functionally they may have increased adhesiveness.[9] Changes in vascular integrity related to aging can manifest as easy bruising.

The effects of aging on hematologic studies[9-11] are presented in Table 30-3. Immune changes related to aging are presented in Chapter 14.

TABLE 30-3 GERONTOLOGIC ASSESSMENT DIFFERENCES

Effects of Aging on Hematologic Studies

Study	Changes
CBC Studies	
Hgb	Normal; possibly slight decrease in men
MCV	May be slightly increased
MCHC	May be slightly decreased
WBC count	Diminished response to infection
Platelets	Unchanged but possible increase in adhesiveness
Clotting Studies	
Partial thromboplastin time	Decreased
Fibrinogen	May be elevated
Factors V, VII, IX	May be elevated
ESR	Increased significantly
D-dimers	Increased
Iron Studies	
Serum iron	Decreased
Total iron-binding capacity	Decreased
Ferritin	Increased
Erythropoietin	May be decreased

MCHC, Mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume.

ASSESSMENT OF HEMATOLOGIC SYSTEM

Much of the evaluation of the hematologic system is based on a thorough health history. Consequently, you need to be knowledgeable about what to include in the health history so that you can phrase questions to elicit the most information.

Subjective Data

Important Health Information

Past Health History. It is important to learn whether the patient has had prior hematologic problems. Specifically ask about previous problems with anemia, bleeding disorders, and blood diseases such as leukemia. Also document other related medical conditions such as malabsorption or liver (e.g., hepatitis, cirrhosis), kidney, or spleen disorders. Patients may have received a kidney transplant, may have lost a spleen to traumatic injury, or may have a history of IV drug or alcohol use that affects their risk for hematologic disorders. A history of recent or recurrent infections or problems with blood clotting is also important to note.

Medications. A complete medication history of prescription and over-the-counter drugs is an important component of a hematologic assessment. Specifically address the use of vitamins, herbal products, or dietary supplements because many patients may not consider them to be drugs. Many drugs may

CASE STUDY

Patient Introduction

iStockphoto/Thinkstock

A.J. is a 90-year-old white woman who is brought to the emergency department by her son. He came from out of town for a visit and found his mother at home, weak and lying in bed. She says she has been slowly getting more and more "cold and tired" but "that is what happens when you live as long as I do." Her son had not seen her for 6 months and was concerned with how pale and frail she looked. He got scared when he noticed that his mother could not even walk to the bathroom without having to stop to catch her breath.

Critical Thinking

As you read through this assessment chapter, think about A.J. with the following questions in mind:

1. What are the possible causes of A.J.'s weakness, pallor, and shortness of breath?
2. What would be your priority assessment of A.J.?
3. What questions would you ask A.J.?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies might you expect to be ordered?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

interfere with normal hematologic function (see eTable 30-1 available on the website for this chapter).[12-14] Herbal therapy can interfere with clotting (see Complementary & Alternative Therapies box in Chapter 38 on p. 851). Antineoplastic agents used to treat malignant disorders (see Chapter 16) and antiretroviral agents used to treat human immunodeficiency virus (HIV) infection (see Chapter 15) may cause bone marrow depression. A patient previously treated with chemotherapy agents, particularly alkylating agents, has a higher risk of developing a secondary malignancy of leukemia or lymphoma. A patient on long-term anticoagulant therapy such as warfarin (Coumadin) could be at risk for bleeding problems.

Surgery or Other Treatments. Ask the patient about specific past surgical procedures, including splenectomy, tumor removal, prosthetic heart valve placement, surgical excision of the duodenum (where iron absorption occurs), partial or total gastrectomy (which removes parietal cells, thus reducing intrinsic factor needed for the absorption of cobalamin [vitamin B_{12}]), gastric bypass (where the duodenum may be bypassed and parietal cell surface area decreased), and ileal resection (where cobalamin absorption takes place). Also assess how wound healing progressed postoperatively and if and when any bleeding problems occurred in relation to the surgery. Discuss wound healing and bleeding as responses to past injuries (including minor trauma) and to dental extractions. Also determine the number of previous blood transfusions and possible complications during administration, since the risk of transfusion reactions and iron overload increases with the number of blood transfusions.

Functional Health Patterns. Key questions to ask a patient with a hematologic problem are presented in Table 30-4.

Health Perception–Health Management Pattern. Ask the patient to describe the usual and present state of health. Gather complete demographic data, including age, gender, race, and ethnic background. Ask if there is any family history of hematologic problems.

GENETIC RISK ALERT

- Hematologic problems that have a strong genetic link include sickle cell anemia, hemophilia, thalassemia, and hemochromatosis.
- People with a family history of these hematologic problems have a much greater risk of developing them.
- Other hematologic problems, such as leukemia, pernicious anemia, and clotting disorders, may have a genetic predisposition.

When taking a family health history, explore the following health problems: jaundice, anemia, malignancies, RBC disorders such as sickle cell disease, bleeding disorders such as hemophilia, and clotting disorders.

Assess risk factors such as alcohol and cigarette use that might disrupt the hematologic system. Explore alcohol use tactfully. Alcohol is a caustic agent to the GI mucosa and can cause damage that results in GI bleeding, esophageal varices, and decreased absorption of cobalamin and other nutrients. Chronic alcohol abusers frequently have vitamin deficiencies. Alcohol also exerts a damaging effect on platelet function and the liver, where clotting factors are produced. Consequently, bleeding problems can develop and should be anticipated in cases of known alcohol abuse. Illicit drug use is also important to document, since many of these drugs may affect hematopoiesis.

Cigarette smoking increases low-density lipoprotein (LDL) cholesterol and levels of CO_2, leading to hypoxia and altering the anticoagulant properties of the endothelium. Smoking increases platelet reactivity, plasma fibrinogen, hematocrit, and blood viscosity.

Nutritional-Metabolic Pattern. Obtain the patient's weight and determine if the patient has experienced anorexia, nausea, vomiting, or oral discomfort. A dietary history may provide clues about the cause of anemia. Iron, cobalamin, and folic acid are necessary for the development of RBCs. Iron and folic acid deficiencies are associated with inadequate intake of foods such as liver, meat, eggs, whole-grain and enriched breads and cereals, potatoes, leafy green vegetables, dried fruits, legumes, and citrus fruits. Folic acid deficiencies may be offset by a diet including foods that are also high in iron.[15]

Hematemesis (bright red, brown, or black vomitus) is a symptom of an underlying problem and should always be investigated. Peptic ulcer disease is a common cause of hematemesis.

Explore any changes in the skin's texture or color. Ask about bleeding of gum tissue. Note any *petechiae* or *ecchymotic* areas on the skin and, if present, document the frequency, size, and cause. The location of petechiae can indicate an accumulation of blood in the skin or mucous membranes. Small vessels leak under pressure, and the platelet numbers are insufficient to stop the bleeding. Petechiae are more likely to occur where clothing constricts the circulation.

Also ask about any lumps or swelling in the neck, armpits, or groin. Specifically, ask what the lumps feel like (i.e., hard or soft, tender or nontender) and if they are mobile or fixed. Primary lymph tumors are usually not painful. A nontender, consistently swollen lymph node may be a sign of a malignancy, such as Hodgkin's or non-Hodgkin's lymphoma. Lymph nodes that are enlarged and tender are usually associated with an acute infection.[16] Explore any reports of fever. Determine if the patient currently has a fever, recurring fevers, chills, or night sweats.

Ask patients if they have a history of cardiac or pulmonary diseases. Cardiovascular disorders such as valvular disease or hypertension may predispose patients to hemolysis. Many of the medications used to treat cardiovascular disease can also cause abnormalities in hematopoietic cell production or coagulation.

TABLE 30-4 HEALTH HISTORY

Hematologic System

Health Perception–Health Management
- Do you have any difficulty performing daily activities because of a lack of energy?*
- Do you smoke cigarettes or drink alcohol?*
- Do you take any prescribed or over-the-counter medications?*
- Are you taking any herbal products?* Home remedies?*
- Have you in the past or are you currently consuming illegal drugs? What agents? What route? How frequently? When did you last use?
- Have you ever received a blood transfusion?*
- Is there any family history of anemia, cancer, bleeding, or clotting problems?*
- Have you had any surgeries?*

Nutritional-Metabolic
- Do you have any difficulties with eating, chewing, or swallowing?*
- Have you had any mouth sores, sore tongue, swollen or sore gums, excessive oral bleeding?*
- What kind of diet do you follow? If a vegetarian, do you eat eggs, milk products, fish, chicken?
- How has your appetite been?
- Have you had any changes in your weight in the past year?*
- Do you take any vitamins, nutritional supplements, or iron?*
- Is nausea and vomiting a problem for you?*
- Have you ever experienced any unusual bleeding or bruising?*
- Have there been recent changes in the condition or color of your skin?*
- Have you experienced night sweats or cold intolerance?*
- Have you noticed any swelling in your armpits, neck, or groin?*

Elimination
- Have you had black or tarry stools?* Have you had light, clay-colored stools?*
- Have you noticed any blood or dark "tea color" in your urine?*
- Has your urine had a foul odor or cloudiness?
- Have you had any decrease in urine output?*
- Do you ever have diarrhea or change in bowel patterns?*

Activity-Exercise
- Do you have any shortness of breath at rest? With activity?*
- Do you have any limitations in joint motion?* Have any of your joints been swollen?*
- Do you have a problem with unsteady gait? Have you fallen recently?*
- After activity, do you ever notice bleeding or bruising?*

Sleep-Rest
- Have you experienced excessive fatigue recently?*
- Are you more fatigued than usual?*
- Do you feel rested on awakening? If no, explain.

Cognitive-Perceptual
- Have you experienced any numbness or tingling?*
- Have you had any problems with your vision, hearing, or taste?*
- Have you noticed any changes in your mental function?*
- Do you have any pain, such as bone, joint, or abdominal pain, or abdominal fullness?*
- Do you have pain when moving your joints?*
- Have your muscles been sore or achy recently?*

Self-Perception–Self-Concept
- Does your health problem make you feel differently about yourself?*
- Do you have any physical changes that cause you distress?*

Role-Relationship
- Does your occupation bring you into contact with hazardous substances?*
- Has your present illness caused a change in your roles and relationships?*

Sexuality-Reproductive
- Has your hematologic problem caused any sexual problems that concern you?*
- *Women*: When was your last menses? Do you consider your cycle normal? How long does your bleeding usually last? Have you had any increase in cramping or clotting?* Have there been any changes in the amount of flow?*
- *Men*: Do you experience impotence?*
- Have you had unprotected sex in the past 6 months?* Was your partner someone new or a person with whom you have had a long-term sexual relationship?

Coping–Stress Tolerance
- Do you have a support system to assist you when needed?
- What coping strategies do you use during exacerbation of symptoms?
- Do you experience any specific symptoms when you feel stressed?*

Value-Belief
- Do you have any personal or religious objection to receiving blood or blood products?*
- Do you have any conflicts between your planned therapy and your value-belief system?*

*If yes, describe.

Pulmonary disorders that lead to hypoxemia may cause chronic stimulation of erythropoietin and result in *polycythemia* (excessive RBCs).

Elimination Pattern. Ask if blood has been noted in the urine or stool or if black, tarry stools have occurred. Ask the patient if he or she has had a recent stool Hemoccult (blood) test or colonoscopy. Document any decrease in urine output or diarrhea.

Activity-Exercise Pattern. Because fatigue is a prominent symptom in many hematologic disorders, ask about feelings of tiredness. Also determine any weakness or complaints of heavy extremities. Document symptoms of apathy, malaise, dyspnea, or palpitations. Note any change in the patient's ability to perform activities of daily living (ADLs), especially as they relate to patient safety and a history of falling.

Sleep-Rest Pattern. Determine whether the patient feels rested after a night's sleep. Fatigue secondary to a hematologic problem often does not resolve after sleep.

Cognitive-Perceptual Pattern. *Arthralgia* (joint pain) may be caused by a hematologic problem and should be assessed. Pain in the joint may indicate an autoimmune disorder, such as rheumatoid arthritis, or may be caused by gout secondary to increased uric acid production as a result of a hematologic malignancy or hemolytic anemia. Aching bones may result from pressure of expanding bone marrow with diseases such as leukemia. *Hemarthrosis* (blood in a joint) occurs in the patient with bleeding disorders and can be painful.

Paresthesias, numbness, and tingling may be related to a hematologic disorder and should be noted. Also assess any changes in vision, hearing, taste, or mental status.

Self-Perception–Self-Concept Pattern. Determine the effect of the health problem on the patient's perception of self and personal abilities. Also assess the effect of certain problems, such as bruising, petechiae, and lymph node swelling, on the patient's personal appearance.

Role-Relationship Pattern. Question the patient about any past or present occupational or household exposures to radiation or chemicals. If such exposure has occurred, determine the type, amount, and duration of the exposure.

A person who has been exposed to radiation, as a treatment modality or by accident, has a higher incidence of certain hematologic problems. The same is true of a person who has been exposed to certain chemicals (e.g., benzene, lead, naphthalene, phenylbutazone). These chemicals are commonly used by potters, dry cleaners, and individuals involved with occupations that use adhesives. Ask the patient about a history in the military. Many Vietnam War veterans were exposed to a dioxin-containing defoliant (Agent Orange), which has been linked with leukemia and lymphoma. Also assess the effect of the present illness on the patient's usual roles and responsibilities.

Sexuality-Reproductive Pattern. Obtain a careful menstrual history from women, including the age at which menarche and menopause began, duration and amount of bleeding, incidence of clotting and cramping, and any associated problems. Ask men if they have any problems related to impotence, since this is common in men with hematologic problems. Also question the patient about sexual behavior because HIV infection is potentially a concern, particularly among high-risk groups.

CASE STUDY

Subjective Data

iStockphoto/Thinkstock

A focused subjective assessment of A.J. revealed the following information:

PMH: History of osteoarthritis. No surgical history. Prefers to take care of self with "natural therapy" and has not seen a health care provider for 10 years.

Medications: Metamucil 1 tbs PO daily; vitamins C, E, and D with calcium.

Health Perception–Health Management: A.J. denies family or personal history of anemia, cancer, or bleeding disorders. She believes she comes from a family with great genes for longevity because they "live off the land." She admits to drinking one glass of red wine with her evening meal "because it's good for your heart." She is a nonsmoker and just can't understand her gradual increase in shortness of breath with exertion. She states she really can't do anything anymore without having to stop and catch her breath. She says "it's tough getting old."

Nutritional-Metabolic: A.J. is living on a fixed income and therefore eats a lot of pasta "because it is cheap." She uses a lot of garlic for flavoring and the "health benefit of it." Although not a vegetarian, she states that she eats little meat.

Elimination: Denies black tarry stool. Occasional constipation. No problems with urination. Urine without odor.

Activity-Exercise: As noted above, A.J. is having difficulty performing ADLs without having to stop and catch her breath. Denies dyspnea at rest. States joints are stiff on arising in morning and after sitting but able to get around OK. States her walking is steady but weak. No history of falling.

Sleep-Rest: Typically sleeps 8-9 hr/night with no difficulty falling asleep. However, she still feels tired and needs to nap on and off during the day.

Cognitive-Perceptual: Denies any numbness or tingling. Admits to being a little hard-of-hearing but can still see "pretty good."

Value-Belief: Prefers natural therapies over traditional medication.

Coping–Stress Tolerance Pattern. The patient with a hematologic problem often needs assistance with ADLs. Ask the patient if adequate support is available to meet daily needs. Determine the patient's usual methods of handling stress. In the patient with platelet disorders or hemophilia, the potential for hemorrhage can be so frightening that usual life patterns may be drastically curtailed, affecting the person's quality of life. Explore the patient's understanding of the problem and provide teaching.

Value-Belief Pattern. Some hematologic problems are treated with blood transfusions or a bone marrow transplant. Determine if these types of treatments conflict with the patient's value-belief system, including the patient's cultural and religious beliefs related to blood and blood transfusions. If conflicts are identified, notify the health care provider.

Objective Data

Physical Examination. A complete physical examination is necessary to accurately examine all systems that affect or are affected by the hematologic system (see Chapter 3). Be aware that disorders of the hematologic system can manifest in various ways. Thus a patient's presenting symptoms may not immediately point to a hematologic problem (Table 30-5). For example, paresthesias of the lower extremities may not immediately appear to reflect a hematologic problem, but when combined with other clinical findings or risk factors, they may indicate cobalamin deficiency and resulting pernicious anemia. Although a full examination should be performed on patients suspected of a hematologic disorder, certain aspects of the physical examination are specifically relevant. These include skin, lymph nodes, spleen, and liver. Examination of the skin is discussed in Chapter 23; spleen and liver examination is found in Chapter 39.

Lymph Node Assessment. Lymph nodes are distributed throughout the body. Superficial lymph nodes can be evaluated by light palpation (Fig. 30-6). Deep lymph nodes cannot be

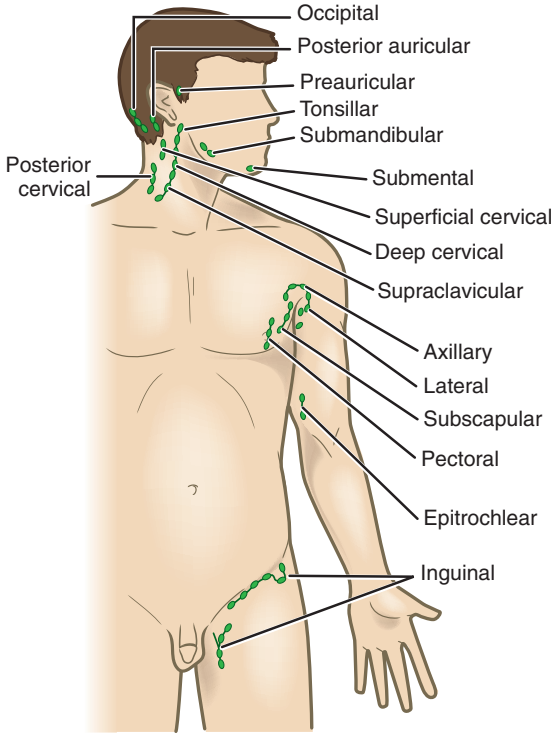

FIG. 30-6 Palpable superficial lymph nodes.

TABLE 30-5 ASSESSMENT ABNORMALITIES

Hematologic System

Finding	Description	Possible Etiology and Significance
Skin		
Pallor of skin or nail beds	Paleness. Decreased or absence of skin coloration.	Low Hgb level (anemia).
Flushing	Transient, episodic redness of skin (usually around face and neck).	Increase in Hgb (polycythemia), congestion of capillaries. Flushing of the palms of the hands or soles of the feet possible indication of anemia.
Jaundice	Yellow appearance of skin and mucous membranes.	Accumulation of bile pigment caused by rapid or excessive hemolysis or liver damage.
Cyanosis	Bluish discoloration of skin and mucous membranes.	Reduced Hgb, excessive concentration of deoxyhemoglobin in blood.
Excoriation	Scratch or abrasion of skin.	Scratching from intense pruritus.
Pruritus	Unpleasant cutaneous sensation that provokes the desire to rub or scratch the skin.	Hodgkin's lymphoma, cutaneous lymphomas, infiltrative leukemias, increased bilirubin.
Leg ulcers	Prominent on the malleoli on the ankles.	Sickle cell disease.
Angioma	Benign tumor consisting of blood or lymph vessels.	Most are congenital. Some may disappear spontaneously.
Telangiectasia	Small angioma with tendency to bleed. Focal red lesions, coarse or fine red lines.	Dilation of small vessels.
Spider nevus	Form of telangiectasia characterized by a round red central portion and branching radiations resembling the profile of a spider. Usually develop on face, neck, or chest.	Elevated estrogen levels as in pregnancy or liver disease.
Purpura	Any of a small group of conditions characterized by ecchymosis or other small hemorrhages in skin and mucous membranes.	Decreased platelets or clotting factors resulting in hemorrhage into the skin. Vascular abnormalities. Break in blood vessel walls resulting from trauma.
Petechiae	Pinpoint, nonraised, perfectly round area >2 mm. Purple, dark red, or brown.	Same as above.
Ecchymosis (bruise)	Small hemorrhagic spot, larger than petechiae; nonelevated. Round or irregular.	Same as above.
Hematoma	A localized collection of blood, usually clotted.	Same as above.
Chloroma	A tumor arising from myeloid tissue and containing a pale green pigment.	Acute myelogenous leukemia that has infiltrated the skin.
Plasmacytoma	A tumor arising from abnormal plasma cells.	Multiple myeloma that has infiltrated tissue.
Eyes		
Jaundiced sclera	Yellow appearance of the sclera.	Accumulation of bile pigment resulting from rapid or excessive hemolysis or liver disease or infiltration.
Conjunctival pallor	Paleness. Decreased or absence of coloration in the conjunctiva.	Low Hgb level (anemia).
Blurred vision, diplopia, visual field cuts	Decreased visual acuity or areas of blindness (field cuts).	Anemia, extreme leukocytosis, polycythemia may cause visual abnormalities. Thrombocytopenia may cause intraocular hemorrhage with visual abnormalities. Excessive clotting may cause thromboses in the circulation to the brain that cause visual field cuts.
Nose		
Epistaxis	Spontaneous bleeding from the nares.	May occur with low platelet counts, especially if the patient bends down for a long time, tries to lift a heavy item, or performs an intense Valsalva maneuver.
Mouth		
Gingival and mucous membrane changes	Pallor.	Low Hgb level (anemia).
	Gingival and mucosal ulceration, swelling, or bleeding.	Neutropenia. Inability of impaired leukocytes to combat oral infections. Thrombocytopenia. Gingival hyperplasia may be present with some types of leukemia.
Smooth tongue	Tongue surface smooth and shiny. Mucosa thin and red from decreased papillae.	Pernicious anemia, iron-deficiency anemia.
Musculoskeletal System		
Bone pain	Pain in pelvis, ribs, spine, sternum.	Multiple myeloma related to enlarged tumors that stretch periosteum; bone invasion by leukemia cells. Bone demineralization resulting from various malignancies. Sickle cell disease.
Joint swelling	Fluid-filled spaces surrounding the joints.	Occurs with hemophilia and sickle cell anemia as bleeding occurs into the joint (hemarthria) causing inflammation.
Arthralgia	Joint pain.	Sickle cell disease from hemarthrosis.

Continued

TABLE 30-5 ASSESSMENT ABNORMALITIES—cont'd

Hematologic System

Finding	Description	Possible Etiology and Significance
Lymph Nodes		
Lymphadenopathy	Lymph nodes enlarged (>1 cm). May be tender to touch.	Infection; foreign infiltrations. Systemic disease such as leukemia, lymphoma, Hodgkin's lymphoma, and metastatic cancer.
Heart and Chest		
Tachycardia	Heart rate >100 beats/min.	Compensatory mechanism in anemia to increase cardiac output.
Palpitations	Feeling the heartbeat, flutter, or pound in the chest.	Anemia, fluid volume overload, hypotension with impending syncope, hypertension, dysrhythmias.
Altered blood pressure	*Orthostasis:* heart rate >20 beats/min increase or blood pressure >20 mm Hg decrease from baseline when moving from a lying position to either sitting or standing.	Orthostasis is a common manifestation in anemia, especially if also accompanied by low blood volume.
	Hypotension: <90 mm Hg systolic or >40 mm Hg drop from baseline.	Hypotension may indicate an infectious process, blood loss, or compromised cardiovascular compensatory mechanisms.
	Hypertension: >140/90 mm Hg.	Hypertension may occur initially as a compensatory mechanism for anemia.
Sternal tenderness	Abnormal sensitivity to touch or pressure on sternum.	Leukemia resulting from increased bone marrow cellularity, causing increase in pressure and bone erosion. Multiple myeloma as a result of stretching of periosteum.
Low O_2 saturation	O_2-carrying capacity as reflected by the O_2 saturation by pulse oximetry.	O_2 saturation may be decreased in cases of severe anemia.
Abdomen		
Hepatomegaly	Palpable liver.	Leukemia, cirrhosis, or fibrosis secondary to iron overload from sickle cell disease or thalassemia.
Splenomegaly	Palpable spleen.	Anemia, thrombocytopenia, leukemia, lymphomas, leukopenia, mononucleosis, malaria, cirrhosis, trauma, portal hypertension.
Distended abdomen	A larger than normal abdominal profile. May be soft or firm, tender or nontender, and accompanied by other symptoms such as nausea, vomiting, or rebound tenderness.	Lymphoma may manifest as abdominal adenopathy, mass(es), or bowel obstruction.
Nervous System		
Paresthesias of feet and hands; ataxia	Numbness sensation and extreme sensitivity experienced in central and peripheral nerves. Impaired muscle movement.	Cobalamin (vitamin B_{12}) deficiency or folate deficiency.
Weakness	Lacking physical strength or energy.	Low Hgb level (anemia).
Headache, nuchal rigidity	Pain in the cranium, potentially involving one area or extending from the frontal area to the back of the neck.	Generalized headache is a common manifestation of mild to moderate anemia. Severe headache with or without visual disturbances may signal intracranial hemorrhage due to thrombocytopenia.

palpated and are best evaluated by radiologic examination. Assess lymph nodes symmetrically and take note of location, size (in centimeters), degree of fixation (e.g., movable, fixed), tenderness, and texture. To assess superficial lymph nodes, lightly palpate the nodes using the pads of the fingers. Then gently roll the skin over the area and concentrate on feeling for possible lymph node enlargement. Ordinarily, lymph nodes are not palpable in adults. If a node is palpable, it should be small (0.5 to 1 cm), mobile, firm, and nontender to be considered a normal finding. A node that is tender, hard, fixed, or enlarged (regardless if it is tender or not) is an abnormal finding and warrants further investigation. Tender nodes are usually a result of inflammation, whereas hard or fixed nodes suggest malignancy.[16]

Develop a sequence when examining the lymph nodes. A convenient sequence is to start at the head and neck. First, palpate the preauricular, posterior auricular, occipital, tonsillar, submandibular, submental, superficial cervical, posterior cervical chain, deep cervical chain, and supraclavicular nodes. Next, palpate the axillary lymph nodes and pectoral, subscapular, and lateral groups of nodes. Then examine the epitrochlear nodes, located in the antecubital fossa between the biceps and triceps muscles. Last, palpate the inguinal lymph nodes, found in the groin.

Palpation of Liver or Spleen. Both the liver and spleen are normally not detectable by palpating the abdomen. When they are enlarged, they may be detectable by percussion or palpation. Measure the degree of enlargement of the liver by the number of fingerbreadths it extends below the rib border. The spleen may be more difficult to detect because of its deep location in the left abdomen. Specific techniques for palpating the liver and spleen are described in Chapter 39.

Skin Assessment. In hematologic disorders, assessment of the skin may be a valuable source of information about the hematologic system. Examine the skin over the entire body in a systematic manner (e.g., starting with the face and oral cavity

FOCUSED ASSESSMENT

Hematologic System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Unusual bleeding or bruising	Y	N
Black, tarry stool	Y	N
Blood in vomitus	Y	N
Swelling in neck, armpits, or groin	Y	N
Dark-colored urine	Y	N
Fatigue	Y	N
Heart palpitations	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values.

CBC	✓
White blood cell count with differential	✓
Clotting: PT, INR, aPTT, platelets	✓
Hgb, Hct	✓

Objective: Physical Examination

Inspect

Skin for lesions or color changes	✓

Auscultate

BP for alteration or orthostasis	✓

Palpate

Pulse for tachycardia	✓
Liver and spleen for enlargement	✓
Lymph nodes for lymphadenopathy	✓

aPTT, Activated partial thromboplastin time; *INR,* international normalized ratio; *PT,* prothrombin time.

and moving downward over the body). In patients with RBC disorders the skin may be pale or pasty, or it may have a cyanotic tinge in severe anemia. Erythrocytosis often produces small vessel occlusions causing a purple, mottled appearance of the face, nose, fingers, or toes. Clubbing of the fingers can be seen with chronic anemia such as in patients with sickle cell disease. Leukocyte disorders may cause infectious skin lesions or malignant nodular lesions. These may occur anywhere and have a variable distribution pattern. During the physical assessment of the skin, look carefully for **petechiae** (small purplish red pinpoint lesions), **ecchymoses** (bruising), and *spider nevus* (a form of *telangiectasia*) (see Table 30-5) because these can indicate bleeding disorders. In general, skin and mucosal bleeding indicates a platelet disorder, whereas spontaneous bleeding into joints or muscles indicates a coagulation factor problem. Excessive bleeding from trauma can be due to either or both.[17]

A *focused assessment* is used to evaluate the status of previously identified hematologic problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the hematologic system is presented in the box above.

DIAGNOSTIC STUDIES OF HEMATOLOGIC SYSTEM

The most direct means of evaluating the hematologic system is through laboratory analysis and other diagnostic studies. Diagnostic tests of the hematologic system are presented in Tables 30-6, 30-7, 30-9, and 30-10.

CASE STUDY

Objective Data: Physical Examination

iStockphoto/Thinkstock

Physical examination findings of A.J. are as follows: BP 100/70 (lying), 88/60 (standing); apical pulse 110 (lying), 124 (standing), but regular in rhythm. Respiratory rate 26, temperature 96.8° F (36° C), O_2 saturation 90% on room air. No jugular venous distention. Weight: 106 lb (48 kg). Height: 5 ft 1 in. Skin pale. No jaundice noted. Conjunctiva pale. Tongue smooth and shiny. Lungs clear but diminished breath sounds in the bases bilaterally. No visible bleeding. No enlarged lymph nodes, spleen, or liver noted. General weakness with dyspnea on exertion. No numbness or tingling or peripheral edema.

As you continue to read this chapter, consider diagnostic studies you would anticipate being performed for A.J.

Laboratory Studies

Complete Blood Count. The complete blood count (CBC) involves several laboratory tests (Table 30-6). In addition to the CBC, a *peripheral smear* may be ordered. The smear is used to look at the *morphology* (shape and appearance) of the blood cells and may assist with the diagnosis. For example, a large number of immature *blast* WBCs may indicate acute leukemia.

Although the status of each cell type is important, the entire system may be disrupted by diseases or by treatment of diseases. When the entire CBC is suppressed, a condition termed **pancytopenia** (marked decrease in the number of RBCs, WBCs, and platelets) exists. The effects of aging on hematologic studies are presented in Table 30-4.

Red Blood Cells. Normal values of some RBC tests are reported separately for men and for women because normal values are based on body mass, and men usually have a larger body mass than women.

The *hemoglobin (Hgb) value* is reduced in cases of anemia, hemorrhage, and hemodilution, such as that occurring when the fluid volume is excessive. Increases in hemoglobin are found in polycythemia or in states of hemoconcentration, which can develop from volume depletion (dehydration).

The *hematocrit (Hct) value* is determined by spinning blood in a centrifuge, which causes RBCs and plasma to separate. The RBCs, being the heavier elements, settle to the bottom. The hematocrit value represents the percentage of RBCs compared with the total blood volume. Reductions and elevations of the hematocrit value are seen in the same conditions that raise and lower the hemoglobin value. The hematocrit value generally is three times the hemoglobin value.

The total RBC count is reported as RBC $\times 10^6/\mu L$. However, the total RBC count is not always reliable in determining the adequacy of RBC function. Consequently, other data, such as hemoglobin, hematocrit, and RBC indices, must also be evaluated. The RBC count is altered by the same conditions that raise and lower the hemoglobin and hematocrit values.

RBC indices are special indicators that reflect RBC volume, color, and hemoglobin saturation (see Table 30-6). These parameters may provide insight into the cause of anemia. (The significance of these parameters is discussed further in Chapter 31.)

White Blood Cells. The WBC count provides two different sets of information. The first is a total count of WBCs in 1 µL of peripheral blood. Elevations in WBC count over 11,000/µL are associated with infection, inflammation, tissue injury or death,

TABLE 30-6 DIAGNOSTIC STUDIES

Complete Blood Count Studies

Study	Description and Purpose	Reference Intervals
Hemoglobin (Hgb)	Measurement of gas-carrying capacity of RBC.	*Female:* 11.7-16.0 g/dL (117-160 g/L) *Male:* 13.2-17.3 g/dL (132-173 g/L)
Hematocrit (Hct)	Measure of packed cell volume of RBCs expressed as a percentage of the total blood volume.	*Female:* 35%-47% (0.35-0.47) *Male:* 39%-50% (0.39-0.50)
Total RBC count	Number of circulating RBCs.	*Female:* 3.8-5.1 × 10^6/μL (3.8-5.1 × 10^{12}/L) *Male:* 4.3-5.7 × 10^6/μL (4.3-5.7 × 10^{12}/L)
Red cell indices		
MCV = $\frac{\text{Hct} \times 10}{\text{RBC} \times 10^6}$	Determination of relative size of RBCs. Low MCV reflection of microcytosis, high MCV reflection of macrocytosis.	80-100 fL
MCH = $\frac{\text{Hgb} \times 10}{\text{RBC} \times 10^6}$	Measurement of average weight of Hgb/RBCs. Low MCH indication of microcytosis or hypochromia, high MCH indication of macrocytosis.	27-34 pg
MCHC = $\frac{\text{Hgb} \times 100}{\text{Hct}}$	Evaluation of RBC saturation with Hgb. Low MCHC indication of hypochromia, high MCHC evident in spherocytosis.	32%-37% (0.32-0.37)
RBC morphology	Examination of the shape and size of RBCs.	No variation in RBC morphology
WBC count	Measurement of total number of leukocytes.	4000-11,000/μL (4-11 × 10^9/L)
WBC differential	Determination of whether each kind of WBC is present in proper proportion. Absolute value of each type of WBC can be determined by multiplying the percentage of cell type by total WBC count and dividing by 100.	*Neutrophils:* 50%-70% (0.50-0.70) *Eosinophils:* 0%-4% (0-0.04) *Basophils:* 0%-2% (0-0.02) *Lymphocytes:* 20%-40% (0.20-0.40) *Monocytes:* 4%-8% (0.04-0.08)
Platelet count	Number of platelets available to maintain platelet clotting functions (not measurement of quality of platelet function).	150,000-400,000/μL (150-400 × 10^9/L)

MCH, Mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume.

and malignancies (e.g., leukemia, lymphoma). Although the degree of WBC elevation does not necessarily predict the severity of illness, it can provide clues to the etiology. Certain types of leukemias are more likely to produce extremely high WBC counts (e.g., greater than 25,000/μL). A WBC count less than 4000/μL **(leukopenia)** is associated with bone marrow depression, severe or chronic illness, and some types of leukemia.

The second aspect of the WBC count, the *differential count,* measures the percentage of each type of leukocyte. The WBC differential provides valuable clues in determining the cause of illness. When infections are severe, more granulocytes are released from the bone marrow as a compensatory mechanism. To meet the increased demand, many young, immature polymorphonuclear neutrophils (bands) are released into circulation. The usual laboratory procedure is to report the WBCs in order of maturity, with the less mature forms on the left side of the written report. Consequently, the existence of many immature cells is termed a *"shift to the left."*

The WBC differential is of considerable significance because it is possible for the total WBC count to remain essentially normal despite a marked change in one type of leukocyte. For example, a patient may have a normal WBC count of 8800/μL, but the differential count may show that the proportion of lymphocytes is reduced to 10%. This is an abnormal finding that warrants further investigation.

When the lymphocyte count is low, an absolute lymphocyte count (ALC) may be tabulated. If the ALC is low, other diagnostic tests may be performed to look for an underlying reason.

When the bone marrow does not produce enough neutrophils, neutropenia occurs. **Neutropenia** is a condition in which the absolute neutrophil count (ANC) is less than 1000 cells/μL; severe neutropenia is associated with an ANC of less than 500 cells/μL. The ANC is determined by multiplying the total WBC count by the percentage of neutrophils. Neutropenia results from a number of disease processes, such as leukemia, or from bone marrow depression (see Chapter 31), and is associated with a high risk of infection and death from sepsis.

Platelet Count. The platelet count is the number of platelets per microliter of blood. Normal platelet counts are between 150,000 and 400,000/μL. Counts below 100,000/μL signify a condition termed **thrombocytopenia.** Bleeding may occur with thrombocytopenia. Spontaneous hemorrhage is possible once platelet counts fall below 10,000/μL.[18] A more extensive description of clotting studies is presented in Table 30-7.

Thrombocytosis is defined as excessive platelets, a disorder that occurs with inflammation and some malignant disorders (see Chapter 31). The most likely complication related to thrombocytosis is excessive clotting.

Blood Typing and Rh Factor. Blood group antigens (A and B) are found only on RBC membranes and form the basis for the ABO blood typing system. The presence or absence of one or both of the two inherited antigens is the basis for the four blood groups: A, B, AB, and O. Blood group A has A antigens, group B has B antigens, group AB has both antigens, and group O has neither A nor B antigens. Each person has antibodies in the serum termed *anti-A* and *anti-B* that react with A or B antigens. These antibodies are found when the corresponding antigen is absent from the RBC surface. For example, B antibodies are found in the serum of people with blood group A (Table 30-8).

Blood reactions based on ABO incompatibilities result from intravascular hemolysis of the RBCs. RBCs *agglutinate* (or clump) when a serum antibody is present to react with the antigens on the RBC membrane. For example, agglutination would occur in the blood of a person with type A blood when he or she receives blood transfused from a person with B antigens (i.e., type B or AB). The anti-B antibodies in the type A

TABLE 30-7 DIAGNOSTIC STUDIES

Clotting Studies

Study	Description and Purpose	Reference Intervals
Activated clotting time (ACT)	Evaluation of intrinsic coagulation status. More accurate than aPTT. Used during dialysis, coronary artery bypass procedure, arteriograms.	70-120 sec
Activated partial thromboplastin time (aPTT)	Assessment of intrinsic coagulation by measuring factors I, II, V, VIII, IX, X, XI, XII. Longer in patients using heparin.	25-35 sec
Antithrombin	Naturally occurring protein synthesized by liver that inhibits coagulation through inactivation of thrombin and other factors. Depleted in DIC.	21-30 mg/dL (210-300 mg/L) or 80%-120% of standard
Bleeding time	Measurement of timed, small skin incision bleeds. Reflection of ability of small blood vessels to constrict.	2-7 min
Capillary fragility test (tourniquet test, Rumpel-Leede test)	Reflection of capillary integrity when positive or negative pressure is applied to various areas of the body. Positive test indication of thrombocytopenia, toxic vascular reactions.	No petechiae or negative
Clot retraction	Reflection of clot shrinkage or retraction from sides of test tube after 24 hr. Used to confirm a platelet problem.	Begins in 1 hr. Maximum by 24 hr
D-dimer	Assay to measure a fragment of fibrin that is formed as a result of fibrin degradation and clot lysis. Used as an adjunctive measure in diagnosis of hypercoagulable conditions (e.g., DIC, pulmonary embolism).	<250 ng/mL (<250 mcg/L)
Fibrin split products (FSPs), or fibrin degradation products (FDPs)	Reflection of degree of fibrinolysis and predisposition to bleed (if present). Screening test for DIC. Elevated levels associated with DIC, advanced malignancy, severe inflammation.	<10 mcg/mL (<10 mg/L)
Fibrinogen	Reflection of level of fibrinogen. Increase in fibrinogen possible indication of enhancement of fibrin formation, making patient hypercoagulable. Decrease in fibrinogen indicates that patient possibly predisposed to bleeding.	200-400 mg/dL (2-4 g/L)
International normalized ratio (INR)	Standardized system of reporting PT based on a reference calibration model and calculated by comparing the patient's PT with a control value.	2-3*
Platelet count	Number of circulating platelets.	150,000-400,000/μL
Prothrombin time (PT)	Assessment of extrinsic coagulation by measurement of factors I, II, V, VII, X.	11-16 sec
Thrombin time	Reflection of adequacy of thrombin. Prolonged thrombin time indicates that coagulation is inadequate secondary to decreased thrombin activity.	17-23 sec

*Desired therapeutic level with warfarin (Coumadin).
DIC, Disseminated intravascular coagulation.

blood would react with the B antigens, thus initiating the process that results in RBC hemolysis.

The *Rh system* is based on a third antigen, D, which is also on the RBC membrane. Rh-positive people have the D antigen, whereas Rh-negative people do not. Rh-positive blood is indicated with a "+" after the ABO group (e.g., AB+). A Coombs test is used to evaluate the person's Rh status (Table 30-9).

As a result of transfusion therapy or during childbirth, an Rh-negative person may be exposed to Rh-positive blood. After exposure during childbirth the mother forms an antibody, anti-D, which acts against Rh antigens. (Rh-positive people normally have no anti-D.) In subsequent pregnancies the mother's anti-D antibodies can cross the placenta and attack the RBCs of a fetus who is Rh-positive, thus causing hemolysis of the RBCs. A pregnant Rh-negative woman should receive Rho(D) immune globulin (RhoGAM) injections to prevent anti-D antibodies from forming.

Iron Metabolism. The laboratory tests used to evaluate iron metabolism include serum iron, total iron-binding capacity (TIBC), serum ferritin, and transferrin saturation. Additional tests for nutritional deficiencies leading to defective RBC production may also be done (see Table 30-9).

Serum iron is a measurement of the amount of protein-bound iron circulating in the serum. TIBC provides a measurement of all proteins that act to bind or transport iron between the tissues and bone marrow. Although this indirect measurement is a general reflection of the amount of transferrin present in the circulation, it overestimates transferrin levels by 16% to 20% because it also measures other proteins that can bind iron. These alternative proteins bind iron only when transferrin is

TABLE 30-8 ABO BLOOD GROUPS AND COMPATIBILITIES*

Recipient's Blood Group	A	B	AB (Universal Recipient)	O (Universal Donor)
RBC antigen	A	B	A and B	Neither
Plasma or serum antibody	Anti-B	Anti-A	Neither anti-A nor anti-B	Anti-A and anti-B
Compatible donor for RBC transfusions	A and O	B and O	A, B, AB, and O	O
Compatible donor for plasma transfusions	A and AB	B and AB	AB	A, B, AB, and O
Percent of population	42%	10%	6%	42%

*ABO blood groups are named for the antigen found on the RBCs. Compatibility is based on the antibodies present in the serum.

TABLE 30-9 DIAGNOSTIC STUDIES

Miscellaneous Blood Studies

Study	Description and Purpose	Normal Values
Bilirubin	Measurement of degree of RBC hemolysis or liver's inability to excrete normal quantities of bilirubin. Increase in indirect bilirubin with hemolytic problems.	*Total:* 0.2-1.2 mg/dL (3.0-21.0 µmol/L) *Direct:* 0.1-0.3 mg/dL (1.7-5.1 µmol/L) *Indirect:* 0.1-1.0 mg/dL (1.7-17.0 µmol/L)
Coombs test	Differentiation among types of hemolytic anemias. Detection of immune antibodies and Rh factor.	Negative
• Direct	Detection of antibodies that are attached to RBCs.	Negative
• Indirect	Detection of antibodies in serum.	Negative
Cobalamin (vitamin B_{12})	Level of cobalamin available for production of new RBCs.	200-835 pg/mL (148-616 pmol/L)
Erythropoietin	Measurement of degree of hormonal stimulation to the bone marrow to stimulate the release of RBCs.	5-30 mU/mL (5-30 U/L)
Erythrocyte sedimentation rate (ESR)	Measurement of sedimentation or settling of RBCs in 1 hr. Inflammatory process causes an alteration in plasma proteins, resulting in aggregation of RBCs and making them heavier. The faster the sedimentation rate, the higher the ESR.	<30 mm/hr (some gender variation)
Ferritin	Major iron storage protein. Is normally present in blood in concentrations directly related to iron storage.	10-250 ng/mL (10-250 mcg/L)
Folic acid (folate)	Amount of folic acid (folate) available for RBC production.	3-16 ng/mL (7-36 nmol/L)
Hemoglobin (Hgb) electrophoresis	Proteins involved in development of the Hgb molecule have a definitive pattern of separation on electrophoresis. This pattern is altered with abnormal Hgb synthesis (e.g., thalassemia) or sickle cell anemia (where Hgb S is increased).	*Normal Hb A1:* >95% *Hb A2:* 1.5%-3.7% *Hb F:* <2% *Hb S:* 0% *Hb C:* 0%
Homocysteine	An amino acid formed from methionine. Rapidly metabolized through pathways that require cobalamin (vitamin B_{12}) and folic acid. Increased in cobalamin and folic acid deficiency.	*Male:* 5.2-12.9 µmol/L *Female:* 3.7-10.4 µmol/L
Iron		
• Serum iron	Reflection of amount of iron combined with proteins in serum. Accurate indication of status of iron storage and use.	50-175 mcg/dL (9-31.3 µmol/L)
• Total iron-binding capacity (TIBC)	Measurement of all proteins available for binding iron. Transferrin represents the largest quantity of iron-binding proteins. Therefore TIBC is an indirect measure of transferrin, an evaluation of amount of extra iron that can be carried.	250-425 mcg/dL (45-76 µmol/L)
Methylmalonic acid (MMA)	Indirect test for cobalamin. MMA metabolism requires cobalamin. Helps differentiate cobalamin deficiency from folic acid deficiency.	<0.2 µmol/L (<2.4 mcg/dL)
Reticulocyte count	Measurement of immature RBCs, a reflection of bone marrow activity in producing RBCs.	0.5%-1.5% of RBC count (0.005-0.015 of RBC count)
Serum protein electrophoresis (SPEP)	Separates proteins in the blood on basis of electric charge. Helps detect hyperglobulinemic states, such as in multiple myeloma or some lymphomas.	Normal banding pattern of albumin and globulins. Increase in any protein ("protein spike") is abnormal.
Transferrin	The largest of proteins that bind to iron. Increased in most people with iron-deficiency anemia.	190-380 mg/dL (1.9-3.8 g/L)
Transferrin saturation (%)	Decreased in iron-deficiency anemia and increased in hemolytic and megaloblastic anemia.	15%-50%

more than half saturated. Also, TIBC varies inversely with tissue iron stores; it is higher when iron stores are low and lower when iron stores are high.

Transferrin saturation is a better indicator of the availability of iron for erythropoiesis than serum iron because, unlike serum iron, the iron bound to transferrin is readily available for the body to use. Transferrin saturation is calculated by dividing serum iron by TIBC and multiplying by 100. For example, a patient with a serum iron level of 100 mcg/dL and a TIBC of 300 mcg/dL would have a transferrin saturation of about 33%.

Under normal conditions, the serum ferritin concentration correlates closely with body iron stores. In normal patients, 1 ng/mL of ferritin corresponds to 8 to 10 mg of stored iron.

Radiologic Studies

Radiologic studies for the hematology system involve primarily the use of computed tomography (CT) or magnetic resonance imaging (MRI) for evaluating the spleen, liver, and lymph nodes. Nursing responsibilities related to these studies are presented in Table 30-10.

Biopsies

Biopsy procedures specific to hematologic assessment are bone marrow examination and lymph node biopsy. In general, these procedures are done because a peripheral blood smear is nonspecific and usually a diagnosis cannot be established from a peripheral blood smear. Furthermore, a biopsy provides additional information about a hematologic problem that is needed for diagnosis and treatment planning.

Bone Marrow Examination. Bone marrow examination is important in the evaluation of many hematologic disorders. The examination of the marrow may involve aspiration only or aspiration with biopsy. The benefits gained from bone marrow examination are (1) a full evaluation of hematopoiesis and (2)

TABLE 30-10 DIAGNOSTIC STUDIES

Hematologic System

Study	Description and Purpose	Nursing Responsibility
Blood Studies	See Tables 30-6, 30-7, and 30-9.	
Urine Studies		
Bence Jones protein	An electrophoretic measurement is used to detect the Bence Jones protein, which is found in most cases of multiple myeloma. Negative finding is considered normal.	Acquire random urine specimen.
Radioisotope Studies		
Liver and spleen scan	Radioactive isotope is injected IV. Images from the radioactive emissions are used to evaluate the structure of spleen and liver. Patient is not a source of radioactivity.	No specific nursing responsibilities.
Bone scan	Same procedure as for the spleen scan except used for evaluating the structure of the bones.	Patient needs to lie still during the imaging. Patient may be asked to drink 4-6 glasses of water and then void before the imaging (to see pelvic bones).
Radiologic Studies		
Skeletal x-ray	X-rays done as a bone survey to detect lytic lesions associated with multiple myeloma. Bone scans do not identify lesions in this condition because there is no uptake of radioactive isotopes due to lack of blood supply.	No specific nursing responsibilities.
Liver, spleen, or abdominal ultrasound	Noninvasive probe is lubricated and slid across the abdomen to detect the density and borders of the abdominal organs. Can detect irregular borders, masses, vascular structure, and biliary tree.	Patients must be comfortable lying flat and having the probe compress the abdomen.
Positron emission tomography (PET)	A nuclear tracer substance is injected and is taken up by metabolically active cells. The follow-up scan shows different-colored tissues based on the metabolic rate. "Hot spots" reflect increased glucose consumption that is typical of tumors. A valuable diagnostic tool to detect active malignancy because it highlights areas with increased metabolism. PET or CT scanning may also be used.	IV access is required for injection of the tracer substance. Patients should have nothing by mouth, except water and medications, for at least 4 hr before the test. IV solutions containing glucose may be held. Patients who are glucose intolerant or diabetic may need adjustments in their medications. Bowel preparation may also be needed, depending on the area being studied.
Computed tomography (CT)	Noninvasive radiologic examination using computer-assisted x-ray evaluates the lymph nodes. Contrast medium often is used in abdominal studies of liver or spleen. Spiral (helical) CT scans are used to evaluate lymph nodes.	Investigate iodine sensitivity if contrast medium used.
Magnetic resonance imaging (MRI)	Noninvasive procedure produces sensitive images of soft tissue without using contrast media. No ionizing radiation is required. Technique is used to evaluate spleen, liver, and lymph nodes.	Instruct patient to remove all metal objects and ask about any history of surgical insertion of staples, plates, or other metal appliances. Inform patient of need to lie still in small chamber.
Biopsies		
Bone marrow	Technique involves removal of bone marrow through a locally anesthetized site to evaluate the status of the blood-forming tissue. It is used to diagnose multiple myeloma, all types of leukemia, and some lymphomas and to stage some solid tumors (e.g., breast cancer). It is also done to assess efficacy of leukemia therapy (see Chapter 31).	Explain procedure to patient. Obtain signed consent form. Ensure that a *time-out** is done before procedure. Consider preprocedure analgesic administration to enhance patient comfort and cooperation. Apply pressure dressing after procedure. Assess biopsy site for bleeding.
Lymph node biopsy	Purpose is to obtain lymph tissue for histologic examination to determine diagnosis and therapy.	Explain procedure to patient. Obtain signed consent form. Use sterile technique in dressing changes after procedure.
• Open	Performed in the operating room or procedure area using either local or general anesthesia. An incision is made, and the lymph node and surrounding tissue are dissected (excised) whenever possible.	Apply direct pressure to the area after the biopsy procedure to achieve hemostasis. Observe site for bleeding and monitor vital signs, especially if the platelet count is low. The sterile dressing should be changed as ordered, and the wound should be inspected for healing and infection.
• Closed (needle) or fine needle	Performed by a physician at the bedside or in an outpatient area. An extremely small needle is used to reduce the risk of tracking malignant cells through normal subcutaneous tissue.	
Molecular, Cytogenetic, and Gene Analysis Studies		
Fluorescence in situ hybridization (FISH) **Comparative genomic hybridization (CGH)** **Spectral karyotyping (SKY)**	Tests are performed on malignant cells, either peripheral blood (e.g., leukemia) or biopsy specimen (bone marrow, lymph node) to assess genetic or chromosomal abnormalities of cancer cells. May be useful in confirming diagnosis and determining treatment modalities and prognosis.	No specific nursing responsibilities. Explain purpose of testing to patient.

*Time-out is done just before the procedure starts to verify patient identification, surgical procedure, and surgical site.

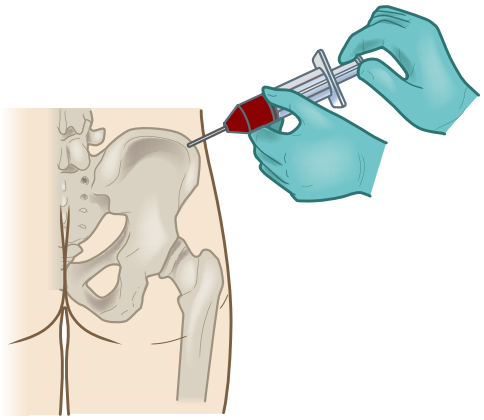

FIG. 30-7 Bone marrow aspiration from the posterior iliac crest.

the ability to obtain specimens for cytopathologic and chromosomal abnormalities. The preferred site for both aspiration and biopsy of bone marrow is the posterior iliac crest.[19] The anterior iliac crest and sternum are alternative sites. However, the sternum is usually used only for aspiration. Bone marrow aspiration and biopsy are performed by a physician or specially credentialed nurse. Local anesthesia and sedation may be used to minimize anxiety and pain that the patient may experience.

For bone marrow aspiration, the skin over the puncture site is cleansed with a bactericidal agent. The skin, subcutaneous tissue, and periosteum are infiltrated with a local anesthetic agent. The patient may be uncomfortable when the periosteum is penetrated. Once the area is anesthetized, a bone marrow needle is inserted through the cortex of the bone. The stylet of the needle is then removed, the hub is attached to a 10-mL syringe, and 0.2 to 0.5 mL of the fluid marrow is aspirated (Fig. 30-7). The patient experiences pain with aspiration. Although it lasts only a few seconds, the pain may be quite uncomfortable. After the marrow aspiration, the needle is removed. Pressure is applied over the aspiration site to ensure hemostasis.

Although complications of bone marrow aspiration are minimal, there is a possibility of damaging underlying structures. This hazard is greatest in aspiration procedures involving the sternum.[20] Other complications include hemorrhage (especially if the patient is thrombocytopenic) and infection (especially if the patient is leukopenic).

The needle aspiration or biopsy site is covered with a sterile pressure dressing. Monitor the patient's vital signs until stable, and assess the site for excess drainage or bleeding. If bleeding is present, advise the patient to lie on the side for 30 to 60 minutes to maintain pressure on the site. If the bed is too soft, have the patient lie on a rolled towel to provide additional pressure. Analgesics for postprocedure pain may be administered. Soreness over the puncture site for 3 to 4 days after the procedure is normal.[20]

CASE STUDY

Objective Data: Diagnostic Studies

iStockphoto/Thinkstock

The health care provider orders the following initial diagnostic studies for A.J.:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- Arterial blood gases
- Chest x-ray

A.J.'s CBC reveals severe anemia with an Hgb of 5.9 g/dL, Hct of 18.2%. The health care provider orders more blood work, including RBC indices, and admits her to the hospital for further evaluation.

Lymph Node Biopsy. Lymph node biopsy involves obtaining lymph tissue for histologic examination to determine the diagnosis and help plan therapy. This may be accomplished by either an open biopsy or a closed (needle) biopsy.

If the results from a needle biopsy are negative, it may only indicate that the cancer cells were not part of the tissue in the biopsy specimen. However, a positive finding is sufficient evidence for confirming a diagnosis. This technique is rarely used to confirm an initial diagnosis because larger specimens are usually required to perform cytopathologic tests, but it may be used to validate disease recurrence or a new site of disease.

Molecular Cytogenetics and Gene Analysis

Testing for specific genetic or chromosomal variations in hematologic conditions is often helpful in diagnosis and staging. These results also help determine the treatment options and prognosis. If a large number of abnormal cells are circulating in the blood, such as in acute leukemia, these tests may be done by obtaining peripheral blood. However, testing is usually done on samples from bone marrow and lymph node biopsies. For example, fluorescence in situ hybridization (FISH) can identify specific areas by attaching a probe to a targeted region of deoxyribonucleic acid (DNA). It may be used to illuminate an abnormal extra chromosome 8, which is common in certain leukemias. Spectral karyotyping (SKY) allows each set of chromosomes to be painted different colors. It can be used to identify the chromosomal translocation of 22 to 9 in the Philadelphia chromosome of chronic myelogenous leukemia. More information on genetics is in Chapter 13.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. An individual who lives at a high altitude may normally have an increased RBC count because
   - **a.** high altitudes cause vascular fluid loss, leading to hemoconcentration.
   - **b.** hypoxia caused by decreased atmospheric oxygen stimulates erythropoiesis.
   - **c.** the function of the spleen in removing old RBCs is impaired at high altitudes.
   - **d.** impaired production of leukocytes and platelets leads to proportionally higher red cell counts.
2. Malignant disorders that arise from granulocytic cells in the bone marrow will have the primary effect of causing
   - **a.** risk for hemorrhage.
   - **b.** altered oxygenation.
   - **c.** decreased production of antibodies.
   - **d.** decreased phagocytosis of bacteria.
3. An anticoagulant such as warfarin (Coumadin) that interferes with prothrombin production will alter the clotting mechanism during
   - **a.** platelet aggregation.
   - **b.** activation of thrombin.
   - **c.** the release of tissue thromboplastin.
   - **d.** stimulation of factor activation complex.

4. When reviewing laboratory results of an 83-year-old patient with an infection, the nurse would expect to find
   a. minimal leukocytosis.
   b. decreased platelet count.
   c. increased hemoglobin and hematocrit levels.
   d. decreased erythrocyte sedimentation rate (ESR).
5. Significant information obtained from the patient's health history that relates to the hematologic system includes
   a. jaundice.
   b. bladder surgery.
   c. early menopause.
   d. multiple pregnancies.
6. While assessing the lymph nodes, the nurse should
   a. apply gentle, firm pressure to deep lymph nodes.
   b. palpate the deep cervical and supraclavicular nodes last.
   c. lightly palpate superficial lymph nodes with the pads of the fingers.
   d. use the tips of the second, third, and fourth fingers to apply deep palpation.
7. If a lymph node is palpated, what is a normal finding?
   a. Hard, fixed nodes
   b. Firm, mobile nodes
   c. Enlarged, tender nodes
   d. Hard, nontender nodes
8. Nursing care for a patient immediately after a bone marrow biopsy and aspiration includes *(select all that apply)*
   a. administering analgesics as necessary.
   b. preparing to administer a blood transfusion.
   c. instructing on need to lie still with a sterile pressure dressing intact.
   d. monitoring vital signs and assessing the site for excess drainage or bleeding.
   e. instructing on the need for preprocedure and postprocedure antibiotic medications.
9. You are taking care of a male patient who has the following laboratory values from his CBC: WBC $6.5 \times 10^3/\mu L$, Hgb 13.4 g/dL, Hct 40%, platelets $50 \times 10^3/\mu L$. What are you most concerned about?
   a. Your patient is neutropenic.
   b. Your patient has an infection.
   c. Your patient is at risk for bleeding.
   d. Your patient is at fall risk due to his anemia.

1. b, 2. d, 3. b, 4. a, 5. a, 6. c, 7. b, 8. a, c, d, 9. c

LEARNING OUTCOMES

1. Describe the general clinical manifestations and complications of anemia.
2. Differentiate the etiologies, clinical manifestations, diagnostic findings, and nursing and collaborative management of iron-deficiency, megaloblastic, and aplastic anemias and anemia of chronic disease.
3. Explain the nursing management of anemia secondary to blood loss.
4. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of anemia caused by increased erythrocyte destruction, including sickle cell disease and acquired hemolytic anemias.
5. Describe the pathophysiology and nursing and collaborative management of polycythemia.
6. Explain the pathophysiology, clinical manifestations, and nursing and collaborative management of various types of thrombocytopenia.
7. Describe the types, clinical manifestations, diagnostic findings, and nursing and collaborative management of hemophilia and von Willebrand disease.
8. Explain the pathophysiology, diagnostic findings, and nursing and collaborative management of disseminated intravascular coagulation.
9. Describe the etiology, clinical manifestations, and nursing and collaborative management of neutropenia.
10. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of myelodysplastic syndrome.
11. Compare and contrast the major types of leukemia regarding distinguishing clinical and laboratory findings.
12. Explain the nursing and collaborative management of acute and chronic leukemias.
13. Compare Hodgkin's lymphoma and non-Hodgkin's lymphomas in terms of clinical manifestations, staging, and nursing and collaborative management.
14. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of multiple myeloma.
15. Describe the spleen disorders and related collaborative care.
16. Describe the nursing management of the patient receiving transfusions of blood and blood components.

CULTURAL & ETHNIC HEALTH DISPARITIES

Hematologic Problems

- Sickle cell disease has a high incidence among African Americans.
- Thalassemia has a high incidence among African Americans and people of Mediterranean origin.
- Tay-Sachs disease has the highest incidence in families of Eastern European Jewish origin, especially the Ashkenazi Jews.
- Pernicious anemia has a high incidence among Scandinavians and African Americans.

ANEMIA

Definition and Classification

Anemia is a deficiency in the number of erythrocytes (red blood cells [RBCs]), the quantity or quality of hemoglobin, and/or the volume of packed RBCs (hematocrit). It is a prevalent condition with many diverse causes such as blood loss, impaired production of erythrocytes, or increased destruction of erythrocytes (Fig. 31-1). Because RBCs transport oxygen (O_2), erythrocyte disorders can lead to tissue hypoxia. This hypoxia accounts for many of the signs and symptoms of anemia. Anemia is not a specific disease. It is a manifestation of a pathologic process.

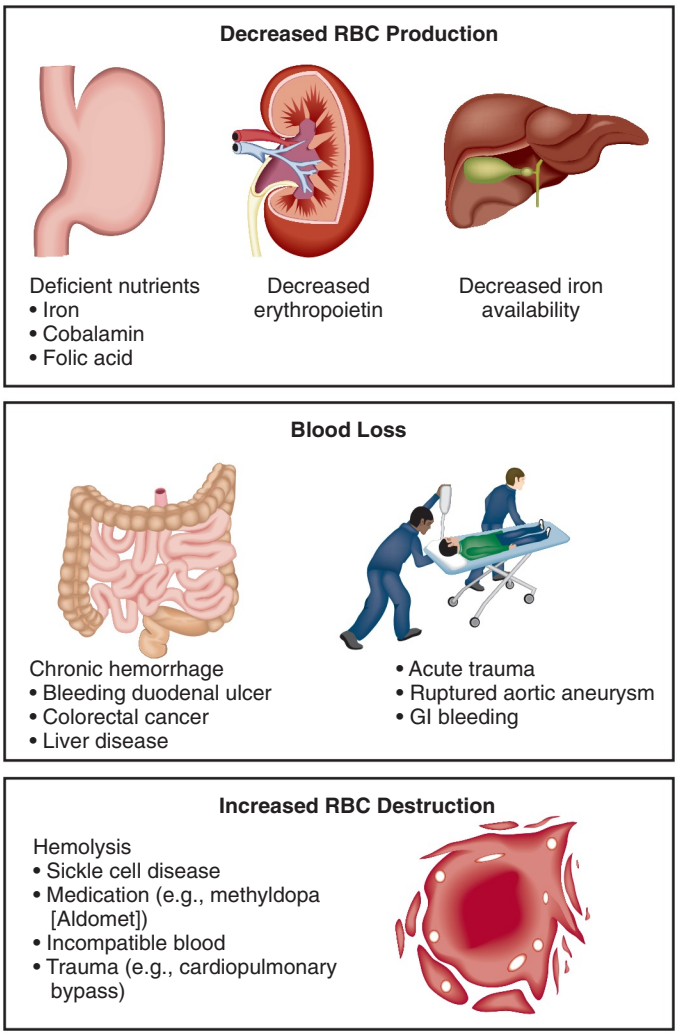

FIG. 31-1 Causes of anemia.

Anemia is classified by review of the complete blood count (CBC), reticulocyte count, and peripheral blood smear. Once anemia is identified, further investigation is done to determine its specific cause.[1]

Anemia can result from primary hematologic problems or can develop as a secondary consequence of diseases or disorders of other body systems. The various types of anemia can be classified according to either *morphology* (cellular characteristic) or *etiology* (cause). Morphologic classification is based on erythrocyte size and color (Table 31-1). Etiologic classification is related to the clinical conditions causing the anemia[2,3] (Table 31-2). Although the morphologic system is the most accurate means of classifying anemias, it is easier to discuss patient care by focusing on the etiology of the anemia.

Clinical Manifestations

The clinical manifestations of anemia are caused by the body's response to tissue hypoxia. Specific manifestations vary depending on the rate at which the anemia has evolved, its severity, and any coexisting disease. Hemoglobin (Hgb) levels are often used to determine the severity of anemia.

Mild states of anemia (Hgb 10 to 12 g/dL [100 to 120 g/L]) may exist without causing symptoms. If symptoms develop, it is because the patient has an underlying disease or is experiencing a compensatory response to heavy exercise. Symptoms include palpitations, dyspnea, and mild fatigue.[2,3]

In moderate anemia (Hgb 6 to 10 g/dL [60 to 100 g/L]) the cardiopulmonary symptoms are increased. The patient may experience them while resting, as well as with activity.

In severe anemia (Hgb less than 6 g/dL [60 g/L]) the patient has many clinical manifestations involving multiple body systems (Table 31-3).

Integumentary Changes. Integumentary changes include pallor, jaundice, and pruritus. Pallor results from reduced amounts of hemoglobin and reduced blood flow to the skin. Jaundice occurs when hemolysis of RBCs results in an increased concentration of serum bilirubin. Pruritus occurs because of increased serum and skin bile salt concentrations. In addition to the skin, the sclera of the eyes and mucous membranes should be evaluated for jaundice because they reflect the integumentary changes more accurately, especially in a dark-skinned individual.

Cardiopulmonary Manifestations. Cardiopulmonary manifestations of severe anemia result from additional attempts by

TABLE 31-1 MORPHOLOGY AND ETIOLOGY OF ANEMIA

Morphology	Etiology
Normocytic, normochromic (normal size and color) MCV 80-100 fL, MCH 27-34 pg	Acute blood loss, hemolysis, chronic kidney disease, chronic disease, cancers, sideroblastic anemia, endocrine disorders, starvation, aplastic anemia, sickle cell anemia, pregnancy
Microcytic, hypochromic (small size, pale color) MCV <80 fL, MCH <27 pg	Iron-deficiency anemia, vitamin B_6 deficiency, copper deficiency, thalassemia, lead poisoning
Macrocytic (megaloblastic), normochromic (large size, normal color) MCV >100 fL, MCH >34 pg	Cobalamin (vitamin B_{12}) deficiency, folic acid deficiency, liver disease (including effects of alcohol abuse), postsplenectomy

MCH, Mean corpuscular hemoglobin; *MCV,* mean corpuscular volume.

the heart and lungs to provide adequate amounts of oxygen to the tissues. Cardiac output is maintained by increasing the heart rate and stroke volume. The low viscosity of the blood contributes to the development of systolic murmurs and bruits. In extreme cases or when concomitant heart disease is present, angina pectoris and myocardial infarction (MI) may occur if myocardial O_2 needs cannot be met. Heart failure (HF), cardiomegaly, pulmonary and systemic congestion, ascites, and peripheral edema may develop if the heart is overworked for an extended period.

TABLE 31-2 CLASSIFICATION OF ANEMIA

Decreased RBC Production

Decreased Hemoglobin Synthesis
- Iron deficiency
- Thalassemias (decreased globin synthesis)
- Sideroblastic anemia (decreased porphyrin)

Defective DNA Synthesis
- Cobalamin (vitamin B_{12}) deficiency
- Folic acid deficiency

Decreased Number of RBC Precursors
- Aplastic anemia and inherited disorders (e.g., Fanconi syndrome)
- Anemia of myeloproliferative diseases (e.g., leukemia) and myelodysplasia
- Chronic diseases or disorders
- Medications and chemicals (e.g., chemotherapy, lead)
- Radiation

Blood Loss

Acute
- Trauma
- Blood vessel rupture
- Splenic sequestration crisis

Chronic
- Gastritis
- Menstrual flow
- Hemorrhoids

Increased RBC Destruction (Hemolytic Anemias)

Hereditary (Intrinsic)
- Abnormal hemoglobin (sickle cell disease)
- Enzyme deficiency (G6PD)
- Membrane abnormalities (paroxysmal nocturnal hemoglobinuria, hereditary spherocytosis)

Acquired (Extrinsic)
- Macroangiopathic: physical trauma (prosthetic heart valves, extracorporeal circulation)
- Microangiopathic: disseminated intravascular coagulopathy (DIC), thrombotic thrombocytopenic purpura (TTP)
- Antibodies (isoimmune and autoimmune)
- Infectious agents (e.g., malaria) and toxins

G6PD, Glucose-6-phosphate dehydrogenase.

NURSING MANAGEMENT ANEMIA

This section discusses general nursing management of anemia. Specific care related to various types of anemia is discussed later in this chapter.

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with anemia are presented in Table 31-4.

NURSING DIAGNOSES

Nursing diagnoses for the patient with anemia include, but are not limited to, those presented in Nursing Care Plan 31-1.

PLANNING

The overall goals are that the patient with anemia will (1) assume normal activities of daily living, (2) maintain adequate nutrition, and (3) develop no complications related to anemia.

NURSING IMPLEMENTATION

The numerous causes of anemia necessitate different nursing interventions specific to the patient's needs. Nevertheless, certain general components of care for all patients with anemia are presented in Nursing Care Plan 31-1.

Correcting the cause of the anemia is ultimately the goal of therapy. Acute interventions may include blood or blood product transfusions, drug therapy (e.g., erythropoietin, vitamin supplements), volume replacement, and O_2 therapy to stabilize the patient. Dietary and lifestyle changes (described in sections on specific types of anemia) can reverse some anemias so that the patient can return to the former state of health. Assess the patient's knowledge regarding adequate nutritional intake and adherence to safety precautions to prevent falls and injury.

GERONTOLOGIC CONSIDERATIONS

ANEMIA

Modest changes in RBC mass occur in older adults. Healthy older men have a modest decline in hemoglobin of about 1 g/dL between ages 70 and 88 years, in part because of the decreased production of testosterone. Only a minimal decrease

TABLE 31-3 MANIFESTATIONS OF ANEMIA

	Severity of Anemia		
Body System	**Mild (Hgb 10-12 g/dL [100-120 g/L])**	**Moderate (Hgb 6-10 g/dL [60-100 g/L])**	**Severe (Hgb <6 g/dL [<60 g/L])**
Integument	None	None	Pallor, jaundice,* pruritus*
Eyes	None	None	Icteric conjunctiva and sclera,* retinal hemorrhage, blurred vision
Mouth	None	None	Glossitis, smooth tongue
Cardiovascular	Palpitations	Increased palpitations, "bounding pulse"	Tachycardia, increased pulse pressure, systolic murmurs, intermittent claudication, angina, heart failure, myocardial infarction
Pulmonary	Exertional dyspnea	Dyspnea	Tachypnea, orthopnea, dyspnea at rest
Neurologic	None	"Roaring in the ears"	Headache, vertigo, irritability, depression, impaired thought processes
Gastrointestinal	None	None	Anorexia, hepatomegaly, splenomegaly, difficulty swallowing, sore mouth
Musculoskeletal	None	None	Bone pain
General	None or mild fatigue	Fatigue	Sensitivity to cold, weight loss, lethargy

*Caused by hemolysis.

TABLE 31-4 NURSING ASSESSMENT

Anemia

Subjective Data

Important Health Information

Past health history: Recent blood loss or trauma; chronic liver, endocrine, or renal disease (including dialysis); GI disease (malabsorption syndrome, ulcers, gastritis, or hemorrhoids); inflammatory disorders (especially Crohn's disease); smoking, exposure to radiation or chemical toxins (arsenic, lead, benzenes, copper); infectious diseases (HIV) or recent travel with possible exposure to infection; angina, myocardial infarction; history of falling

Medications: Use of vitamin and iron supplements; aspirin, anticoagulants, oral contraceptives, phenobarbital, penicillins, nonsteroidal antiinflammatory drugs, omeprazole, phenacetin, phenytoin (Dilantin), sulfonamides, herbal products

Surgery or other treatments: Recent surgery, small bowel resection, gastrectomy, prosthetic heart valves, chemotherapy, radiation therapy

Dietary history: General dietary patterns, consumption of alcohol

Functional Health Patterns

Health perception–health management: Family history of anemia; malaise

Nutritional-metabolic: Nausea, vomiting, anorexia, weight loss; dysphagia, dyspepsia, heartburn; night sweats, cold intolerance

Elimination: Hematuria, decreased urine output; diarrhea, constipation, flatulence, tarry stools, bloody stools

Activity-exercise: Fatigue, muscle weakness and decreased strength; dyspnea, orthopnea, cough, hemoptysis; palpitations; shortness of breath with activity

Cognitive-perceptual: Headache; abdominal, chest, and bone pain; painful tongue; paresthesias of feet and hands; pruritus; disturbances in vision, taste, or hearing; vertigo; hypersensitivity to cold; dizziness

Sexuality-reproductive: Menorrhagia, metrorrhagia; recent or current pregnancy; male impotence

Objective Data

General

Lethargy, apathy, general lymphadenopathy, fever

Integumentary

Pale skin and mucous membranes; blue, pale white, or icteric sclera; cheilitis (inflammation of the lips); poor skin turgor; brittle, spoon-shaped fingernails; jaundice; petechiae; ecchymoses; nose or gingival bleeding; poor healing; dry, brittle, thinning hair

Respiratory

Tachypnea

Cardiovascular

Tachycardia, systolic murmur, dysrhythmias; postural hypotension, widened pulse pressure, bruits (especially carotid); intermittent claudication, ankle edema

Gastrointestinal

Hepatosplenomegaly; glossitis; beefy, red tongue; stomatitis; abdominal distention; anorexia

Neurologic

Headache, roaring in the ears, confusion, impaired judgment, irritability, ataxia, unsteady gait, paralysis, loss of vibration sense

Possible Diagnostic Findings

↓ RBCs, ↓ Hgb; ↓ Hct; ↑ or ↓ reticulocytes, MCV, serum iron, ferritin, folate, or cobalamin (vitamin B_{12}); heme (guaiac)–positive stools; ↓ serum erythropoietin level; ↑ or ↓ LDH, bilirubin, transferrin (see Table 31-6)

LDH, Lactate dehydrogenase; *MCV,* mean corpuscular volume.

NURSING CARE PLAN 31-1

Patient With Anemia

NURSING DIAGNOSIS* **Fatigue** *related to* inadequate oxygenation of the blood *as evidenced by* increased pulse and blood pressure in response to activity, anorexia, impaired concentration, and/or patient verbalization of an overwhelming lack of energy

PATIENT GOALS
1. Participates in activities of daily living without abnormal increases in blood pressure and pulse
2. Reports increased endurance for activity

Outcomes (NOC)

Fatigue Level

- Exhaustion _____
- Loss of appetite _____
- Decreased motivation _____
- Lassitude _____

Measurement Scale
1 = Severe
2 = Substantial
3 = Moderate
4 = Mild
5 = None

Energy Conservation

- Recognizes energy limitations _____
- Balances activity and rest _____
- Uses energy conservation techniques _____
- Organizes activities to conserve energy _____
- Maintains adequate nutrition _____

Measurement Scale
1 = Never demonstrated
2 = Rarely demonstrated
3 = Sometimes demonstrated
4 = Often demonstrated
5 = Consistently demonstrated

Interventions (NIC) and *Rationales*

Energy Management

- Correct physiologic status deficits (e.g., chemotherapy-induced anemia) as priority items.
- Encourage alternate rest and activity periods *to provide activity without tiring the patient.*
- Monitor cardiorespiratory response to activity (e.g., tachycardia, dysrhythmias, dyspnea, diaphoresis, pallor, respiratory rate) *to evaluate activity intolerance.*
- Limit number of visitors and interruptions by visitors *to provide rest periods.*
- Assist the patient in assigning priority to activities to accommodate energy levels *to promote tolerance for important activities.*
- Arrange physical activities (e.g., avoid activity immediately after meals) *to reduce competition for O_2 supply to vital functions.*
- Assist with regular physical activities (e.g., ambulation, transfers, personal care) *to minimize fatigue and risk of injury from falls.*
- Instruct patient and caregiver to recognize signs and symptoms of fatigue that require reduction in activity *to promote self-care.*
- Instruct patient and caregiver to notify health care provider if signs and symptoms of fatigue persist *to review treatment plan.*

*Nursing diagnoses listed in order of priority.

Continued

NURSING CARE PLAN 31-1—cont'd

Patient With Anemia

NURSING DIAGNOSIS **Imbalanced nutrition: less than body requirements** *related to* inadequate nutritional intake and anorexia *as evidenced by* weight loss, low serum albumin, decreased iron level, vitamin deficiencies

PATIENT GOALS
1. Maintains dietary intake that provides minimum daily requirements of nutrients
2. Attains normal blood values of nutrients necessary to prevent anemia

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Nutritional Status	***Nutrition Management***
• Nutrient intake _____	• Determine, in collaboration with dietitian, number of calories and type of nutrients needed to meet nutritional requirements *to plan interventions.*
• Weight/height ratio _____	• Teach patient how to keep a food diary *to help evaluate nutritional intake.*
Nutritional Status: Biochemical Measures	• Monitor recorded intake for nutritional content and calories *to evaluate nutritional status.*
• Serum albumin _____	• Provide appropriate information about nutritional needs and how to meet them *to increase intake of essential nutrients needed.*
• Serum transferrin _____	• Encourage increased intake of protein, iron, and vitamin C *to provide nutrients needed for maximum iron absorption and hemoglobin production.*
• Hemoglobin _____	• Encourage increased intake of foods high in iron *to provide nutrient needed for hemoglobin production.*
• Hematocrit _____	
• Total iron-binding capacity _____	
Measurement Scale 1 = Severe deviation from normal range 2 = Substantial deviation from normal range 3 = Moderate deviation from normal range 4 = Mild deviation from normal range 5 = No deviation from normal range	

NURSING DIAGNOSIS **Ineffective self-health management** *related to* lack of knowledge about appropriate nutrition and medication regimen *as evidenced by* questioning about lifestyle adjustments, diet, medications

PATIENT GOAL Verbalizes knowledge necessary to maintain adequate nutrition and management of medication regimen

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Knowledge: Diet	***Nutritional Counseling***
• Recommended diet _____	• Facilitate identification of eating behaviors to be changed.
• Dietary goals _____	• Use accepted nutritional standards to assist patient in evaluating adequacy of dietary intake *to evaluate adequacy.*
• Healthy nutritional practices _____	• Discuss nutritional requirements and patient's perceptions of prescribed or recommended diet.
• Potential food and medication interactions _____	• Provide referral or consultation with other members of the health care team *to help patient maintain gains and adjustments throughout recovery.*
Knowledge: Medication	• Review with patient measurements of hemoglobin values *to evaluate response to therapeutic plan.*
• Identification of correct name of medication(s) _____	***Teaching: Prescribed Medication***
• Medication therapeutic effects ____	• Instruct the patient on the purpose and action of each medication.
• Medication adverse effects _____	• Instruct the patient on dosage, route, and duration of each medication *to improve adherence.*
• Correct use of prescribed medication _____	• Instruct the patient on possible adverse effects of each medication *to ensure early detection of untoward responses to medication.*
• Required laboratory tests for monitoring medication _____	
Measurement Scale 1 = No knowledge 2 = Limited knowledge 3 = Moderate knowledge 4 = Substantial knowledge 5 = Extensive knowledge	

in hemoglobin (about 0.2 g/dL) occurs between these ages in healthy women.

For older adults with anemia, about one third have a nutritional type of anemia (e.g., iron, folate, cobalamin). About another third have renal insufficiency and/or chronic inflammation, and the other third have anemia that is unexplained.

Cobalamin (vitamin B_{12}) and folate deficiency may occur in about 14% of older adults because of pernicious anemia, insufficient dietary intake, and malabsorption caused by low stomach acidity.[4] Multiple co-morbid conditions in older adults increase the likelihood of many types of anemia occurring.

Clinical manifestations of anemia in older adults may include pallor, confusion, ataxia, fatigue, worsening angina, and heart failure.[2] Unfortunately, anemia may go unrecognized in older adults because these manifestations may be mistaken for normal aging changes or overlooked because of another health problem. By recognizing signs of anemia, you can play a pivotal role in health assessment and related interventions for older adults.

ANEMIA CAUSED BY DECREASED ERYTHROCYTE PRODUCTION

Normally RBC production (termed *erythropoiesis*) is in equilibrium with RBC destruction and loss. This balance ensures that an adequate number of erythrocytes is available at all times. The normal life span of an RBC is 120 days. Three alterations

in erythropoiesis may occur that decrease RBC production: (1) decreased hemoglobin synthesis may lead to iron-deficiency anemia, thalassemia, and sideroblastic anemia; (2) defective deoxyribonucleic acid (DNA) synthesis in RBCs (e.g., cobalamin deficiency, folic acid deficiency) may lead to megaloblastic anemias; and (3) diminished availability of erythrocyte precursors may result in aplastic anemia and anemia of chronic disease (see Table 31-2).

IRON-DEFICIENCY ANEMIA

Iron-deficiency anemia, one of the most common chronic hematologic disorders, is found in 2% to 5% of adult men and postmenopausal women in developed countries. Those most susceptible to iron-deficiency anemia are the very young, those on poor diets, and women in their reproductive years.[5,6] Normally, 1 mg of iron is lost daily through feces, sweat, and urine.[7]

Etiology

Iron-deficiency anemia may develop as a result of inadequate dietary intake, malabsorption, blood loss, or hemolysis. (Normal iron metabolism is discussed in Chapter 30 on p. 616.) Normal dietary iron intake is usually sufficient to meet the needs of men and older women, but it may be inadequate for those individuals who have higher iron needs (e.g., menstruating or pregnant women). Table 31-5 lists nutrients needed for erythropoiesis.[8,9]

Malabsorption of iron may occur after certain types of gastrointestinal (GI) surgery and in malabsorption syndromes. Surgical procedures may involve removal or bypass of the duodenum (see Chapter 42). As iron absorption occurs in the duodenum, malabsorption syndromes may involve disease of the duodenum in which the absorption surface is altered or destroyed.

Blood loss is a major cause of iron deficiency in adults. Two milliliters of whole blood contain 1 mg of iron. The major sources of chronic blood loss are from the GI and genitourinary (GU) systems. GI bleeding is often not apparent and therefore may exist for a considerable time before the problem is identified. Loss of 50 to 75 mL of blood from the upper GI tract is required for stools to appear black *(melena)*. The black color results from the iron in the RBCs. Common causes of GI blood loss are peptic ulcer, gastritis, esophagitis, diverticuli, hemorrhoids, and neoplasia. GU blood loss occurs primarily from menstrual bleeding. The average monthly menstrual blood loss is about 45 mL and causes the loss of about 22 mg of iron. Postmenopausal bleeding can contribute to anemia in a susceptible older woman. In addition to anemia of chronic kidney disease, dialysis treatment may induce iron-deficiency anemia because of the blood lost in the dialysis equipment and frequent blood sampling.

Clinical Manifestations

In the early course of iron-deficiency anemia the patient may not have any symptoms. As the disease becomes chronic, any of the general manifestations of anemia may develop (see Table 31-3). In addition, specific clinical manifestations may occur related to iron-deficiency anemia. Pallor is the most common finding, and *glossitis* (inflammation of the tongue) is the second most common. Another finding is *cheilitis* (inflammation of the lips). In addition, the patient may report headache, paresthesias, and a burning sensation of the tongue, all of which are caused by lack of iron in the tissues.

TABLE 31-5 NUTRITIONAL THERAPY

Nutrients for Erythropoiesis

Role in Erythropoiesis	Food Sources
Cobalamin (Vitamin B_{12})	
RBC maturation	Red meats, especially liver, eggs, enriched grain products, milk and dairy foods, fish
Copper	
Mobilization of iron from tissues to plasma*	Shellfish, whole grains, beans, nuts, potatoes, organ meats, dark green leafy vegetables, dried prunes
Folic Acid	
RBC maturation	Green leafy vegetables, liver, meat, fish, legumes, whole grains, orange juice, peanuts
Iron	
Hemoglobin synthesis	Liver and muscle meats, eggs, dried fruits, legumes, dark green leafy vegetables, whole-grain and enriched bread and cereals, potatoes
Niacin	
Needed for maturation of RBC	High-protein foods such as peanut butter, beans, meats, avocado; enriched and fortified grains
Pantothenic Acid (Vitamin B_5)	
Heme synthesis	Meats, vegetables, cereal grains, legumes, eggs, milk
Pyridoxine (Vitamin B_6)	
Hemoglobin synthesis	Meats, fortified cereals, whole grains, legumes, potatoes, cornmeal, bananas, nuts
Riboflavin (Vitamin B_2)	
Oxidative reactions	Milk and dairy foods, enriched bread and other grain products, salmon, chicken, eggs, leafy green vegetables
Vitamin E	
Possible role in heme synthesis. Protection against oxidative damage to RBCs	Vegetable oils, salad dressings, margarine, wheat germ, whole-grain products, seeds, nuts, peanut butter
Amino Acids	
Synthesis of nucleoproteins	Eggs, meat, milk and milk products (cheese, ice cream), poultry, fish, legumes, nuts
Ascorbic Acid (Vitamin C)	
Conversion of folic acid to its active forms, aids in iron absorption	Citrus fruits, green leafy vegetables, strawberries, cantaloupe

*Supplementation rarely needed and large amounts of copper are poisonous.

Diagnostic Studies

Laboratory abnormalities characteristic of iron-deficiency anemia are presented in Table 31-6. Other diagnostic studies (e.g., stool guaiac test) are done to determine the cause of the

TABLE 31-7 COLLABORATIVE CARE

Iron-Deficiency Anemia

Diagnostic

- History and physical examination
- Hct and Hgb levels
- RBC count, including morphology
- Reticulocyte count
- Serum iron
- Serum ferritin
- Serum transferrin
- Total iron-binding capacity (TIBC)
- Stool examination for occult blood

Collaborative Therapy

- Identification and treatment of underlying cause
- Ferrous sulfate or ferrous gluconate
- Iron dextran, sodium ferrous gluconate, iron sucrose IM or IV
- Nutritional and diet therapy (see Table 31-5)
- Transfusion of packed RBCs (symptomatic patient only)

iron deficiency. Endoscopy and colonoscopy may be used to detect GI bleeding. A bone marrow biopsy may be done if other tests are inconclusive.

Collaborative Care

The main goal is to treat the underlying disease that is causing reduced intake (e.g., malnutrition, alcoholism) or absorption of iron. In addition, efforts are directed toward replacing iron (Table 31-7). Teach the patient which foods are good sources of iron (see Table 31-5). If nutrition is already adequate, increasing iron intake by dietary means may not be practical. Consequently, oral or occasionally parenteral iron supplements are used. If the iron deficiency is from acute blood loss, the patient may require a transfusion of packed RBCs.

Drug Therapy. Oral iron should be used whenever possible because it is inexpensive and convenient. Many iron preparations are available. When administering iron, consider the following five factors:

1. Iron is absorbed best from the duodenum and proximal jejunum. Therefore enteric-coated or sustained-release capsules, which release iron farther down in the GI tract, are counterproductive and expensive.
2. The daily dose should provide 150 to 200 mg of elemental iron. This can be ingested in three or four daily doses, with each tablet or capsule of the iron preparation containing between 50 and 100 mg of iron (e.g., a 300-mg tablet of ferrous sulfate contains 60 mg of elemental iron).
3. Iron is best absorbed as ferrous sulfate (Fe^{2+}) in an acidic environment. For this reason and to avoid binding the iron with food, iron should be taken about an hour before meals, when the duodenal mucosa is most acidic. Taking iron with vitamin C (ascorbic acid) or orange juice, which contains ascorbic acid, enhances iron absorption. Gastric side effects, however, may necessitate ingesting iron with meals.
4. Undiluted liquid iron may stain the patient's teeth. Therefore it should be diluted and ingested through a straw.
5. GI side effects of iron administration may occur, including heartburn, constipation, and diarrhea. If side effects develop, the dose and type of iron supplement may be adjusted. For example, many individuals who need supplemental iron cannot tolerate ferrous sulfate because of the effects of the sulfate base. However, ferrous gluconate may be an acceptable substitute. Tell patients that the use of iron preparations will cause their stools to become black because the GI tract excretes excess iron. Constipation is common, and the patient should be started on stool softeners and laxatives, if needed, when started on iron.

DRUG ALERT: Iron

- Some preparations of IV iron have a risk of an allergic reaction, and the patient should be monitored accordingly.
- Oral iron should be taken about 1 hr before meals.
- Vitamin C (ascorbic acid) enhances iron absorption.

In some situations it may be necessary to administer iron parenterally. Parenteral use of iron is indicated for malabsorption, intolerance of oral iron, a need for iron beyond oral limits, or poor patient adherence in taking the oral preparations of iron. Parenteral iron can be given intramuscularly (IM) or IV. An iron-dextran complex (INFeD) contains 50 mg/mL of elemental iron available in 2-mL single-dose vials. Sodium ferrous gluconate and iron sucrose are alternatives and may carry less risk of life-threatening anaphylaxis.[10]

Because IM iron solutions may stain the skin, separate needles should be used for withdrawing the solution and for injecting the medication. Use a Z-track injection technique.

NURSING MANAGEMENT IRON-DEFICIENCY ANEMIA

Certain groups of individuals are at an increased risk for the development of iron-deficiency anemia. These include premenopausal and pregnant women, persons from low socioeco-

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Does Intermittent Iron Supplementation Improve Anemia?

Clinical Question

In menstruating women (P) does intermittent iron supplementation (I) compared to no iron, placebo, or daily use (C) reduce anemia (O)?

Best Available Evidence

Randomized and quasi-randomized controlled trials

Critical Appraisal and Synthesis of Evidence

- Twenty-one trials (n = 10,258) of menstruating women taking iron supplements intermittently compared with no intervention, placebo, or use of the same supplements on a daily basis.
- Intermittent iron supplementation reduced the risk of anemia and improved hemoglobin and ferritin concentrations. However, women using supplements intermittently had anemia more frequently than women who were taking daily supplementation.
- Frequency of use of intermittent supplements (one, two, or three times per week) did not affect findings.

Conclusion

- Intermittent iron supplementation in menstruating women is beneficial and an effective alternative when daily supplementation is not done.

Implications for Nursing Practice

- Many people who need iron supplementation do not take iron on a regular basis. The reasons include not liking the side effects or forgetting to take it.
- Encourage intermittent iron supplementation if usage is recommended and daily use is not feasible for the patient. It is better to take iron once in awhile than not at all.
- Inform women that side effects of iron, including nausea, constipation, and teeth staining, decrease with intermittent use as compared to daily supplementation.

Reference for Evidence

Fernández-Gaxiola A, De-Regil L: Intermittent iron supplementation for reducing anaemia and its associated impairments in menstruating women, *Cochrane Database Syst Rev* 12:CD009218, 2011.

P, Patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcomes of interest (see p. 12).

nomic backgrounds, older adults, and individuals experiencing blood loss. Diet teaching, with an emphasis on foods high in iron and ways to maximize absorption, is important for these groups.

Appropriate nursing measures are presented in Nursing Care Plan 31-1. Discuss with the patient the need for diagnostic studies to identify the cause. Reassess the hemoglobin and RBC counts to evaluate the response to therapy. Emphasize adherence with dietary and drug therapy. To replenish the body's iron stores, the patient needs to take iron therapy for 2 to 3 months after the hemoglobin level returns to normal. Patients who require lifelong iron supplementation should be monitored for potential liver problems related to the iron storage.

THALASSEMIA

Etiology

Thalassemia is a group of diseases involving inadequate production of normal hemoglobin, and therefore decreased erythrocyte production. Thalassemia is due to an absent or reduced globulin protein. α-Globin chains are absent or reduced in α-thalassemia, and β-globin chains are absent or reduced in β-thalassemia. Hemolysis also occurs in thalassemia, but insufficient production of normal hemoglobin is the predominant problem. Thalassemia is commonly found in members of ethnic groups whose origins are near the Mediterranean Sea and equatorial or near-equatorial regions of Asia, the Middle East, and Africa.

Genetic Link

Thalassemia has an autosomal recessive genetic basis (see Table 13-2). An individual with thalassemia may have a heterozygous or homozygous form of the disease. A person who is heterozygous has one thalassemic gene and one normal gene and is said to have *thalassemia minor* (or thalassemic trait), which is a mild form of the disease. A homozygous person has two thalassemic genes, causing a severe condition known as *thalassemia major.*[11]

Clinical Manifestations

The patient with thalassemia minor is frequently asymptomatic. The patient has mild to moderate anemia with *microcytosis* (small cells) and *hypochromia* (pale cells).

Thalassemia major is a life-threatening disease in which growth, both physical and mental, is often retarded. The person who has thalassemia major is pale and displays other general symptoms of anemia (see Table 31-3). The symptoms develop in childhood by 2 years of age and can cause growth and developmental deficits. Jaundice from the hemolysis of RBCs is prominent. In addition, the person has pronounced splenomegaly, since the spleen continuously tries to remove the damaged red cells. Hepatomegaly and cardiomyopathy may occur from iron deposition. As the bone marrow responds to the reduced oxygen-carrying capacity of the blood, RBC production is stimulated and the marrow becomes packed with immature erythroid precursors that die. This stimulates further erythropoiesis, leading to chronic bone marrow hyperplasia and expansion of the marrow space. This may cause thickening of the cranium and maxillary cavity. Thrombocytosis after spleen dysfunction and/or removal may occur.

Patients with thalassemia may have hepatitis C because of having received blood transfusions before donated blood was screened for hepatitis C virus (screening started in 1992). Hepatitis C may result in cirrhosis and hepatocellular carcinoma. Cardiac complications from iron overload, pulmonary disease, and hypertension also contribute to early death. Endocrinopathies (hypogonadotrophic hypogonadism) and thrombosis may also be complications of the disease.

Collaborative Care

The laboratory abnormalities of thalassemia major are summarized in Table 31-6. No specific drug or diet therapies are effective in treating thalassemia. Thalassemia minor requires no treatment because the body adapts to the reduction of normal hemoglobin.

Thalassemia major is managed with blood transfusions or exchange transfusions in conjunction with oral deferasirox (Exjade), or deferiprone (Ferriprox) or deferoxamine (Desferal) (chelating agents that bind to iron) is given IV or subcutaneously to reduce the iron overloading (hemochromatosis) that

occurs with chronic transfusion therapy.[11] Folic acid is given if there is evidence of hemolysis. Transfusions are administered to keep the hemoglobin level at approximately 10 g/dL (100 g/L) to maintain the patient's own erythropoiesis without causing the spleen to enlarge. Zinc supplementation may be needed, since zinc is reduced with chelation therapy. Ascorbic acid supplementation may be needed during chelation therapy, since it increases urine excretion of iron. Other than during chelation therapy, ascorbic acid should not be taken because it increases the absorption of dietary iron. Iron supplements should not be given.

Because RBCs are sequestered in the enlarged spleen, thalassemia major may be treated by splenectomy. Hepatic, cardiac, and pulmonary organ function should be monitored and treated as appropriate.

Although hematopoietic stem cell transplantation (HSCT) remains the only cure for patients with thalassemia, the risk of this procedure may outweigh its benefits. With proper iron chelation therapy, patients are living longer.

MEGALOBLASTIC ANEMIAS

Megaloblastic anemias are a group of disorders caused by impaired DNA synthesis and characterized by the presence of large RBCs. When DNA synthesis is impaired, defective RBC maturation results. The RBCs are large *(macrocytic)* and abnormal and are referred to as *megaloblasts.* Macrocytic RBCs are easily destroyed because they have fragile cell membranes. Although the overwhelming majority of megaloblastic anemias result from cobalamin (vitamin B_{12}) and folic acid deficiencies, this type of RBC deformity can also occur from suppression of DNA synthesis by drugs, inborn errors of cobalamin and folic acid metabolism, and *erythroleukemia* (malignant blood disorder characterized by a proliferation of erythropoietic cells in bone marrow) (Table 31-8).

Cobalamin (Vitamin B_{12}) Deficiency

Normally, a protein termed *intrinsic factor* (IF) is secreted by the parietal cells of the gastric mucosa. IF is required for cobalamin (extrinsic factor) absorption. (Cobalamin is normally absorbed in the distal ileum.) Therefore if IF is not secreted, cobalamin will not be absorbed.

Etiology

Pernicious Anemia. The most common cause of cobalamin deficiency is **pernicious anemia,** which is caused by an absence of IF. In pernicious anemia the gastric mucosa is not secreting IF because of either gastric mucosal atrophy or autoimmune destruction of parietal cells. In the autoimmune process antibodies are directed against the gastric parietal cells and/or IF itself. Because parietal cells also secrete hydrochloric acid (HCl), in pernicious anemia there is a decrease in HCl in the stomach. An acid environment in the stomach is required for the secretion of IF.

Pernicious anemia is a disease of insidious onset that begins in middle age or later (usually after age 40), with 60 years being the most common age at diagnosis. Pernicious anemia occurs frequently in persons of Northern European ancestry (particularly Scandinavians) and African Americans. In African Americans the disease tends to begin early, occurs with higher frequency in women, and is often severe.

TABLE 31-8 CLASSIFICATION OF MEGALOBLASTIC ANEMIA

Cobalamin (Vitamin B_{12}) Deficiency
- Dietary deficiency
- Deficiency of gastric intrinsic factor
  - Pernicious anemia
  - Gastrectomy
- Intestinal malabsorption
- Increased requirement
- Chronic alcoholism

Folic Acid Deficiency
- Dietary deficiency (e.g., leafy green vegetables, citrus fruits)
- Malabsorption syndromes
- Drugs interfering with absorption or use of folic acid
  - Methotrexate
  - Antiseizure drugs (e.g., phenobarbital, phenytoin [Dilantin])
- Increased requirement
- Alcohol abuse
- Anorexia
- Hemodialysis patients (folic acid lost during dialysis)

Drug-Induced Suppression of DNA Synthesis
- Folate antagonists
- Metabolic inhibitors
- Alkylating agents

Inborn Errors
- Defective folate metabolism
- Defective transport of cobalamin

Erythroleukemia

Other Causes of Cobalamin Deficiency. Cobalamin deficiency can also occur in patients who have had GI surgery (e.g., gastrectomy, gastric bypass); patients who have had a small bowel resection involving the ileum; and patients with Crohn's disease, ileitis, celiac disease, diverticuli of the small intestine, or chronic atrophic gastritis (see Table 31-8). In these cases, cobalamin deficiency results from the loss of IF-secreting gastric mucosal cells or impaired absorption of cobalamin in the distal ileum. Cobalamin deficiency is also found in chronic alcoholics, long-term users of H_2-histamine receptor blockers and proton pump inhibitors, and those who are strict vegetarians.[2,3]

Clinical Manifestations

General manifestations of anemia related to cobalamin deficiency develop because of tissue hypoxia (see Table 31-3). GI manifestations include a sore, red, beefy, and shiny tongue; anorexia, nausea, and vomiting; and abdominal pain. Typical neuromuscular manifestations include weakness, paresthesias of the feet and hands, reduced vibratory and position senses, ataxia, muscle weakness, and impaired thought processes ranging from confusion to dementia. Because cobalamin deficiency–related anemia has an insidious onset, it may take several months for these manifestations to develop.

Diagnostic Studies

Laboratory data reflective of cobalamin deficiency anemia are presented in Table 31-6. The RBCs appear large (macrocytic) and have abnormal shapes. This structure contributes to erythrocyte destruction because the cell membrane is fragile. Serum cobalamin levels are reduced.

Serum folate levels are also obtained. If they are normal and cobalamin levels are low, it suggests that megaloblastic anemia is due to a cobalamin deficiency. A serum test for anti-IF antibodies may be done that is specific for pernicious anemia. Because the potential for gastric cancer is increased in patients with pernicious anemia, an upper GI endoscopy and biopsy of the gastric mucosa may also be done.

Testing of serum methylmalonic acid (MMA) (elevated mainly in cobalamin deficiency) and serum homocysteine (elevated in both cobalamin and folic acid deficiencies) helps determine the cause of this type of anemia.

Collaborative Care

Regardless of how much is ingested, the patient is not able to absorb cobalamin if IF is lacking or if absorption in the ileum is impaired. For this reason, increasing dietary cobalamin does not correct this anemia. However, instruct the patient on adequate dietary intake to maintain good nutrition (see Table 31-5).

Parenteral vitamin B_{12} (cyanocobalamin or hydroxocobalamin) or intranasal cyanocobalamin (Nascobal, CaloMist) is the treatment of choice. Without cobalamin administration, these individuals will die in 1 to 3 years. A typical treatment schedule consists of 1000 mcg/day of cobalamin IM for 2 weeks and then weekly until the hemoglobin is normal, and then monthly for life. High-dose oral cobalamin and sublingual cobalamin are also available for those in whom GI absorption is intact. As long as supplemental cobalamin is used, the anemia can be reversed. However, if the person has had long-standing neuromuscular complications, they may not be reversible.

Folic Acid Deficiency

Folic acid (folate) deficiency also causes megaloblastic anemia. Folic acid is required for DNA synthesis leading to RBC formation and maturation. Common causes of folic acid deficiency are listed in Table 31-8.

The clinical manifestations of folic acid deficiency are similar to those of cobalamin deficiency. The disease develops insidiously, and the patient's symptoms may be attributed to other coexisting problems (e.g., cirrhosis, esophageal varices). GI disturbances include dyspepsia and a smooth, beefy red tongue. The absence of neurologic problems is an important diagnostic finding and differentiates folic acid deficiency from cobalamin deficiency.

The diagnostic findings for folic acid deficiency are presented in Table 31-6. In addition, the serum folate level is low (normal is 3 to 25 mg/mL [7 to 57 mol/L]) and the serum cobalamin level is normal.

Folic acid deficiency is treated by replacement therapy. The usual dosage is 1 mg/day by mouth. In malabsorption states or with chronic alcoholism, up to 5 mg/day may be required. The duration of treatment depends on the reason for the deficiency. Encourage the patient to eat foods containing large amounts of folic acid (see Table 31-5).

NURSING MANAGEMENT MEGALOBLASTIC ANEMIA

Because of the familial predisposition for pernicious anemia, the most common type of cobalamin deficiency, patients who have a positive family history of pernicious anemia should be evaluated for symptoms. Although the disease cannot be prevented, early detection and treatment can lead to reversal of symptoms. Also consider signs and symptoms of other possible megaloblastic anemias and bring them to the attention of the health care provider.

The nursing measures presented in Nursing Care Plan 31-1, for the patient with anemia, are appropriate for the patient with cobalamin or folic acid deficiency anemia. In addition to these measures, ensure that injuries are not sustained because of the diminished sensitivity to heat and pain resulting from the neurologic impairment. Protect the patient from falling, burns, and trauma. If heat therapy is required, evaluate the patient's skin at frequent intervals to detect redness.

Ongoing care focuses on ensuring good patient adherence with treatment. Carefully assess for neurologic difficulties that were not fully corrected by adequate replacement therapy. Because the potential for gastric cancer may be increased in patients with atrophic gastritis-related pernicious anemia, the patient should have frequent and careful appropriate screenings.

ANEMIA OF CHRONIC DISEASE

Anemia of chronic disease (also called anemia of inflammation) can be caused by chronic inflammation, autoimmune and infectious disorders (human immunodeficiency virus [HIV], hepatitis, malaria), HF, or malignant diseases. Bleeding episodes can also contribute to anemia of chronic disease.

Anemia of chronic disease is associated with an underproduction of RBCs and mild shortening of RBC survival. The RBCs are usually normocytic, normochromic, and hypoproliferative. The anemia is usually mild, but it can become more severe if the underlying disorder is not treated.

This type of anemia, which usually develops after 1 to 2 months of disease activity, has an immune basis. The cytokines released in these conditions, particularly interleukin 6 (IL-6), cause an increased uptake and retention of iron within macrophages (see Fig. 30-3). This leads to a diversion of iron from circulation into storage sites with subsequent limited iron available for erythropoiesis. There is also reduced RBC life span, suppressed production of erythropoietin, and an ineffective bone marrow response to erythropoietin.[12]

For any chronic disease, additional factors may contribute to the anemia. For example, with renal disease, the primary factor causing anemia is decreased erythropoietin, a hormone made in the kidneys that stimulates erythropoiesis. With impaired renal function, erythropoietin production is decreased (see Chapter 47).

Anemia of chronic disease must first be recognized and differentiated from anemia of other etiologies. Findings of elevated serum ferritin and increased iron stores distinguish it from iron-deficiency anemia. Normal folate and cobalamin blood levels distinguish it from those types of anemias. The best treatment of anemia of chronic disease is correction of the underlying disorder. If the anemia is severe, blood transfusions may be indicated, but they are not recommended for long-term treatment. Erythropoietin therapy (epoetin alfa [Epogen], darbepoetin) is used for anemia related to renal disease (see Chapter 47) and may be used for anemia related to cancer and its therapies (see Chapter 16 and Table 16-14). However, erythropoietin therapy needs to be used conservatively because of the increased risk of thromboembolism and death in some patients.[12,13] IV

iron may be administered, if necessary, to improve the response to therapy with erythropoietin.

APLASTIC ANEMIA

Aplastic anemia is a disease in which the patient has peripheral blood *pancytopenia* (decrease of all blood cell types—RBCs, white blood cells [WBCs], and platelets) and hypocellular bone marrow. The spectrum of the anemia can range from a chronic condition managed with erythropoietin or blood transfusions to a critical condition with hemorrhage and sepsis. The incidence of aplastic anemia is low, affecting approximately 2 of every 1 million persons per year.[14]

Etiology

Aplastic anemia has various etiologic classifications, but is divided into two major groups: *congenital* or *acquired* (Table 31-9). Approximately 75% of the acquired aplastic anemias are idiopathic and thought to have an autoimmune basis.

Clinical Manifestations

Aplastic anemia can manifest abruptly (over days) or insidiously over weeks to months and can vary from mild to severe. Clinically the patient may have symptoms caused by suppression of any or all bone marrow elements. General manifestations of anemia such as fatigue and dyspnea, as well as cardiovascular and cerebral responses, may be seen (see Table 31-3). The patient with neutropenia (low neutrophil count) is susceptible to infection and is at risk for septic shock and death. Even a low-grade fever (above 100.4° F [38° C]) should be considered a medical emergency. Thrombocytopenia is manifested by a predisposition to bleeding (e.g., petechiae, ecchymosis, epistaxis).

Diagnostic Studies

The diagnosis is confirmed by laboratory studies. Because all marrow elements are affected, hemoglobin, WBC, and platelet values are often decreased in aplastic anemia. Other RBC indices are generally normal (see Table 31-6). The condition is therefore classified as a normocytic, normochromic anemia. The reticulocyte count is low. Bleeding time is prolonged.

Aplastic anemia can be further evaluated by assessing various iron studies. The serum iron and total iron-binding capacity (TIBC) may be elevated as initial signs of erythropoiesis suppression. Bone marrow biopsy, aspiration, and pathologic examination may be done for any anemic state. However, the findings are especially important in aplastic anemia because the marrow is hypocellular with increased yellow marrow (fat content).

TABLE 31-9 CAUSES OF APLASTIC ANEMIA

Congenital (Chromosomal Alterations)	Acquired
• Fanconi syndrome • Congenital dyskeratosis • Amegakaryocytic thrombocytopenia • Shwachman-Diamond syndrome	• Idiopathic or autoimmune • Chemical agents and toxins (e.g., benzene, insecticides, arsenic, alcohol) • Drugs (e.g., alkylating agents, antiseizure drugs, antimetabolites, antimicrobials, gold) • Radiation • Viral and bacterial infections (e.g., hepatitis, parvovirus)

NURSING AND COLLABORATIVE MANAGEMENT APLASTIC ANEMIA

Management of aplastic anemia is based on identifying and removing the causative agent (when possible) and providing supportive care until the pancytopenia reverses. Nursing interventions appropriate for the patient with pancytopenia from aplastic anemia are presented in Nursing Care Plan 31-1 for anemia and in eNursing Care Plan 31-1 for thrombocytopenia and eNursing Care Plan 31-2 for neutropenia (available on the website for this chapter). Nursing actions are directed at preventing complications from infection and hemorrhage.

The prognosis of severe untreated aplastic anemia is poor. The median survival of untreated severe aplastic anemia is 3 to 6 months (20% survive longer than 1 year).[3] However, advances in medical management, including HSCT and immunosuppressive therapy with antithymocyte globulin (ATG) and cyclosporine or high-dose cyclophosphamide (Cytoxan), have improved outcomes significantly. ATG is a horse serum that contains polyclonal antibodies against human T cells. It can cause anaphylaxis and a serum sickness. The rationale for this therapy is that idiopathic aplastic anemia is considered an autoimmune disorder resulting from activated cytotoxic T cells that target and destroy the patient's own hematopoietic stem cells. (ATG and cyclosporine are discussed in Chapter 14 and Table 14-16.)

The treatment of choice for adults less than 55 years of age who do not respond to the immunosuppressive therapy and who have a human leukocyte antigen (HLA)–matched donor is an HSCT. The best results occur in younger patients who have not had previous blood transfusions. Prior transfusions increase the risk of graft rejection. (HSCT is discussed in Chapter 16.)

For older adults without an HLA-matched donor, the treatment of choice is immunosuppression with ATG or cyclosporine or high-dose cyclophosphamide. High-dose corticosteroids may also be used. However, this therapy may be only partially beneficial. Patients who need ongoing supportive blood transfusion should be on an iron-binding agent to prevent iron overload.

ANEMIA CAUSED BY BLOOD LOSS

Anemia resulting from blood loss may be caused by either acute or chronic problems.

ACUTE BLOOD LOSS

Acute blood loss occurs as a result of sudden hemorrhage. Causes of acute blood loss include trauma, complications of surgery, and conditions or diseases that disrupt vascular integrity. There are two clinical concerns in such situations. First, a sudden reduction in the total blood volume can lead to hypovolemic shock. Second, if the acute loss is more gradual, the body maintains its blood volume by slowly increasing the plasma volume. Although the circulating fluid volume is preserved, the number of RBCs available to carry oxygen is significantly diminished.

Clinical Manifestations

The clinical manifestations of anemia from acute blood loss are caused by the body's attempts to maintain an adequate blood

TABLE 31-10 MANIFESTATIONS OF ACUTE BLOOD LOSS

Volume Lost*		
%	mL	Manifestations
10	500	None or rare vasovagal syncope.
20	1000	No detectable signs or symptoms at rest. Tachycardia with exercise and slight postural hypotension.
30	1500	Normal supine blood pressure and pulse at rest. Postural hypotension and tachycardia with exercise.
40	2000	Blood pressure, central venous pressure, and cardiac output below normal at rest; air hunger; rapid, thready pulse and cold, clammy skin.
50	2500	Shock, lactic acidosis, and potential death.

*Based on an adult with a total blood volume of 5 L.

volume and meet oxygen requirements. Table 31-10 summarizes the clinical manifestations of patients with varying degrees of blood volume loss. It is essential to understand that the clinical signs and symptoms the patient is experiencing are more important than the laboratory values. For example, an adult with a bleeding peptic ulcer who had a 750-mL hematemesis (15% of a normal total blood volume) within the past 30 minutes may have postural hypotension, but have normal values for hemoglobin and hematocrit. Over the next 36 to 48 hours, most of the blood volume deficit will be replaced by the movement of fluid from the extravascular into the intravascular space. Only then will the hemoglobin and hematocrit reflect the blood loss.

Assess the patient's expression of pain. Internal hemorrhage may cause pain because of tissue distention, organ displacement, and nerve compression. Pain may be localized or referred. In the case of retroperitoneal bleeding, the patient may not experience abdominal pain. Instead the patient may have numbness and pain in a lower extremity secondary to compression of the lateral cutaneous nerve, which is located in the region of the first to third lumbar vertebrae. The major complication of acute blood loss is shock (see Chapter 67).

Diagnostic Studies

When blood volume loss is sudden, plasma volume has not yet had a chance to increase, the loss of RBCs is not reflected in laboratory data, and values may seem normal or high for 2 to 3 days. However, once the plasma volume is replaced, the RBC mass is less concentrated. At this time, RBC, hemoglobin, and hematocrit levels are low and reflect the actual blood loss.

Collaborative Care

Collaborative care is initially concerned with (1) replacing blood volume to prevent shock and (2) identifying the source of the hemorrhage and stopping the blood loss. IV fluids used in emergencies include dextran, hetastarch, albumin, and crystalloid electrolyte solutions such as lactated Ringer's solution. The amount of infusion varies with the solution used. (Management of shock is discussed in Chapter 67.)

Once volume replacement is established, attention can be directed to correcting the RBC loss. The body needs 2 to 5 days to manufacture more RBCs in response to increased erythropoietin. Consequently, blood transfusions (packed RBCs) may be needed if the blood loss is significant. In addition, if the bleeding is related to a platelet or clotting disorder, replacement of that deficiency is addressed.

The patient may also need supplemental iron because the availability of iron affects the marrow production of erythrocytes. When anemia exists after acute blood loss, dietary sources of iron will probably not be adequate to maintain iron stores. Therefore oral or parenteral iron preparations are administered.

NURSING MANAGEMENT ACUTE BLOOD LOSS

In the case of trauma it may be impossible to prevent the loss of blood. For the postoperative patient, carefully monitor the blood loss from various drainage tubes and dressings and implement appropriate actions. The nursing care for the patient with anemia resulting from acute blood loss most likely includes administration of blood products (described at the end of this chapter).

The anemia should begin to correct itself once the source of hemorrhage is identified, blood loss is controlled, and fluid and blood volumes are replaced. There should be no need for long-term treatment of this type of anemia.

CHRONIC BLOOD LOSS

The sources of chronic blood loss are similar to those of iron-deficiency anemia (e.g., bleeding ulcer, hemorrhoids, menstrual and postmenopausal blood loss). The effects of chronic blood loss are usually related to the depletion of iron stores and considered as iron-deficiency anemia. Management of chronic blood loss anemia involves identifying the source and stopping the bleeding. Supplemental iron may be required.

ANEMIA CAUSED BY INCREASED ERYTHROCYTE DESTRUCTION

The third major cause of anemia is termed **hemolytic anemia,** a condition caused by the destruction or hemolysis of RBCs at a rate that exceeds production. Hemolysis can occur because of problems intrinsic or extrinsic to the RBCs. *Intrinsic hemolytic anemias,* which are usually hereditary, result from defects in the RBCs themselves (see Table 31-2).

More common are the *acquired hemolytic anemias*. In this type of anemia the RBCs are normal, but damage is caused by external factors (see Table 31-2). The spleen is the primary site of the destruction of RBCs that are old, defective, or moderately damaged. Fig. 31-2 indicates the sequence of events involved in extravascular hemolysis.

The patient with hemolytic anemia has the general manifestations of anemia and specific manifestations related to this type of anemia (see Table 31-3). Jaundice is likely because the increased destruction of RBCs causes an elevation in bilirubin levels. The spleen and liver may enlarge because of their hyperactivity, which is related to macrophage phagocytosis of the defective erythrocytes.

In all causes of hemolysis, a major focus of treatment is to maintain renal function. When RBCs are hemolyzed, the hemoglobin molecule is released and filtered by the kidneys. The accumulation of hemoglobin molecules can obstruct the renal tubules and lead to acute tubular necrosis (see Chapter 47).

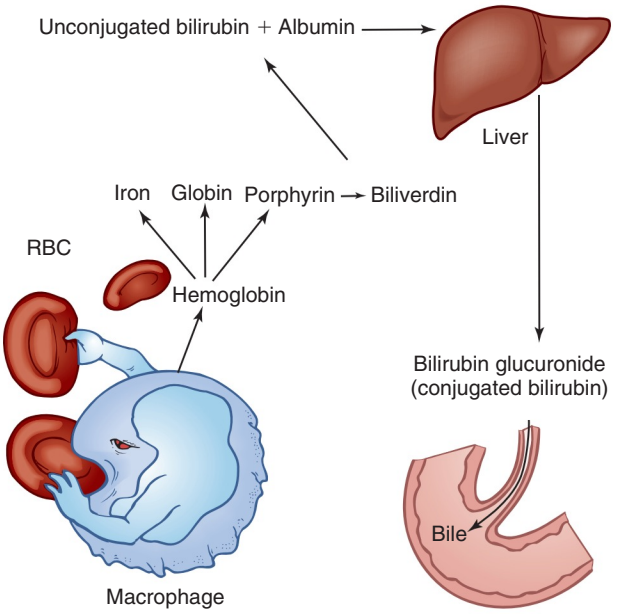

FIG. 31-2 Sequence of events in extravascular hemolysis.

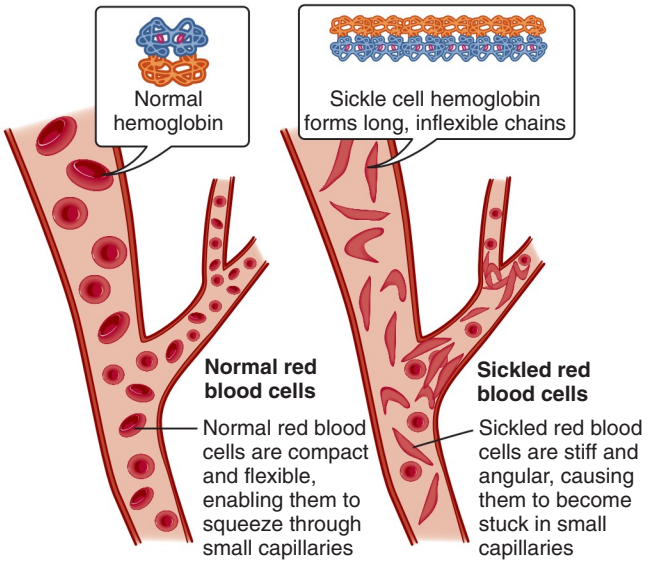

FIG. 31-3 In sickle cell, the hemoglobin forms long inflexible chains and alters the shape of the red blood cells (RBCs). The sickled RBCs can become stuck in the capillaries and occlude the blood flow.

SICKLE CELL DISEASE

Sickle cell disease (SCD) is a group of inherited, autosomal recessive disorders characterized by an abnormal form of hemoglobin in the RBC. (Autosomal recessive genetic disorders are discussed in Chapter 13 and Table 13-2.) Because this is a genetic disorder, SCD is usually identified during infancy or early childhood. It is an incurable disease that is often fatal by middle age because of renal failure, infection, pulmonary failure, and/or stroke.[3]

SCD affects about 100,000 Americans and is predominant in African Americans, occurring in an estimated 1 in about 500 live births. It can also affect people of Mediterranean, Caribbean, South and Central American, Arabian, or East Indian ancestry.[15]

Etiology and Pathophysiology

Genetic Link

In SCD the abnormal hemoglobin, *hemoglobin S* (Hgb S), results from the substitution of valine for glutamic acid on the β-globin chain of hemoglobin (see Fig. 13-3). Hgb S causes the erythrocyte to stiffen and elongate, taking on a sickle shape in response to low oxygen levels (Fig. 31-3).

Types of SCD disorders include sickle cell anemia, sickle cell–thalassemia, sickle cell Hgb C disease, and sickle cell trait. *Sickle cell anemia,* the most severe of the SCD syndromes, occurs when a person is homozygous for hemoglobin S (Hgb SS); the person has inherited Hgb S from both parents. *Sickle cell–thalassemia* and *sickle cell Hgb C* occur when a person inherits Hgb S from one parent and another type of abnormal hemoglobin (such as thalassemia or hemoglobin C) from the other parent. Both of these forms of SCD are less common and less severe than sickle cell anemia. *Sickle cell trait* occurs when a person is heterozygous for hemoglobin S (Hgb AS); the person has inherited hemoglobin S from one parent and normal hemoglobin (Hgb A) from the other parent. Sickle cell trait is typically a mild to asymptomatic condition.

Sickling Episodes. The major pathophysiologic event of SCD is the sickling of RBCs (see Fig. 31-3). Sickling episodes are most commonly triggered by low oxygen tension in the blood. Hypoxia or deoxygenation of the RBCs can be caused by viral or bacterial infection, high altitude, emotional or physical stress, surgery, and blood loss. Infection is the most common precipitating factor. Other events that can trigger or sustain a sickling episode include dehydration, increased hydrogen ion concentration (acidosis), increased plasma osmolality, decreased plasma volume, and low body temperature. A sickling episode can also occur without an obvious cause.

Sickled RBCs become rigid and take on an elongated, crescent shape (see Fig. 31-3). Sickled cells cannot easily pass through capillaries or other small vessels and can cause vascular occlusion, leading to acute or chronic tissue injury. The resulting hemostasis promotes a self-perpetuating cycle of local hypoxia, deoxygenation of more erythrocytes, and more sickling. Circulating sickled cells are hemolyzed by the spleen, leading to anemia. Initially the sickling of cells is reversible with reoxygenation, but it eventually becomes irreversible because of cell membrane damage from recurrent sickling. Thus vaso-occlusive phenomena and hemolysis are the clinical hallmarks of SCD.

Sickle cell crisis is a severe, painful, acute exacerbation of RBC sickling causing a vaso-occlusive crisis. As blood flow is impaired by sickled cells, vasospasm occurs, further restricting blood flow. Severe capillary hypoxia causes changes in membrane permeability, leading to plasma loss, hemoconcentration, thrombi, and further circulatory stagnation. Tissue ischemia, infarction, and necrosis eventually occur from lack of oxygen. Shock is a possible life-threatening consequence of sickle cell crisis because of severe oxygen depletion of the tissues and a reduction of the circulating fluid volume. Sickle cell crisis can begin suddenly and persist for days to weeks.

The frequency, extent, and severity of sickling episodes are highly variable and unpredictable, but largely depend on the percentage of Hgb S present. Individuals with sickle cell anemia have the most severe form because the erythrocytes contain a high percentage of Hgb S.

GENETICS IN CLINICAL PRACTICE

Sickle Cell Disease

Genetic Basis
- Autosomal recessive disorder.
- Mutation in β-globin *(HBB)* gene located on chromosome 11.
- Various versions of β-globin result from different mutations in the *HBB* gene.
- Hgb S variant involves substitution of valine for glutamic acid in the β-globin gene in sickle cell anemia.

Incidence
- Most common inherited blood disorder in the United States.
- Affects 8 of every 100,000 people.
- Affects 1 in 350 to 500 African Americans.
- Affects 1 in 1000 to 1400 Hispanic Americans.
- Also affects people of Mediterranean, Caribbean, Arabian, and East Indian descent.

Genetic Testing
- DNA testing is available.
- Electrophoresis of hemoglobin and sickling screening test are more commonly used.

Clinical Implications
- Requires ongoing continuity of care and extensive patient teaching.
- Sickle cell trait is the carrier state for sickle cell disease and represents a mild type of sickle cell disease; 1 in 10 to 12 African Americans and 1 in 25 Hispanics have sickle cell trait.
- If both parents have the trait, there is a 1 in 4 chance that their baby will have sickle cell disease.
- Management of sickle cell disease should focus on the prevention of sickle cell crisis (e.g., prevention of dehydration and infection).
- Genetic counseling is recommended for individuals with a family history of sickle cell disease. Individuals should understand the risks of transmitting the genetic mutation.

Clinical Manifestations

The effects of SCD vary greatly from person to person, the severity of which may be due to genetic polymorphisms. Many people with sickle cell anemia are in reasonably good health the majority of the time. However, they may have chronic health problems and pain because of organ tissue hypoxia and damage (e.g., involving the kidneys or liver).

The typical patient is anemic but asymptomatic except during sickling episodes. Because most individuals with sickle cell anemia have dark skin, pallor is more readily detected by examining the mucous membranes. The skin may have a grayish cast. Because of the hemolysis, jaundice is common and patients are prone to gallstones (cholelithiasis).

The primary symptom associated with sickling is pain. The pain severity can range from trivial to excruciating. During sickle cell crisis the pain is severe because of ischemia of tissue. The episodes can affect any area of the body or several sites simultaneously, with the back, chest, extremities, and abdomen being most commonly affected. Pain episodes are often accompanied by clinical manifestations such as fever, swelling, tenderness, tachypnea, hypertension, nausea, and vomiting.

Complications

With repeated episodes of sickling, there is gradual involvement of all body systems, especially the spleen, lungs, kidneys, and brain. Organs that have a high need for oxygen are most often affected and form the basis for many of the complications of SCD (Fig. 31-4). Infection is a major cause of morbidity and mortality in patients with SCD. One reason for this is the failure of the spleen to phagocytize foreign substances as it becomes infarcted and dysfunctional (usually by 2 to 4 years of age) from the sickled RBCs. The spleen becomes small because of repeated scarring, a phenomenon termed *autosplenectomy.*

Pneumonia is the most common infection and often is of pneumococcal origin. Infections can be so severe that they cause an aplastic and hemolytic crisis and gallstones. *Aplastic crisis* can be so severe that it causes a temporary shutdown of RBC production in the bone marrow.

Acute chest syndrome is a term used to describe acute pulmonary complications that include pneumonia, tissue infarction, and fat embolism. It is characterized by fever, chest pain, cough, pulmonary infiltrates, and dyspnea. Pulmonary infarctions may cause pulmonary hypertension, MI, HF, and ultimately cor pulmonale. The heart may become ischemic and enlarged, leading to HF. Retinal vessel obstruction may result in hemorrhage, scarring, retinal detachment, and blindness. The kidneys may be injured from the increased blood viscosity and the lack of oxygen, and renal failure may occur. Pulmonary embolism or stroke can result from thrombosis and infarction of cerebral blood vessels. Bone changes may include osteoporosis and osteosclerosis after infarction. Chronic leg ulcers can result from the hypoxia and are especially prevalent around the ankles. *Priapism* (persistent penile erection) may occur if penile veins become occluded.

Diagnostic Studies

A peripheral blood smear may reveal sickled cells and abnormal reticulocytes. The presence of Hgb S can be diagnosed by the sickling test, which uses RBCs (in vitro) and exposes them to a deoxygenation agent.

As a result of the accelerated RBC breakdown, the patient has characteristic clinical findings of hemolysis (jaundice, elevated serum bilirubin levels) and abnormal laboratory test results (see Table 31-6). Hemoglobin electrophoresis may be done to determine the amount of hemoglobin S. Skeletal x-rays demonstrate bone and joint deformities and flattening. Magnetic resonance imaging (MRI) may be used to diagnose a stroke caused by blocked cerebral vessels from sickled cells. Doppler studies may be used to assess for deep vein thromboses. Other tests may be indicated, such as a chest x-ray, to diagnose infection or organ malfunction.

NURSING AND COLLABORATIVE MANAGEMENT SICKLE CELL DISEASE

Collaborative care for a patient with SCD is directed toward (1) alleviating the symptoms from the complications of the disease; (2) minimizing end-organ damage; and (3) promptly treating serious sequelae, such as acute chest syndrome, that can lead to immediate death. Teach patients with SCD to avoid high altitudes, maintain adequate fluid intake, and treat infections promptly. Pneumovax, *Haemophilus influenzae,* influenza, and hepatitis immunizations should be administered. Chronic leg ulcers may be treated with rest, antibiotics, warm saline soaks, mechanical or enzyme debridement, and grafting if necessary.

Priapism is managed with pain medication, fluids, and nifedipine (Procardia). If it does not resolve within a few hours, a urologist can be called to inject the corpus cavernosum with a dilute solution of epinephrine to preserve penile function.

Sickle cell crises may require hospitalization. Oxygen may be administered to treat hypoxia and control sickling. Because

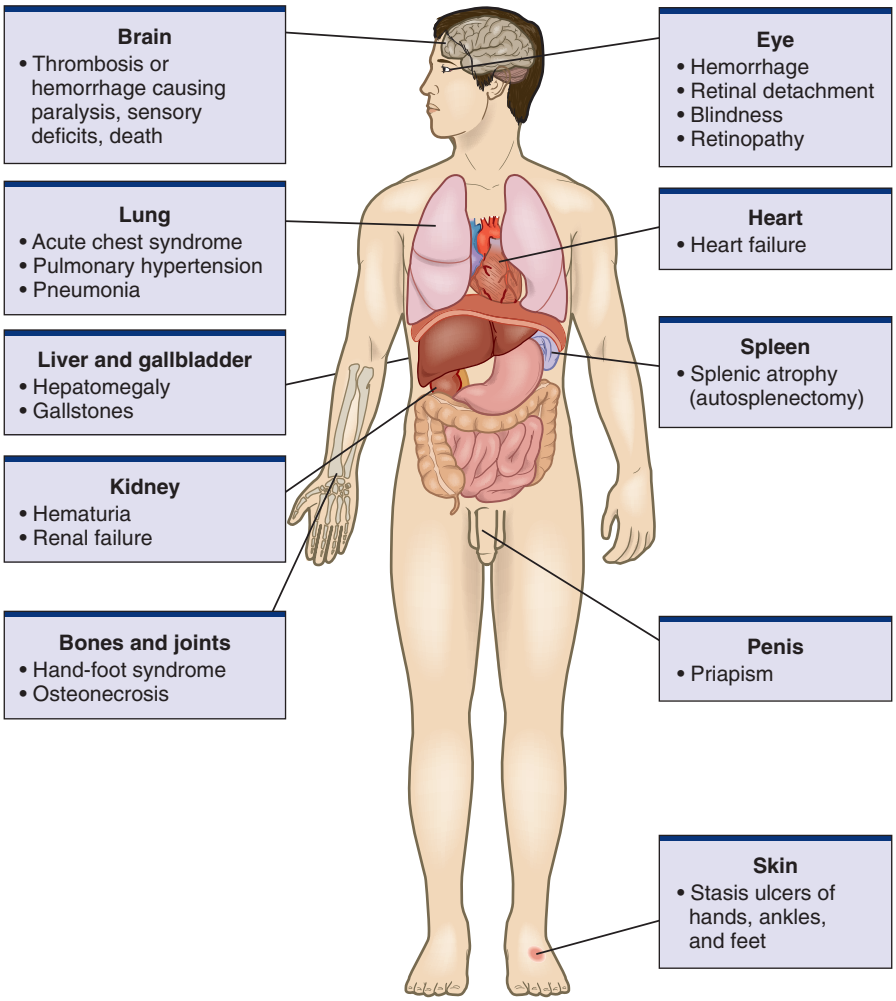

FIG. 31-4 Clinical manifestations and complications of sickle cell disease.

respiratory failure is the most common cause of death, vigilantly assess for any changes in respiratory status.[16] Rest may be instituted to reduce metabolic requirements, and deep vein thrombosis prophylaxis (using anticoagulants) should be prescribed. Fluids and electrolytes are administered to reduce blood viscosity and maintain renal function. Transfusion therapy is indicated when an aplastic crisis occurs. Aggressive total RBC exchange transfusion programs may be implemented for patients who have frequent crises or serious complications such as acute chest syndrome. These patients, like those with thalassemia major, may require iron chelation therapy to reduce transfusion-produced iron overload.

Undertreatment of sickle cell pain is a major problem. Lack of understanding can lead health care professionals to underestimate how much pain these patients suffer. Patients, because of their prior opioid treatment, may be tolerant, and thus large doses may be needed to reduce the pain to a tolerable level. During an acute crisis, optimal pain control usually includes large doses of continuous (rather than as-needed [PRN]) opioid analgesics along with breakthrough analgesia, often in the form of patient-controlled analgesia (PCA) (PCA is discussed in Chapter 9). Morphine and hydromorphone are the drugs of choice. Meperidine (Demerol) is contraindicated because high doses can lead to the accumulation of a toxic metabolite, normeperidine, which can cause seizures.

Because patients may be experiencing different types and sites of pain, a multimodal and interdisciplinary approach should be used that incorporates emotional aspects of pain (see Chapter 9). Adjunctive measures, such as nonsteroidal anti-inflammatory agents, antineuropathic pain medications (e.g., tricyclic antidepressants, antiseizure medications), local anesthetics, or nerve blocks may be used.

Although pain is the most common symptom of patients with SCD seeking medical care, infection is a frequent complication and must be treated. Patients with acute chest syndrome are treated with broad-spectrum antibiotics, O_2 therapy, fluid therapy, and possibly exchange transfusion. Blood transfusions have little if any role in the treatment between crises, since patients develop antibodies to RBCs and iron overload. However, because chronic hemolysis results in increased use of folic acid stores, routine oral folic acid should be taken.

Although many antisickling agents have been tried, hydroxyurea (Hydrea), which is a chemotherapy drug, is the only one that has been shown to be clinically beneficial.[17] This drug increases the production of hemoglobin F (fetal hemoglobin), decreases the reactive neutrophil count, increases RBC volume and hydration, and alters the adhesion of sickle RBCs to the endothelium. The increase in Hgb F is accompanied by a reduction in hemolysis, an increase in hemoglobin concentration, and a decrease in sickled cells and painful crises.[11]

ETHICAL/LEGAL DILEMMAS

Pain Management

Situation

N.C., a 21-year-old African American man, is admitted to the emergency department (ED) in sickle cell crisis with complaints of excruciating pain. He is known to several of the nurses and physicians in the ED. One of the nurses remarks to you that it must be time for his "fix" of pain drugs.

Ethical/Legal Points for Consideration

- The standard of care for pain requires that (1) a pain assessment is done based on the patient's self-report, (2) the best possible relief of pain is provided under the circumstances, and (3) competent and compassionate care is provided to all patients.
- The pain assessment also includes reviewing the patient's medical record to determine if there are health care issues or conditions (e.g., frequent ED visits to request pain medication) that may affect the patient's response to pain and pain management.
- As a nurse, you have a duty to notify the health care professional of those issues or conditions. You also need to document behaviors exhibited by the patient related to pain management. Make sure that the documentation is objective (factual observations) rather than labeling (the patient was in withdrawal).
- When pain relief is inadequate, as a nurse, you are responsible for notifying the health care professional. Efforts to notify must continue and be appropriately documented until the managing health care professional has assessed the patient and made a plan of care based on that assessment.

Discussion Questions

1. How can you educate your colleagues regarding pain assessment and management?
2. What important factors would need to be included in your assessment and management of N.C.?

Hematopoietic stem cell transplantation (HSCT) is the only available treatment that can cure some patients with SCD. The selection of appropriate recipients, scarcity of appropriate donors, risk, and cost-effectiveness limit the use of HSCT for SCD. (HSCT is discussed in Chapter 16.)

Patient teaching and support are important in the long-term care of the patient with SCD. The patient and caregiver must understand the basis of the disease and the reasons for supportive care and ongoing pertinent screening tailored to SCD manifestations, such as eye examinations. Teach the patient ways to avoid crises, including taking steps to avoid dehydration and hypoxia, such as avoiding high altitudes and seeking medical attention quickly to counteract problems such as upper respiratory tract infections. Teaching about pain control is also needed because the pain during a crisis may be severe and often requires considerable analgesia. Minor pain episodes that are not associated with infection or other symptoms warranting medical attention can sometimes be managed at home.

Recurrent episodes of severe acute pain and unrelenting chronic pain can be disabling and depressing. The quality of life of patients with SCD can be profoundly affected. Occupational and physical therapists can help the patient achieve optimum physical functioning and independence. Cognitive behavioral therapy may help patients with SCD cope with anxiety and depression. Support groups may also be helpful.

ACQUIRED HEMOLYTIC ANEMIA

Acquired hemolytic anemia results from hemolysis of RBCs from extrinsic factors. These factors can be separated into four categories: (1) macroangiopathic (physical trauma), (2) microangiopathic, (3) antibody reactions, and (4) infectious agents and toxins (see Table 31-2).

Macroangiopathic or physical destruction of RBCs results from the exertion of extreme force on the cells. Traumatic events causing disruption of the RBC membrane include hemodialysis, extracorporeal circulation used in cardiopulmonary bypass, and prosthetic heart valves. In addition, the force needed to push blood through abnormal vessels, such as those that have been burned, irradiated, or affected by vascular disease (e.g., diabetes mellitus), may also physically damage RBCs.

Microangiopathic destruction of RBCs is a result of fragmentation of the cells as they try to pass by abnormal arterial or venous microcirculation. The RBCs are sheared as they try to pass by excessive platelet aggregation and/or fibrin polymer formation, such as is seen in thrombotic thrombocytopenic purpura (TTP) and disseminated intravascular coagulation (DIC) (discussed later in this chapter).

Antibodies may destroy RBCs by the mechanisms involved in antigen-antibody reactions. The reactions may be of an isoimmune or autoimmune type. *Isoimmune reactions* occur when antibodies develop against antigens from another person of the same species. In blood transfusion reactions the recipient's antibodies hemolyze donor cells. *Autoimmune reactions* result when individuals develop antibodies against their own RBCs. Autoimmune hemolytic reactions may be idiopathic, developing with no prior hemolytic history as a result of immunoglobulin G (IgG) covering the RBCs, or secondary to other autoimmune diseases (e.g., systemic lupus erythematosus), leukemia, lymphoma, or medications (penicillin, ibuprofen, metformin, chlorpromazine, procainamide).

Infectious agents and toxins cause the fourth type of acquired hemolytic disorder. Infectious agents cause hemolysis in three ways: (1) by invading the RBC and destroying its contents (e.g., parasites such as in malaria), (2) by releasing hemolytic substances (e.g., *Clostridium perfringens*), and (3) by generating an antigen-antibody reaction (e.g., *Mycoplasma pneumoniae*). Various agents may be toxic to RBCs and cause hemolysis. These hemolytic toxins involve chemicals such as oxidative drugs, arsenic, lead, copper, and bee stings or spider bites.

Laboratory findings in hemolytic anemia are presented in Table 31-6. Treatment and management of acquired hemolytic anemias involve general supportive care until the causative agent can be eliminated or at least made less injurious to the RBCs. Because a hemolytic crisis is a potential consequence, be ready to institute appropriate emergency therapy. This includes aggressive hydration and electrolyte replacement to reduce the risk of kidney injury caused by hemoglobin (from RBC lysis) clogging the kidney tubules and subsequent shock. Additional supportive care may include administering corticosteroids and blood products or removing the spleen.

For chronic hemolytic anemia, folate may need to be replaced. To suppress the RBC destruction, immunosuppressive agents may be used, such as rituximab (Rituxan), a monoclonal antibody to B-cell CD20, and eculizumab (Soliris), a monoclonal antibody to complement protein C5.

OTHER RED BLOOD CELL DISORDERS

HEMOCHROMATOSIS

Hemochromatosis is an iron overload disorder. Although it is primarily caused by a genetic defect, hemochromatosis may

GENETICS IN CLINICAL PRACTICE

Hemochromatosis

Genetic Basis
- Autosomal recessive disorder.
- Caused by mutations in the *HAMP*, *HFE*, *HFE2*, *SLC40A1*, and *TFR2* genes.
- These genes play an important role in regulating the absorption, transport, and storage of iron.
- Mutations in these genes impair the control of iron absorption during digestion and alter the distribution of iron to other parts of the body. As a result, iron accumulates in tissues and organs.

Incidence
- Most common genetic disease in people of European ancestry.
- One in 8 are carriers of the single HH gene mutation.
- Affects 1 in 200 to 500 in the United States.
- Very low prevalence in other ethnic populations.

Genetic Testing
- DNA testing is available and recommended for all first-degree relatives of people with the disease.
- American Hemochromatosis Society recommends genetic testing regardless of family history.
- Useful diagnostic tests include serum iron concentration, total iron-binding capacity, and transferrin saturation.

Clinical Implications
- Most of the 33 million Americans who have the gene mutation do not know it.
- Clinical expression is variable depending on dietary iron, blood loss, and other modifying factors.
- Early treatment can prevent serious complications.
- If untreated, progressive iron deposits can lead to multiple organ failure.

occur secondary to diseases such as sideroblastic anemia. It may also be caused by liver disease and chronic blood transfusions that are used to treat thalassemia and SCD.[18]

Genetic Link

The genetic disorder *(hereditary hemochromatosis)* is an autosomal recessive disorder characterized by increased intestinal iron absorption and, as a result, increased tissue iron deposition.[18] (Autosomal recessive disorders are discussed in Chapter 13 and Table 13-2.) It is the most common genetic disorder among whites, with an incidence of about 5 per 1000 whites of European ancestry.[19]

The normal range for total body iron is 2 to 6 g. Individuals with hemochromatosis accumulate iron at a rate of 0.5 to 1.0 g/yr and may exceed total iron concentrations of 50 g. Symptoms of hemochromatosis usually develop between 40 and 60 years of age.

Early symptoms are nonspecific and include fatigue, arthralgia, impotence, abdominal pain, and weight loss. Later, the excess iron accumulates in the liver and causes liver enlargement and eventually cirrhosis. Then other organs become affected, resulting in diabetes mellitus, skin pigment changes (bronzing), cardiac changes (e.g., cardiomyopathy), arthritis, and testicular atrophy. Physical examination reveals an enlarged liver and spleen and pigmentation changes in the skin.

Laboratory values demonstrate an elevated serum iron, TIBC, and serum ferritin. Testing for known genetic mutations confirms the diagnosis. Liver biopsy can quantify the amount of iron and establish the degree of organ damage.

The goal of treatment is to remove excess iron from the body and minimize any symptoms the patient may have. Iron removal is achieved by removing 500 mL of blood each week for 2 to 3 years until the iron stores in the body are depleted. Then blood is removed less frequently to maintain iron levels within normal limits.

Iron chelating agents may be used. Deferoxamine, which chelates and removes accumulated iron via the kidneys, can be administered IV or subcutaneously. Deferasirox and deferiprone are oral agents that chelate iron. Chelating agents form a complex with iron and promote its excretion from the body.[20]

Management of organ involvement (e.g., diabetes mellitus, HF) is the same as conventional treatment for these problems. Iron accumulation can also be reduced by dietary modifications such as avoidance of vitamin C and iron supplements, uncooked seafood, and iron-rich foods. The most common causes of death are cirrhosis, liver failure, hepatocellular cancer, and cardiac failure. With early diagnosis and treatment, life expectancy is normal. However, many cases go undetected and untreated.

POLYCYTHEMIA

Polycythemia is the production and presence of increased numbers of RBCs. The increase in RBCs can be so great that blood circulation is impaired as a result of the increased blood viscosity *(hyperviscosity)* and volume *(hypervolemia)*.

Etiology and Pathophysiology

The two types of polycythemia are primary polycythemia, or polycythemia vera, and secondary polycythemia (Fig. 31-5). Their etiologies and pathogenesis differ, although their complications and clinical manifestations are similar.

Primary Polycythemia. *Polycythemia vera* is a chronic myeloproliferative disorder. Therefore not only are RBCs involved, but also WBCs and platelets, leading to increased production of each of these blood cells. The disease develops insidiously and follows a chronic, vacillating course. The median age at diagnosis is 60 years old, with a slight male predominance. In polycythemia vera there is enhanced blood viscosity and blood volume and congestion of organs and tissues with blood. Splenomegaly (which occurs in 90% of patients) and hepatomegaly are common. These patients have hypercoagulopathies that predispose them to clotting.

Genetic Link

Polycythemia vera is associated with mutations in the *Janus kinase-2 (JAK2)* gene. The *JAK2* gene provides instructions for making a protein that promotes proliferation of cells, especially blood cells from hematopoietic stem cells. Polycythemia vera begins with one or more DNA mutations of a single hematopoietic stem cell. Most cases of polycythemia vera are not inherited. This condition is associated with genetic changes that are somatic, which means they are acquired during a person's lifetime and are present only in certain cells.

Secondary Polycythemia. *Secondary polycythemia* can be either hypoxia driven or hypoxia independent. In hypoxia-driven secondary polycythemia, hypoxia stimulates erythropoietin (EPO) production in the kidney, which in turn stimulates RBC production. The need for oxygen may result from high altitude, pulmonary disease, cardiovascular disease, alveolar hypoventilation, defective oxygen transport, or tissue hypoxia. EPO levels may return to normal once the hemoglobin is

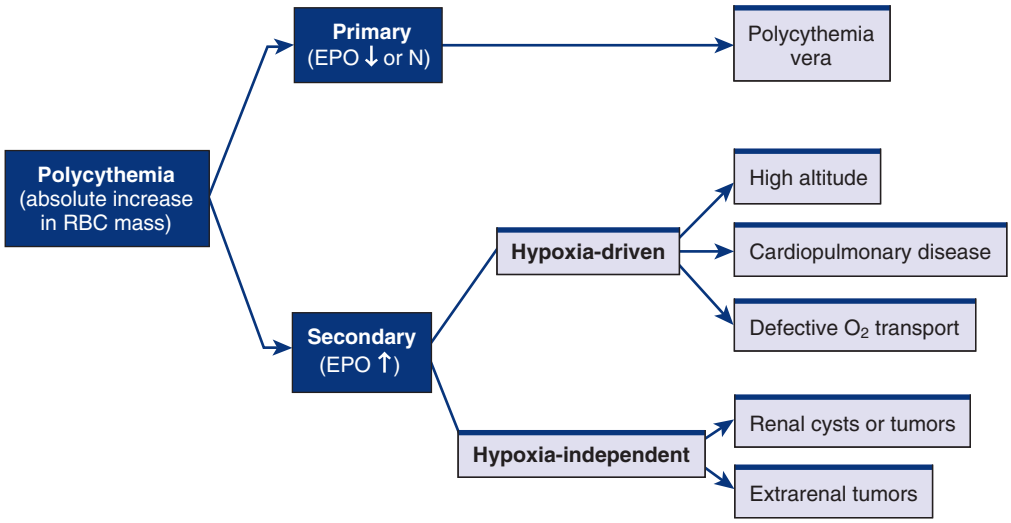

FIG. 31-5 Differentiating between primary and secondary polycythemia. *EPO,* Erythropoietin; *N,* normal.

stabilized at a higher level. In this situation, secondary polycythemia is a physiologic response in which the body tries to compensate for a problem, rather than a pathologic response. (Hypoxia-driven secondary polycythemia is discussed in the section on chronic obstructive pulmonary disease in Chapter 29.)

In hypoxia-independent secondary polycythemia, EPO is produced by a malignant or benign tumor tissue. Serum EPO levels often remain elevated in these situations. Splenomegaly does not accompany secondary polycythemia.

Clinical Manifestations and Complications

Circulatory manifestations of polycythemia vera occur because of the hypertension caused by hypervolemia and hyperviscosity. They are often the first manifestations and include subjective complaints of headache, vertigo, dizziness, tinnitus, and visual disturbances. Generalized pruritus (often exacerbated by a hot bath) may be a striking symptom and is related to histamine release from an increased number of basophils. Paresthesias and *erythromelalgia* (painful burning and redness of the hands and feet) may also be present. In addition, the patient may experience angina, HF, intermittent claudication, and thrombophlebitis, which may be complicated by embolization. These manifestations are caused by blood vessel distention, impaired blood flow, circulatory stasis, thrombosis, and tissue hypoxia caused by the hypervolemia and hyperviscosity. The most common serious acute complication is stroke secondary to thrombosis.

Hemorrhagic phenomena caused by either vessel rupture from overdistention or inadequate platelet function may result in petechiae, ecchymoses, epistaxis, or GI bleeding. Hemorrhage can be acute and catastrophic. Hepatomegaly and splenomegaly from organ engorgement may contribute to patient complaints of satiety and fullness. The patient may also experience pain from peptic ulcer caused either by increased gastric secretions or by liver and spleen engorgement. *Plethora* (ruddy complexion) may also be present. Hyperuricemia is caused by the increase in RBC destruction that accompanies excessive RBC production. Uric acid is one of the products of cell destruction. As RBC destruction increases, uric acid production also increases, thus leading to hyperuricemia and possible gout.

Although the incidence is low, myelofibrosis and leukemia develop in some patients with polycythemia vera. These disorders may be caused by the chemotherapeutic drugs used to treat the disease, or they may be secondary to a disorder in the stem cells that progresses to erythroleukemia. The major cause of morbidity and mortality from polycythemia vera is related to thrombosis (e.g., stroke).

Diagnostic Studies

The following laboratory manifestations are seen in a patient with polycythemia vera: (1) elevated hemoglobin and RBC count with microcytosis; (2) low to normal EPO level (secondary polycythemia has a high level); (3) elevated WBC count with basophilia; (4) elevated platelet count (thrombocytosis) and platelet dysfunction; (5) elevated leukocyte alkaline phosphatase, uric acid, and cobalamin levels; and (6) elevated histamine levels. Bone marrow examination in polycythemia vera shows hypercellularity of RBCs, WBCs, and platelets.

Collaborative Care

Treatment is directed toward reducing blood volume and viscosity and bone marrow activity. Phlebotomy is the mainstay of treatment. The aim of phlebotomy is to reduce the hematocrit and keep it less than 45% to 48%. Generally, at the time of diagnosis 300 to 500 mL of blood may be removed every other day until the hematocrit is reduced to normal levels. An individual managed with repeated phlebotomies eventually becomes deficient in iron, although this effect is rarely symptomatic. Avoid iron supplementation. Hydration therapy is used to reduce the blood's viscosity. Myelosuppressive agents such as hydroxyurea, busulfan (Myleran), and chlorambucil are used.

Ruxolitinib (Jakafi), which is a new drug inhibiting the expression of the *JAK2* mutation, is used for patients who have polycythemia-related myelofibrosis. Low-dose aspirin is used to prevent clotting. α-Interferon (α-IFN) is of particular use in women of childbearing age or those with intractable pruritus. Anagrelide (Agrylin) may be used to reduce the platelet count and inhibit platelet aggregation. Allopurinol (Zyloprim) may reduce the number of acute gouty attacks.[21]

NURSING MANAGEMENT
POLYCYTHEMIA VERA

Primary polycythemia (polycythemia vera) is not preventable. When acute exacerbations of polycythemia vera develop, you have several responsibilities. Depending on the institution's policies, you may either assist with or perform the phlebotomy. Evaluate fluid intake and output during hydration therapy to avoid fluid overload (which further complicates the circulatory congestion) and underhydration (which can make the blood even more viscous). If myelosuppressive agents are used, administer the drugs as ordered, observe the patient, and teach the patient about medication side effects.

Assess the patient's nutritional status, since inadequate food intake can result from GI symptoms of fullness, pain, and dyspepsia. Begin activities and/or medications to decrease thrombus formation. Initiate active or passive leg exercises and ambulation when possible.

Because of its chronic nature, polycythemia vera requires ongoing evaluation. Phlebotomy may need to be done every 2 to 3 months, reducing the blood volume by about 500 mL each time. Evaluate the patient for complications.

PROBLEMS OF HEMOSTASIS

Hemostasis involves the vascular endothelium, platelets, and coagulation factors, which normally function together to stop hemorrhage and repair vascular injury. (These mechanisms are described in Chapter 30.) Disruption in any of these components may result in bleeding or thrombotic disorders.

Three major disorders of hemostasis discussed in this section are (1) thrombocytopenia (low platelet count), (2) hemophilia and von Willebrand disease (inherited disorders of specific clotting factors), and (3) disseminated intravascular coagulation (DIC).

THROMBOCYTOPENIA

Etiology and Pathophysiology

Thrombocytopenia is a reduction of platelets below 150,000/μL (150×10^9/L). Acute, severe, or prolonged decreases from this normal range can result in abnormal hemostasis that manifests as prolonged bleeding from minor trauma or spontaneous bleeding without injury.

Platelet disorders can be inherited (e.g., Wiskott-Aldrich syndrome), but the vast majority are acquired (Table 31-11). A common cause of acquired disorders is the ingestion of certain herbs or drugs[22,23] (Table 31-12). Although some agents are directly myelosuppressive (e.g., chemotherapy, ganciclovir [Cytovene]), the usual mechanism of thrombocytopenia caused by herbs or drugs is accelerated platelet destruction caused by drug-dependent antibodies. Antibodies attack the platelets when the offending agent binds to the platelet surface.

A careful review of the patient's history helps to identify the cause of thrombocytopenia. For example, quinine is in tonic water and in many herbal preparations. In addition, some drugs can affect platelet aggregation. Aspirin doses as low as 81 mg (baby aspirin) can alter platelet aggregation. Normal function is restored when new platelets are formed.

Immune Thrombocytopenic Purpura. The most common acquired thrombocytopenia is a syndrome of abnormal destruction of circulating platelets termed *immune thrombocytopenic purpura* (ITP). It was originally termed *idiopathic thrombocytopenic purpura* because its cause was unknown. However, it is now known that ITP is primarily an autoimmune disease. In ITP, platelets are coated with antibodies. Although these platelets function normally, when they reach the spleen, the antibody-coated platelets are recognized as foreign and are destroyed by macrophages. Decreased platelet production contributes to ITP.

TABLE 31-11 CAUSES OF THROMBOCYTOPENIA

Inherited
- Fanconi syndrome (pancytopenia)
- Hereditary thrombocytopenia

Acquired

Immune
- Immune thrombocytopenic purpura (ITP)
- Neonatal alloimmune thrombocytopenia

Nonimmune
- Shortened circulation (increased consumption)
  - Thrombotic thrombocytopenic purpura (TTP)
  - Disseminated intravascular coagulation (DIC)
  - Heparin-induced thrombocytopenia (HIT)
  - Splenomegaly or splenic sequestration
- Turbulent blood flow (hemangiomas, abnormal cardiac valves, intraaortic balloon pumps)
- Decreased production
  - Drug-induced marrow suppression
  - Chemotherapy
  - Viral infection (hepatitis C virus, HIV, cytomegalovirus)
  - Bacterial infection (sepsis)
  - Alcoholism, bone marrow suppression
  - Myelodysplastic syndrome (MDS)
  - Myelofibrosis
  - Aplastic anemia
  - Hematologic malignancy (leukemias, lymphomas, myeloma)
  - Solid tumor infiltrating bone marrow
  - Radiation to the bone

TABLE 31-12 DRUG AND HERBAL CAUSES OF THROMBOCYTOPENIA*

- Thiazide diuretics
- Alcohol
- Chemotherapeutic drugs
- Digoxin
- Nonsteroidal antiinflammatory drugs: ibuprofen (Advil, Motrin), indomethacin (Indocin), naproxen (Naproxyn, Aleve)
- Antibiotics: penicillins, cephalosporins, sulfonamides
- Other antiinfectives: rifampin (Rifadin), ganciclovir (Cytovene), amphotericin B
- Analgesics: aspirin and aspirin-containing drugs, acetaminophen
- Antipsychotic and antiseizure agents: haloperidol (Haldol), valproate (Depakene), lithium
- Platelet glycoprotein inhibitors: abciximab (ReoPro), tirofiban (Aggrastat), eptifibatide (Integrilin), clopidogrel (Plavix)
- H_2-receptor antagonists: cimetidine (Tagamet), ranitidine (Zantac)
- Gold compounds: auranofin (Ridaura)
- Spices: ginger, cumin, turmeric, cloves
- Vitamins: vitamin C, vitamin E
- Heparin
- Herbs: angelica, bilberry, feverfew, garlic, ginkgo biloba, ginseng
- Quinine compounds: tonic water

*List is not all-inclusive.

Sometimes infection, such as *Helicobacter pylori* or viral infection, contributes to this disorder.[23]

Platelets normally survive 8 to 10 days. However, in ITP survival of platelets is shortened. The clinical syndrome manifests as an acute condition in children and a chronic condition in adults. Chronic ITP may occur in women between 15 and 40 years of age or older individuals. Chronic ITP has a gradual onset, and transient remissions may occur.[23]

Thrombotic Thrombocytopenic Purpura. *Thrombotic thrombocytopenic purpura* (TTP) is an uncommon syndrome characterized by hemolytic anemia, thrombocytopenia, neurologic abnormalities, fever (in the absence of infection), and renal abnormalities; not all features are present in all patients. Because it is almost always associated with hemolytic-uremic syndrome (HUS), it is often referred to as TTP-HUS. The disease is associated with enhanced aggregation of platelets, which form microthrombi that deposit in arterioles and capillaries.

In most cases the syndrome is caused by the deficiency of a plasma enzyme (ADAMTS13) that usually breaks down the von Willebrand clotting factor (vWF) into normal size. (vWF is the most important protein mediating platelet adhesion to damaged endothelial cells.) Without the enzyme, unusually large amounts of vWF attach to activated platelets, thereby promoting platelet aggregation.

TTP is seen primarily in adults between 20 and 50 years of age, with a slight female predominance. The syndrome may be idiopathic (thought to be due to an autoimmune disorder against ADAMTS13), but it may be due to certain drug toxicities (e.g., chemotherapy, cyclosporine, quinine, oral contraceptives, valacyclovir [Valtrex], clopidogrel [Plavix]), pregnancy or preeclampsia, infection, or a known autoimmune disorder such as systemic lupus erythematosus or scleroderma. TTP is a medical emergency because bleeding and clotting occur simultaneously.[24]

Heparin-Induced Thrombocytopenia. One of the risks associated with the broad and increasing use of heparin is the development of the life-threatening condition called *heparin-induced thrombocytopenia* (HIT), also called *heparin-induced thrombocytopenia and thrombosis syndrome* (HITTS). Typically, patients develop thrombocytopenia 5 to 10 days after the onset of heparin therapy. HIT should be suspected if the platelet count falls by more than 50% or falls to below 150,000/μL. As many as 5% of patients on heparin therapy develop HIT.[24]

The major clinical problem of HIT is venous thrombosis; arterial thrombosis can also develop. Deep vein thromboses and pulmonary emboli most commonly result as a complication of the thromboses. Additional complications may include arterial vascular infarcts resulting in skin necrosis, stroke, and end-organ damage (e.g., kidneys). Symptoms of bleeding are unusual because the platelet count rarely drops below 60,000/μL.

In HIT, platelet destruction and vascular endothelial injury are the two major responses to an immune-mediated response to heparin. Platelet factor 4 (PF4) binds to heparin (this protein is made and released by platelets). This complex then binds to the platelet surface, leading to further platelet activation and release of more PF4, thus creating a positive feedback loop. Antibodies are created against this complex, and they are removed prematurely from circulation, leading to thrombocytopenia and platelet-fibrin thrombi. Platelet aggregation also induces heparin to be neutralized. Thus more heparin is required to maintain therapeutic activated partial thromboplastin times (aPTT).

FIG. 31-6 Acute idiopathic thrombocytopenic purpura commonly manifests with purpuric lesions of this kind, although they may often be widespread by the time medical attention is sought.

Clinical Manifestations

Many patients with thrombocytopenia are usually asymptomatic. The most common symptom is bleeding, usually mucosal or cutaneous. Mucosal bleeding may manifest as epistaxis and gingival bleeding, and large bullous hemorrhages may appear on the buccal mucosa because of the lack of vessel protection by the submucosal tissue.

Bleeding into the skin is manifested as petechiae, purpura, or superficial ecchymoses (Fig. 31-6). *Petechiae* are small, flat, pinpoint, red or reddish brown microhemorrhages. When the platelet count is low, RBCs may leak out of the blood vessels and into the skin to cause petechiae. When petechiae are numerous, the resulting reddish skin bruise is called *purpura.* Larger purplish lesions caused by hemorrhage are termed *ecchymoses.* Ecchymoses may be flat or raised; pain and tenderness sometimes are present.

Prolonged bleeding after routine procedures such as venipuncture or IM injection may indicate thrombocytopenia. Because the bleeding may be internal, be aware of manifestations that reflect this type of blood loss, including weakness, fainting, dizziness, tachycardia, abdominal pain, and hypotension.

The major complication of thrombocytopenia is hemorrhage. The hemorrhage may be insidious or acute, and internal or external. It may occur in any area of the body, including the joints, retina, and brain. Cerebral hemorrhage may be fatal. Insidious hemorrhage may first be detected by discovering the anemia that accompanies blood loss.

Because thrombocytopenia can be accompanied by vascular thromboses in some of these disorders, signs and symptoms of vascular ischemic problems can manifest (see Chapter 38). For example, subtle confusion, headache, or even serious manifestations such as seizures and coma due to TTP-related thrombosis may be seen. Because signs and symptoms may be subtle, astute and thorough assessment of the patient is essential.

Diagnostic Studies

The platelet count is decreased in thrombocytopenia. Any reduction below 150,000/μL (150×10^9/L) may be termed *thrombocytopenia.* However, prolonged bleeding from trauma or injury does not usually occur until platelet counts are less than 50,000/μL (50×10^9/L). When the count drops below 20,000/μL (20×10^9/L), spontaneous, life-threatening hemorrhages (e.g., intracranial bleeding) can occur. Platelet transfusions are generally not recommended until the count is below 10,000/μL (10×10^9/L) unless the patient is actively bleeding.

TABLE 31-13 LABORATORY RESULTS IN THROMBOCYTOPENIA

Laboratory Test	Immune Thrombocytopenic Purpura	Thrombotic Thrombocytopenic Purpura	Heparin-Induced Thrombocytopenia	Disseminated Intravascular Coagulation
Platelets	↓↓↓	↓↓↓	↓↓	↓↓↓

Other Tests	ITP platelet antigen-specific assay, ^{14}C-serotonin release assay, *Helicobacter pylori*, bone marrow biopsy	ADAMTS13	^{14}C-serotonin release assay, PF4-heparin complex	

aPTT, Activated partial thromboplastin time; *ITP,* idiopathic thrombocytopenic purpura; *LDH,* lactate dehydrogenase; *N,* normal; *PF4,* platelet factor 4; *PT,* prothrombin time.

Examination of the peripheral blood smear may help distinguish acquired disorders such as ITP and TTP from congenital disorders, which may be indicated by abnormally sized platelets. The patient's medical history and clinical examination, along with comparisons of laboratory parameters, help to determine the etiology of the thrombocytopenia. Table 31-13 compares the types of thrombocytopenia.[23,24]

Laboratory tests that assess secondary hemostasis or coagulation, such as the prothrombin time (PT) and aPTT, can be normal even in severe thrombocytopenia. If they are elevated, this may point toward DIC. Bone marrow examination is done to rule out production problems as the cause of thrombocytopenia (e.g., leukemia, aplastic anemia, other myeloproliferative disorders).

Specific assays, such as ITP antigen-specific assay, ^{14}C-serotonin release assay, or enzyme-linked immunosorbent assay (ELISA) for PF4-heparin complex for HIT, can be done to assist with the diagnosis. In TTP, testing for deficiency of ADAMTS13 is not always diagnostic, so an increase of lactate dehydrogenase (LDH) may help establish the diagnosis.[23,24] When thrombocytopenia occurs with anemia characterized by altered RBC morphology, including *spherocytes* (small, globular, completely hemoglobinated erythrocytes), fragmented cells (schistocytes), and pronounced reticulocytosis, a diagnosis of TTP should be suspected. These findings are partially a result of intravascular fibrin deposition causing a "slicing" of RBCs. In TTP, thrombocytopenia may be severe, but coagulation studies are normal.

Bone marrow analysis is performed if other test results are inconclusive, especially in older patients because of a higher suspicion of an underlying bone marrow disorder. When destruction of circulating platelets is the cause, bone marrow analysis shows *megakaryocytes* (precursors of platelets) to be normal or increased, even though circulating platelets are reduced. The absence or decreased number of megakaryocytes on bone marrow biopsy is consistent with thrombocytopenia caused by decreased bone marrow production (e.g., aplastic anemia). Special blood analyses using flow cytometry and other techniques can detect antiplatelet antibodies as the source of destruction.

Collaborative Care

Collaborative care of thrombocytopenia differs based on the etiology. Removal or treatment of the underlying cause or disorder is sometimes sufficient. The patient with thrombocytopenia should avoid aspirin and other medications that affect platelet function or production. The following sections discuss management strategies for the different causes of thrombocytopenia (Table 31-14).

Immune Thrombocytopenic Purpura. Multiple therapies are used to manage the patient with ITP.[25] If the patient is asymptomatic, therapy may not be used unless the patient's platelet count is below 30,000/μL. Corticosteroids (e.g., prednisone, methylprednisolone) are used initially to treat ITP because of their ability to suppress the phagocytic response of splenic macrophages. This alters the spleen's recognition of platelets and increases the life span of the platelets. In addition, corticosteroids depress antibody formation and reduce capillary leakage.

High doses of IV immunoglobulin (IVIG) and a component of IVIG, anti-Rh_o(D) (anti-D, WinRho), may be used in the patient who is unresponsive to corticosteroids or splenectomy, or for whom splenectomy is not an option. It is believed that one way these agents work is by competing with the antiplatelet antibodies for macrophage receptors in the spleen. Rituximab may be used for its ability to lyse activated B cells, therapy reducing the immune recognition of platelets.

Splenectomy may be indicated if the patient does not respond to the above treatments. Splenectomy can usually be done laparoscopically, and 60% to 70% of patients benefit from splenectomy, resulting in a complete or partial remission.[26] The effectiveness of splenectomy is based on four factors. First, the spleen contains an abundance of the macrophages that sequester and destroy platelets. Second, structural features of the spleen enhance the interaction between antibody-coated platelets and macrophages. Third, some antibody synthesis occurs in the spleen; thus antiplatelet antibodies decrease after splenec-

TABLE 31-14 COLLABORATIVE CARE

Thrombocytopenia

Diagnostic
- History and physical examination
- Bone marrow aspiration and biopsy
- CBC, including platelet count
- Specific studies (see Table 31-13)

Collaborative Therapy

Immune Thrombocytopenic Purpura
- Corticosteroids
- IV immunoglobulin (IVIG)
- Anti-Rh_o(D)
- Rituximab
- Splenectomy
- Romiplostim (Nplate)
- Eltrombopag (Promacta)
- Danazol
- Immunosuppressives (e.g., cyclosporine, cyclophosphamide [Cytoxan], azathioprine [Imuran], mycophenolate mofetil [CellCept])
- High-dose cyclophosphamide or combination chemotherapy
- Platelet transfusions

Thrombotic Thrombocytopenic Purpura
- Identification and treatment of cause
- Plasmapheresis (plasma exchange)
- High-dose prednisone
- Dextran
- Chemotherapy (vincristine [Oncovin], vinblastine [Velban])
- Immunosuppressives (cyclophosphamide, rituximab [Rituxan])
- Splenectomy

Heparin-Induced Thrombocytopenia
- Direct thrombin inhibitor (lepirudin [Refludan], argatroban [Acova])
- Indirect thrombin inhibitor (fondaparinux [Arixtra])
- Warfarin (Coumadin)
- Plasmapheresis (plasma exchange)
- Protamine sulfate
- Thrombolytic agents

Decreased Platelet Production
- Identification and treatment or removal of cause
- Corticosteroids
- Platelet transfusions

tomy. Fourth, the spleen normally sequesters approximately one third of the platelets, so its removal increases the number of platelets in circulation.

Romiplostim (Nplate) and eltrombopag (Promacta) are used for patients with chronic ITP who have had an insufficient response to the other treatments or who have a contraindication to splenectomy. These drugs are thrombopoietin receptor agonists, thus increasing platelet production.[27] Danazol (Danocrine), an androgen, may be used along with corticosteroids in some patients. Although the mechanism is not totally understood, danazol increases $CD4^+$ T cells, thereby decreasing the immune response. Immunosuppressive therapy may be used in refractory cases[23] (see Table 31-14).

Platelet transfusions may be used to increase platelet counts in cases of life-threatening hemorrhage. Platelets should not be administered prophylactically because of the possibility of antibody formation. The usual indication for administering platelets is for a platelet count less than 10,000/μL or if there is anticipated bleeding before a procedure. Epsilon-aminocaproic acid (EACA, Amicar), an antifibrinolytic agent, may be used for severe bleeding.

Thrombotic Thrombocytopenic Purpura. TTP may be treated in a variety of ways. The first step is to treat the underlying disorder (e.g., infection) or remove the causative agent, if identified. If untreated, TTP usually results in irreversible renal failure and death. Plasma exchange (plasmapheresis) (see Chapter 14) is used to aggressively reverse platelet consumption by supplying the appropriate vWF and enzyme (ADAMTS13) and removing the large vWF molecules that bind with platelets. Treatment should be continued daily until the patient's platelet counts normalize and hemolysis has ceased. Corticosteroids may be added to this treatment. Recently, rituximab has been used for patients refractory to plasma exchange; it decreases the level of inhibitory ADAMTS13 IgG antibodies. Other immunosuppressants such as cyclosporine or cyclophosphamide may also be used. Splenectomy may be considered in patients refractory to plasma exchange or immunosuppression. The administration of platelets is generally contraindicated because this may lead to new vWF-platelet complexes and increased clotting.

Heparin-Induced Thrombocytopenia. Heparin must be discontinued when HIT is first recognized. Heparin flushes for vascular catheters should also be stopped.

To maintain anticoagulation, the patient should be started on a direct thrombin inhibitor, such as lepirudin (Refludan) or argatroban (Acova). Fondaparinux (Arixtra), a factor Xa inhibitor (indirect thrombin inhibitor), may be used. Warfarin should be started only when the platelet count has reached 150,000/μL. If the clotting is severe, the most commonly used treatment modalities are plasmapheresis to clear the platelet-aggregating IgG from the blood, protamine sulfate to interrupt the circulating heparin, thrombolytic agents to treat the thromboembolic events, and surgery to remove clots. Platelet transfusions are not effective because they may enhance thromboembolic events.

Patients who have had HIT should never be given heparin or low-molecular-weight heparin (LMWH). This should be clearly marked on the patient's medical record.

Acquired Thrombocytopenia From Decreased Platelet Production. The management of acquired thrombocytopenia is based on identifying the cause and treating the disease or removing the causative agent. If the precipitating factor is unknown, the patient may receive corticosteroids. Platelet transfusions are given if life-threatening hemorrhage develops.

Often acquired thrombocytopenia is caused by another underlying condition (e.g., aplastic anemia, leukemia) or therapy used to treat another problem. For example, in acute leukemia all blood cell types may be depressed. Additionally, the patient may receive chemotherapeutic drugs that cause bone marrow suppression. If the patient can be adequately supported throughout the course of chemotherapy-induced thrombocytopenia, the thrombocytopenia will also resolve.

NURSING MANAGEMENT THROMBOCYTOPENIA

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with thrombocytopenia are presented in Table 31-15.

NURSING DIAGNOSES

Nursing diagnoses for the patient with thrombocytopenia may include, but are not limited to, the following.

TABLE 31-15 NURSING ASSESSMENT

Thrombocytopenia

Subjective Data

Important Health Information

Past health history: Recent hemorrhage, excessive bleeding, or viral illness; HIV infection; cancer (especially leukemia or lymphoma); aplastic anemia; systemic lupus erythematosus; cirrhosis; exposure to radiation or toxic chemicals; disseminated intravascular coagulation

Medications: See Table 31-12

Functional Health Patterns

Health perception–health management: Family history of bleeding problems; malaise

Nutritional-metabolic: Bleeding gingiva; coffee-ground or bloody vomitus; easy bruising

Elimination: Hematuria, dark or bloody stools

Activity-exercise: Fatigue, weakness, fainting; epistaxis, hemoptysis; dyspnea

Cognitive-perceptual: Pain and tenderness in bleeding areas (e.g., abdomen, head, extremities); headache

Sexuality-reproductive: Menorrhagia, metrorrhagia

Objective Data

General

Fever, lethargy

Integumentary

Petechiae, ecchymoses, purpura

Gastrointestinal

Splenomegaly, abdominal distention; guaiac-positive stools

Possible Diagnostic Findings

Platelet count <150,000/μL (150 × 10^9/L), prolonged bleeding time, ↓ hemoglobin and hematocrit; normal or ↑ megakaryocytes in bone marrow examination

- Impaired oral mucous membrane *related to* low platelet counts and/or effects of pathologic conditions and treatment
- Risk for bleeding *related to* decreased platelets
- Deficient knowledge *related to* lack of information regarding the disease process and treatment

PLANNING

The overall goals are that the patient with thrombocytopenia will (1) have no gross or occult bleeding, (2) maintain vascular integrity, and (3) manage home care to prevent any complications related to an increased risk for bleeding.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Discourage excessive use of over-the-counter (OTC) medications known to be possible causes of acquired thrombocytopenia. Many medications contain aspirin as an ingredient. Aspirin reduces platelet adhesiveness, thus contributing to bleeding.

Encourage persons to have a complete medical evaluation if manifestations of bleeding tendencies (e.g., prolonged epistaxis, petechiae) develop. Observe for early signs of thrombocytopenia in the patient receiving cancer chemotherapy drugs.

ACUTE INTERVENTION. The goal during acute episodes of thrombocytopenia is to prevent or control hemorrhage (see eNursing Care Plan 31-1 on the website for this chapter). In the patient with thrombocytopenia, bleeding is usually from superficial sites. Deep bleeding (into muscles, joints, and abdomen) usually occurs only when clotting factors are diminished. Emphasize that a seemingly minor nosebleed or new petechiae may indicate potential hemorrhage and the health care provider should be notified.

Bleeding from the posterior nasopharynx may be difficult to detect because the blood may be swallowed. If a subcutaneous injection is unavoidable, the use of a small-gauge needle and application of direct pressure for at least 5 to 10 minutes after injection is indicated, or application of an ice pack may be helpful. Avoid IM injections. Help the patient understand the importance of adherence to self-care measures that reduce the risk of bleeding (Table 31-16).

Note that many of these disorders may be accompanied by vascular clotting, and appropriate assessment and management should be taken (see Chapter 38). As bleeding occurs, red blood cell and coagulation factors are consumed along with platelets, so it is important to monitor all blood cell and coagulation studies.

TABLE 31-16 PATIENT & CAREGIVER TEACHING GUIDE

Thrombocytopenia

Include the following instructions when teaching a patient or caregiver the precautions to take when the platelet count is low.

1. Notify your health care provider of any manifestations of bleeding. These include the following:
   - Black, tarry, or bloody bowel movements
   - Black or bloody vomit, sputum, or urine
   - Bruising or small red or purple spots on the skin
   - Bleeding from the mouth or anywhere in the body
   - Headache or changes in how well you can see
   - Difficulty talking, sudden weakness of an arm or leg, confusion
2. Ask your health care provider regarding restrictions in your normal activities, such as vigorous exercise, lifting weights. Generally, walking can be done safely and should be done with sturdy shoes or slippers. If you are weak and at risk for falling, get help or supervision when getting out of bed or chair.
3. Do not blow your nose forcefully; gently pat it with a tissue if needed. For a nosebleed, keep your head up and apply firm pressure to the nostrils and bridge of your nose. If bleeding continues, place an ice bag over the bridge of your nose and the nape of your neck. If you are unable to stop a nosebleed after 10 min, call your health care provider.
4. Do not bend down with your head lower than your waist.
5. Prevent constipation by drinking plenty of fluids. Do not strain when having a bowel movement. Your health care provider may prescribe a stool softener. Do not use a suppository, an enema, or a rectal thermometer without the permission of your health care provider.
6. Shave only with an electric razor; do not use blades.
7. Do not pluck your eyebrows or other body hair.
8. Do not puncture your skin, such as getting tattoos or body piercing.
9. Avoid using any medication that can prolong bleeding, such as aspirin. Other medications and herbs can have similar effects. If you are unsure about any medication, ask your health care provider or pharmacist about it in relation to your thrombocytopenia.
10. Use a soft-bristle toothbrush to prevent injuring the gums. Flossing is usually safe if it is done gently using the thin tape floss. Do not use alcohol-based mouthwashes, since they can dry your gums and increase bleeding.
11. Women who are menstruating should keep track of the number of pads that are used per day. When you start using more pads per day than usual or bleed more days, notify your health care provider. Do not use tampons; use sanitary pads only.
12. Ask your health care provider before you have any invasive procedures done, such as a dental cleaning, manicure, or pedicure.

In a woman with thrombocytopenia, menstrual blood loss may exceed the usual amount and duration. Counting sanitary napkins used during menses is another important intervention to detect excess blood loss. Blood loss of 50 mL will completely soak a sanitary napkin. Suppression of menses with hormonal agents may be indicated during predictable periods of thrombocytopenia (e.g., during chemotherapy and HSCT) to reduce blood loss from menses.

Closely monitor the platelet count, coagulation studies, hemoglobin, and hematocrit. Together these provide important information regarding potential or actual bleeding.

The proper administration of platelet transfusions is an important nursing responsibility. This is discussed under Blood Component Therapy later in this chapter.

AMBULATORY AND HOME CARE. Monitor the patient with ITP who is receiving treatment for the response to therapy. Teach the person with acquired thrombocytopenia to avoid causative agents when possible (see Table 31-12). If the causative agents cannot be avoided (e.g., chemotherapy), teach the patient to avoid injury or trauma during these periods and to be aware of the clinical signs and symptoms of bleeding caused by thrombocytopenia (see Table 31-16).

Patients with either ITP or acquired thrombocytopenia should have planned periodic medical evaluations to assess their status. These regular evaluations can be used to assess and treat situations in which exacerbations and bleeding are likely to occur. The impact of either an acute or a chronic condition on the patient's quality of life should also be addressed appropriately.

EVALUATION

The expected outcomes are that the patient with thrombocytopenia will

- Have no evidence of bleeding or bruising
- Verbalize required knowledge and skills to manage disease process at home

HEMOPHILIA AND VON WILLEBRAND DISEASE

Hemophilia is an X-linked recessive genetic disorder caused by a defective or deficient coagulation factor. The two major types of hemophilia, which can occur in mild to severe forms, are *hemophilia A* (classic hemophilia, factor VIII deficiency) and *hemophilia B* (Christmas disease, factor IX deficiency). *von Willebrand disease* is a related disorder involving a deficiency of the von Willebrand coagulation protein. Factor VIII is synthesized in the liver and circulates as a complex with von Willebrand factor (vWF).

Hemophilia A is the most common form of hemophilia, accounting for about 85% to 90% of all cases. Hemophilia B accounts for about 10% to 15% of all cases. von Willebrand disease is considered the most common congenital bleeding disorder, with estimates as high as 1 or 2 in 100.[28]

Genetic Link

The inheritance patterns of hemophilia and von Willebrand disease are compared in Table 31-17. (X-linked genetic disorders are discussed in Chapter 13 and Table 13-2.)

Clinical Manifestations and Complications

All clinical manifestations relate to bleeding, and any bleeding episode in persons with hemophilia may lead to a life-threatening hemorrhage. Clinical manifestations and complications related to hemophilia include (1) slow, persistent, prolonged bleeding from minor trauma and small cuts; (2) delayed bleeding after minor injuries (the delay may be several hours or days); (3) uncontrollable hemorrhage after dental extractions or irritation of the gingiva with a hard-bristle toothbrush; (4) epistaxis, especially after a blow to the face; (5) GI bleeding from ulcers and gastritis; (6) hematuria and potential renal failure from GU trauma and splenic rupture resulting from falls or abdominal trauma; (7) ecchymoses and subcutaneous hematomas (Fig. 31-7); (8) neurologic signs, such as pain, anesthesia, and paralysis, which may develop from nerve compression caused by hematoma formation; and (9) hemarthrosis (bleeding into the joints) (Fig. 31-8), which may lead to joint injury and deformity severe enough to cause crippling (most commonly in knees, elbows, shoulders, hips, and ankles).

TABLE 31-17 TYPES OF HEMOPHILIA

Type	Inheritance Pattern
Hemophilia A	
Factor VIII	Recessive sex-linked (transmitted by female carriers, displayed almost exclusively in men)
Hemophilia B	
Factor IX	Recessive sex-linked (transmitted by female carriers, displayed almost exclusively in men)
von Willebrand Disease	
vWF, variable factor VIII deficiencies and platelet dysfunction	Autosomal dominant, seen in both genders Recessive (in severe forms of the disease)

vWF, von Willebrand factor.

GENETICS IN CLINICAL PRACTICE

Hemophilia A and B

Genetic Basis

- X-linked recessive disorder.
- *Hemophilia A:* Caused by mutations in the *F8* gene that provides instructions for making coagulation factor VIII.
- *Hemophilia B:* Caused by mutations in the *F9* gene that provides instructions for making coagulation factor IX.
- Mutations in the *F8* or *F9* gene lead to the production of an abnormal version or reduced amounts of these coagulation factors.

Incidence

- *Hemophilia A:* 1 in 5000 to 10,000 male births.
- *Hemophilia B:* 1 in 30,000 to 50,000 male births.

Genetic Testing

- DNA testing is available.

Clinical Implications

- Female carriers transmit the genetic defect to 50% of their sons, and 50% of their daughters are carriers.
- Males with hemophilia do not transmit the genetic defect to their sons, but all of their daughters are carriers.
- Female hemophilia can occur if a male with hemophilia mates with a female carrier. However, this is a rare situation.
- Clinical manifestations of hemophilia A and B are similar.
- Replacement therapy is available for factors VIII and IX (see Table 31-19).

FIG. 31-7 Severe ecchymoses in a person with hemophilia after a fall.

FIG. 31-8 Acute hemarthrosis of the knee is a common complication of hemophilia.

TABLE 31-18 LABORATORY RESULTS IN HEMOPHILIA

Test	Results
Prothrombin time	Normal. No involvement of extrinsic system.
Thrombin time	Normal. No impairment of thrombin-fibrinogen reaction.
Platelet count	Normal. Adequate platelet production.
Partial thromboplastin time	Prolonged because of deficiency in intrinsic clotting system factor.
Bleeding time	Prolonged in von Willebrand disease because of structurally defective platelets. Normal in hemophilia A and B because platelets not affected.
Factor assays	Reductions of factor VIII in hemophilia A, factor IX in hemophilia B, vWF in von Willebrand disease.

vWF, von Willebrand factor.

TABLE 31-19 DRUG THERAPY

Replacement Factors for Hemophilia

Factor VIII	Factor IX	For Patients Who Have Inhibitors
Advate	AlphaNine SD	NovoSeven (factor VIIa)
Alphanate	Bebulin VH	Autoplex T
Helixate FS	Benefix	FEIBA (factor VIII inhibitor bypassing activity)
Hemofil M	Mononine	
Humate-P	Profilnine SD	
Koāte-DVI		
Kogenate FS		
Monoclate P		
Recombinate		
Xyntha		

In children these manifestations may lead to the diagnosis. In adults these developments may be the first sign of a newly diagnosed mild form of the disease that escaped detection through a childhood free of major injuries, dental procedures, or surgeries.

Diagnostic Studies

Laboratory studies are used to determine the type of hemophilia present. Any factor deficiency within the intrinsic system (factor VIII, IX, XI, or XII or vWF) will yield the laboratory results presented in Table 31-18.

Collaborative Care

The goals of collaborative care are to prevent and treat bleeding. Collaborative care for persons with hemophilia or von Willebrand disease requires (1) preventive care, (2) the use of replacement therapy during acute bleeding episodes and as prophylaxis, and (3) the treatment of the complications of the disease and its therapy. Today most patients can expect almost normal life spans free of bloodborne illnesses because of improved preparation of replacement products, improved screening of blood donor populations, and use of recombinant replacement factors.[29]

Replacement of deficient clotting factors is the primary means of supporting a patient with hemophilia. In addition to treating acute crises, replacement therapy may be given before surgery and dental care as a prophylactic measure.[30] Examples of replacement therapy are listed in Table 31-19. Fresh frozen plasma, once commonly used for replacement therapy, is rarely used today.

For mild hemophilia A and certain subtypes of von Willebrand disease, desmopressin acetate (also known as DDAVP), a synthetic analog of vasopressin, may be used to stimulate an increase in factor VIII and vWF. This drug acts on platelets and endothelial cells to cause the release of vWF, which subsequently binds with factor VIII, thus increasing their concentration. It can be administered IV, subcutaneously, or by intranasal spray. Beneficial effects (e.g., decreased bleeding time) of DDAVP, when administered IV, are seen within 30 minutes and can last for more than 12 hours. Because the effect of DDAVP is relatively short lived, the patient must be closely monitored and repeated doses may be necessary. It is an appropriate therapy for minor bleeding episodes and dental procedures. The intranasal form may be indicated for home therapy for some patients with mild to moderate forms of the disease.

Antifibrinolytic therapy (tranexamic acid [Cyklokapron] and epsilon-aminocaproic acid) inhibits fibrinolysis by inhibiting plasminogen activation in the fibrin clot, thereby enhancing clot stability. These agents are used to stabilize clots in areas of increased fibrinolysis, such as the oral cavity, and in patients with difficult episodes of epistaxis and menorrhagia.[31]

Complications of the treatment of hemophilia include development of inhibitors to factors VIII or IX, transfusion-transmitted infectious disorders (hepatitis, HIV), allergic reactions, and thrombotic complications with the use of factor IX because it contains activated coagulation factors. Patients with vWF may also develop alloantibodies against vWF concentrates, the infusion of which could cause life-threatening anaphylaxis. Thus replacement factors for these patients should not contain vWF.

The most common difficulties with acute management are starting factor replacement therapy too late and stopping it too soon. Generally, minor bleeding episodes should be treated for at least 72 hours. Surgery and traumatic injuries may need more prolonged therapy. Chronically, development of inhibitors to the factor products has occurred and requires individualized expert patient management. Designated treatment centers in the United States and many other countries provide interdisciplinary care of hemophilia and related disorders. Gene therapy has been used on an experimental basis to treat hemophilia.[32]

NURSING MANAGEMENT HEMOPHILIA

NURSING IMPLEMENTATION

HEALTH PROMOTION. Because of the hereditary nature of hemophilia, referral of affected persons for genetic counseling before reproduction is an important measure. This is especially important because many persons with hemophilia live into adulthood. Reproductive concerns and long-term effects are issues that you should include in the patient's care plan.

ACUTE INTERVENTION. Interventions are related primarily to controlling bleeding and include the following:

1. Stop the topical bleeding as quickly as possible by applying direct pressure or ice, packing the area with Gelfoam or fibrin foam, and applying topical hemostatic agents such as thrombin.
2. Administer the specific coagulation factor to raise the patient's level of the deficient coagulation factor. Monitor the patient for signs and symptoms, such as hypersensitivity.
3. When joint bleeding occurs, in addition to administering replacement factors, it is important to totally rest the involved joint to prevent crippling deformities from hemarthrosis. Pack the joint in ice. Give analgesics (e.g., acetaminophen, codeine) to reduce severe pain. Aspirin and aspirin-containing compounds should never be used. As soon as bleeding ceases, encourage mobilization of the affected area through range-of-motion exercises and physical therapy. Weight bearing is avoided until all swelling has resolved and muscle strength has returned.
4. Manage any life-threatening complications that may develop as a result of hemorrhage or side effects from coagulation factors. Examples include nursing interventions to prevent or treat airway obstruction from hemorrhage into the neck and pharynx, recognition of compartment syndrome in an extremity, and early assessment and treatment of intracranial bleeding.

AMBULATORY AND HOME CARE. Home management is a primary consideration for the patient with hemophilia because the disease follows a progressive, chronic course. The quality and the length of life may be significantly affected by the patient's knowledge of the illness and how to live with it. The patient and caregiver can be referred to a local chapter of the Hemophilia Federation of America to encourage associations with other individuals who are dealing with the problems of hemophilia. Provide ongoing assessment of the patient's adaptation to the illness. Psychosocial support and assistance should be readily available as needed.

Most of the long-term care measures are related to patient teaching. Teach the patient to recognize disease-related problems and to learn which problems can be resolved at home and which require hospitalization. Immediate medical attention is required for severe pain or swelling of a muscle or joint that restricts movement or inhibits sleep and for a head injury, swelling in the neck or mouth, abdominal pain, hematuria, melena, and skin wounds in need of suturing.

Teach the patient to perform daily oral hygiene without causing trauma. Understanding how to prevent injuries is another consideration. Advise the patient to participate only in noncontact sports (e.g., golf) and to wear gloves when doing household chores to prevent cuts or abrasions from knives, hammers, and other tools. The patient should wear a Medic Alert tag to ensure that health care providers know about the hemophilia in case of an accident. Many patients or their caregivers can be taught to self-administer the factor replacement therapies at home.

EVALUATION

The overall expected outcomes are similar to those for the patient with thrombocytopenia (see p. 655).

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is a serious bleeding and thrombotic disorder that results from abnormally initiated and accelerated clotting. Subsequent decreases in clotting factors and platelets ensue, which may lead to uncontrollable hemorrhage. The term *disseminated intravascular coagulation* can be misleading because it suggests that blood is clotting. However, this condition is characterized by the profuse bleeding that results from the depletion of platelets and clotting factors. DIC is always caused by an underlying disease or condition. The underlying problem must be treated for the DIC to resolve.

Etiology and Pathophysiology

DIC is not a disease. It is an abnormal response of the normal clotting cascade stimulated by a disease process or disorder.[33] The diseases and disorders known to predispose a patient to DIC are listed in Table 31-20. DIC can occur as an acute, catastrophic condition or it may exist at a subacute or chronic level. Each condition may have one or multiple triggering mechanisms to start the clotting cascade. For example, tumors and traumatized or necrotic tissue release tissue factors into circulation. Endotoxin from gram-negative bacteria activates several steps in the coagulation cascade.

Tissue factor is released at the site of tissue injury and by some malignancies, such as leukemia, and enhances normal coagulation mechanisms. Abundant intravascular thrombin, the most powerful coagulant, is produced (Fig. 31-9). It catalyzes the conversion of fibrinogen to fibrin and enhances platelet aggregation. There is widespread fibrin and platelet deposition in capillaries and arterioles, resulting in thrombosis. This process can lead to multiorgan failure.

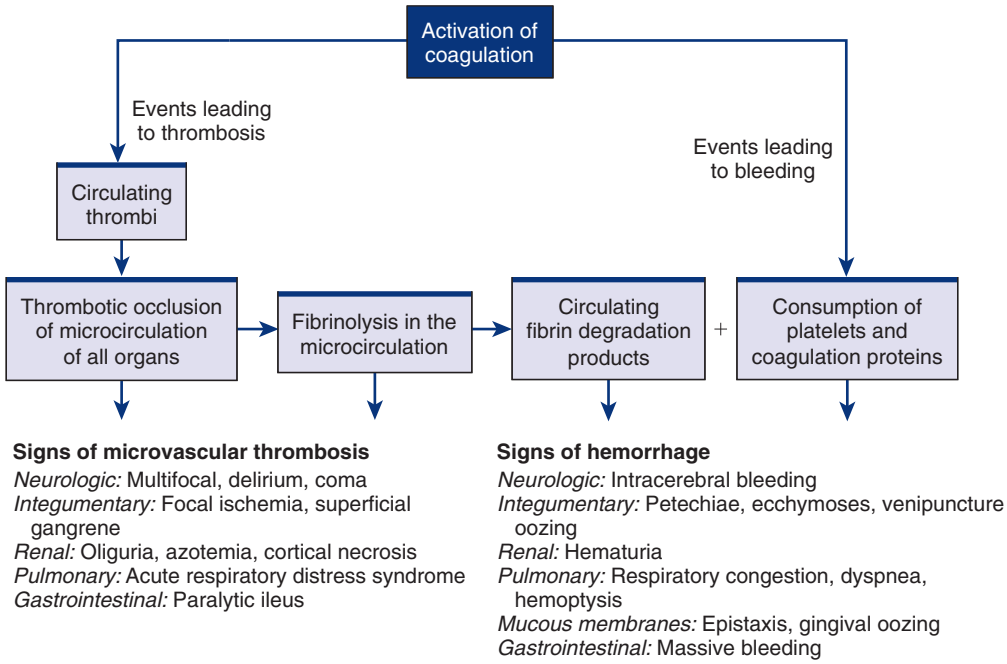

FIG. 31-9 The sequence of events that occur during disseminated intravascular coagulation (DIC).

In addition, clotting inhibitory mechanisms, such as antithrombin III (AT III) and protein C, are depressed. Excessive clotting activates the fibrinolytic system, which in turn breaks down the newly formed clot, creating fibrin split products (FSPs). These products have anticoagulant properties and inhibit normal blood clotting. Ultimately, as FSPs accumulate and clotting factors are depleted, the blood loses its ability to clot. Therefore a stable clot cannot be formed at injury sites, which predisposes the patient to hemorrhage.

Chronic and subacute DIC is most commonly seen in patients with long-standing illnesses such as malignant disorders or autoimmune diseases. Occasionally these patients have subclinical disease manifested only by laboratory abnormalities. However, the clinical spectrum ranges from easy bruising to hemorrhage, and from hypercoagulability to thrombosis.

TABLE 31-20 RISK FACTORS FOR DIC

Acute DIC

Shock
- Hemorrhagic
- Cardiogenic
- Anaphylactic

Septicemia (bacterial, viral, fungal, parasitic)

Hemolytic processes
- Transfusion of mismatched blood
- Acute hemolysis from infection or immunologic disorders

Obstetric conditions
- Abruptio placentae
- Amniotic fluid embolism
- Septic abortion
- HELLP syndrome

Malignancies
- Acute leukemia
- Lymphoma
- Tumor lysis syndrome

Tissue damage
- Extensive burns and trauma
- Heatstroke
- Severe head injury
- Transplant rejections
- Postoperative damage, especially after extracorporeal membrane oxygenation
- Fat and pulmonary emboli
- Snakebites
- Glomerulonephritis
- Acute anoxia (e.g., after cardiac arrest)
- Prosthetic devices
- Fulminant hepatitis

Subacute DIC

Malignancy
- Myeloproliferative/lymphoproliferative malignancies
- Metastatic cancer

Obstetric
- Retained dead fetus

Chronic DIC

Liver disease

Systemic lupus erythematosus

Malignancy

DIC, Disseminated intravascular coagulation; *HELLP syndrome,* a life-threatening liver disorder thought to be a type of severe preeclampsia, it is characterized by **H**emolysis (destruction of red blood cells), **E**levated **L**iver enzymes (which indicate liver damage), and **L**ow **P**latelet count.

Clinical Manifestations

DIC has both bleeding and thrombotic manifestations. Multiple factors cause bleeding manifestations of DIC (see Fig. 31-9) and result from consumption and depletion of platelets and coagulation factors, as well as clot lysis and formation of FSPs that have anticoagulant properties. Bleeding in a person with no previous history or obvious cause should be questioned because it may be one of the first manifestations of acute DIC.

Bleeding manifestations include (1) *integumentary manifestations* such as pallor, petechiae, purpura (Fig. 31-10), oozing

FIG. 31-10 Disseminated intravascular coagulation (DIC) resulting from staphylococcal septicemia. Note the characteristic skin hemorrhage ranging from small purpuric lesions to larger ecchymoses.

blood, venipuncture site bleeding, hematomas, and occult hemorrhage; (2) respiratory manifestations such as tachypnea, hemoptysis, and orthopnea; (3) cardiovascular manifestations such as tachycardia and hypotension; (4) GI manifestations such as upper and lower GI bleeding, abdominal distention, and bloody stools; (5) urinary manifestations such as hematuria; (6) neurologic manifestations such as vision changes, dizziness, headache, changes in mental status, and irritability; and (7) musculoskeletal complaints such as bone and joint pain.

Thrombotic manifestations are a result of fibrin or platelet deposition in the microvasculature (see Fig. 31-9). They include (1) integumentary manifestations, such as cyanosis, ischemic tissue necrosis (e.g., gangrene), and hemorrhagic necrosis; (2) respiratory manifestations, such as tachypnea, dyspnea, pulmonary emboli, and acute respiratory distress syndrome (ARDS); (3) cardiovascular manifestations, such as electrocardiogram (ECG) changes and venous distention; (4) GI manifestations, such as abdominal pain and paralytic ileus; and (5) kidney damage and oliguria, leading to failure.

Diagnostic Studies

Tests to diagnose acute DIC are listed in Table 31-21. As more clots are made in the body, more breakdown products from fibrinogen and fibrin are also formed. These are termed *fibrin split products* (FSPs), and they interfere with blood coagulation by (1) coating the platelets and interfering with platelet function; (2) interfering with thrombin and thus disrupting coagulation; and (3) attaching to fibrinogen, which interferes with the polymerization process necessary to form a stable clot. D-dimer, a polymer resulting from the breakdown of fibrin (and not fibrinogen), is a specific marker for the degree of fibrinolysis. In general, tests that measure raw materials needed for coagulation (e.g., platelets, fibrinogen) are reduced, and values that measure times to clot are prolonged. Fragmented erythrocytes (schistocytes), indicative of partial occlusion of small vessels by fibrin thrombi, may be found on blood smears.

TABLE 31-21 LABORATORY RESULTS IN ACUTE DIC

Test	Finding in Acute DIC
Screening Tests	
Prothrombin time (PT)	Prolonged
Partial thromboplastin time (PTT)	Prolonged
Activated partial thromboplastin time (aPTT)	Prolonged
Thrombin time	Prolonged
Fibrinogen	Reduced
Platelets	Reduced
Special Tests	
Fibrin split products (FSPs)	Elevated
Factor assays (prothrombin and factors V, VIII, X, XIII)	Reduced but may give misleading results, since V and VIII rise with inflammation
D-dimers (cross-linked fibrin fragments)	Elevated
Antithrombin III (AT III)	Reduced
Proteins C and S	Reduced
Plasminogen, tissue plasminogen activator	Reduced
Peripheral blood smear	Schistocytes present
Soluble fibrin monomer	Positive

DIC, Disseminated intravascular coagulation.

Collaborative Care

It is important to diagnose DIC quickly, stabilize the patient if needed (e.g., oxygenation, volume replacement), treat the underlying causative disease or problem, and control the ongoing thrombosis and bleeding. Depending on its severity, a variety of different methods are used to manage DIC (Fig. 31-11). First, if chronic DIC is diagnosed in a patient who is not bleeding, no therapy for DIC is necessary. Treatment of the underlying disease may be sufficient to reverse the DIC (e.g., chemotherapy when DIC is caused by malignancy). Second, when the patient with DIC is bleeding, therapy is directed toward providing support with necessary blood products while treating the primary disorder.

The blood products are administered cautiously based on specific component deficiencies to patients who have serious bleeding, are at high risk for bleeding (e.g., surgery), or require invasive procedures. Blood product support with platelets, cryoprecipitate, and fresh frozen plasma (FFP) is usually reserved for a patient with life-threatening hemorrhage. Therapy stabilizes a patient, prevents exsanguination or massive thrombosis, and permits institution of definitive therapy to treat the underlying cause. In general, platelets are given to correct thrombocytopenia if the platelet count is less than 20,000/μL or less than 50,000/μL with bleeding. Cryoprecipitate replaces factor VIII and fibrinogen and is given if the fibrinogen level is below 100 mg/dL. Fresh frozen plasma replaces all clotting factors except platelets and provides a source of antithrombin.

A patient with manifestations of thrombosis is often treated by anticoagulation with heparin or low-molecular-weight heparin. Heparin is used in the treatment of DIC only when the benefit (reduce clotting) outweighs the risk (further bleeding). Antithrombin III (ATnativ) may be useful in fulminant DIC, although it increases the risk of bleeding. Chronic DIC does not respond to oral anticoagulants, but it can be controlled with long-term use of heparin.

NURSING MANAGEMENT DISSEMINATED INTRAVASCULAR COAGULATION

NURSING DIAGNOSES

Nursing diagnoses for the patient with DIC may include, but are not limited to, the following:

- Ineffective peripheral tissue perfusion *related to* bleeding and sluggish or diminished blood flow secondary to thrombosis
- Acute pain *related to* bleeding into tissues and diagnostic procedures
- Decreased cardiac output *related to* fluid volume deficit
- Anxiety *related to* fear of the unknown, disease process, diagnostic procedures, and therapy

NURSING IMPLEMENTATION

Be alert to the possible development of DIC and especially to the precipitating factors listed in Table 31-20. Remember that because DIC is secondary to an underlying disease, the causative problem needs to be managed while providing supportive care for the manifestations of DIC.

Appropriate nursing interventions are essential to the survival of a patient with acute DIC. Astute ongoing assessment, active attention to manifestations of DIC, and prompt administration of prescribed therapies are crucial. Table 31-15 and

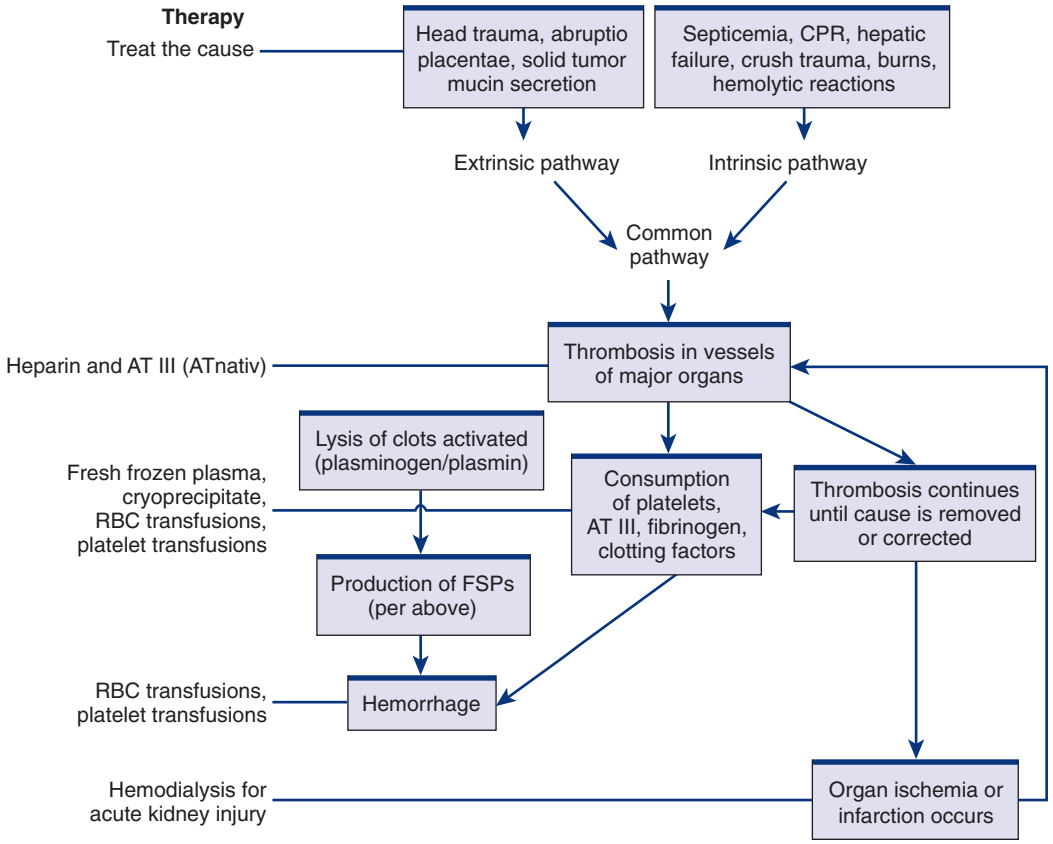

FIG. 31-11 Intended sites of action for therapies in disseminated intravascular coagulation (DIC). *AT III,* Antithrombin III; *FSPs,* fibrin split products.

eNursing Care Plan 31-1 (available on the website for this chapter) provide assessments and interventions appropriate for the patient with DIC.

Early detection of bleeding, both occult and overt, must be a primary goal. Assess for signs of external bleeding (e.g., petechiae, oozing at IV or injection sites), signs of internal bleeding (e.g., increased heart rate, changes in mental status, increasing abdominal girth, pain), and any indications that microthrombi may be causing clinically significant organ damage (e.g., decreased renal output). Minimize tissue damage and protect the patient from additional foci of bleeding.

An additional nursing responsibility is to administer blood products and medications correctly. (Blood product transfusion is discussed later in this chapter.)

NEUTROPENIA

Leukopenia refers to a decrease in the total WBC count (granulocytes, monocytes, and lymphocytes). *Granulocytopenia* is a deficiency of granulocytes, which include neutrophils, eosinophils, and basophils. The neutrophilic granulocytes, which play a major role in phagocytizing pathogenic microbes, are closely monitored in clinical practice as an indicator of a patient's risk for infection. A reduction in neutrophils is termed **neutropenia.** (Some clinicians use the terms *granulocytopenia* and *neutropenia* interchangeably because the largest constituency of granulocytes is the neutrophils.) The *absolute neutrophil count* (ANC) is determined by multiplying the total WBC count by the percentage of neutrophils. *Neutropenia* is defined as ANC less than 1000 cells/μL (1×10^9/L). (Normally, neutrophils range from 2200 to 7700 cells/μL.) *Severe neutropenia* is defined as an ANC less than 500 cells/μL.

In considering the clinical significance of neutropenia, it is important to know whether the decrease in the neutrophil count was gradual or rapid, the degree of neutropenia, and the duration. The faster the drop and the longer the duration, the greater the likelihood of life-threatening infection, sepsis, or death. Other factors and co-morbid conditions, such as being older than 60, having an existing infection, being in the hospital, and having diabetes, can increase the risk of a serious infection.

Neutropenia is a clinical consequence that occurs with a variety of conditions or diseases[34,35] (Table 31-22). It can also be an expected effect, a side effect, or an unintentional effect of taking certain drugs. The most common cause of neutropenia is the use of chemotherapy and immunosuppressive therapy in the treatment of malignancies and autoimmune diseases. A term that is often used to describe the lowest point of neutropenia (and other blood cells) in a patient treated with chemotherapy is *nadir*.

Clinical Manifestations

The patient with neutropenia is predisposed to infection with opportunistic pathogens and nonpathogenic organisms from the normal body flora. When the WBC count is depressed or immature WBCs are present, normal phagocytic mechanisms are impaired. Also the classic signs of inflammation—redness, heat, and swelling—may not occur. WBCs are the major component of pus. Therefore in the patient with neutropenia, pus formation (e.g., as a visible skin lesion or as pulmonary infiltrates on a chest x-ray) is also absent.

TABLE 31-22 CAUSES OF NEUTROPENIA

Drugs*
- Antitumor antibiotics (daunorubicin [Cerubidine], doxorubicin [Adriamycin])
- Alkylating agents (nitrogen mustards, busulfan [Myleran])
- Antimetabolites (methotrexate, 6-mercaptopurine [6-MP])
- Antiinflammatory drugs (phenylbutazone)
- Cardiovascular drugs (captopril [Capoten], procainamide [Pronestyl])
- Diuretics (thiazides, furosemide [Lasix])
- Psychotropic and antidepressant agents (clozapine)
- Miscellaneous (gold, penicillamine)
- Antimicrobial agents (ganciclovir, penicillin G, amphotericin B, vancomycin, trimethoprim/sulfamethoxazole [Bactrim])

Hematologic Disorders
- Idiopathic neutropenia
- Congenital (cyclic neutropenia)
- Aplastic anemia
- Fanconi syndrome
- Leukemia
- Myelodysplastic syndrome

Autoimmune Disorders
- Systemic lupus erythematosus
- Felty syndrome
- Rheumatoid arthritis

Infections
- Viral (e.g., hepatitis, influenza, HIV, measles)
- Fulminant bacterial infection (e.g., typhoid fever, miliary tuberculosis)
- Parasitic
- Rickettsial

Others
- Severe sepsis
- Bone marrow infiltration (e.g., carcinoma, tuberculosis, lymphoma)
- Hypersplenism (e.g., portal hypertension, Felty syndrome, storage diseases [e.g., Gaucher disease])
- Nutritional deficiencies (cobalamin, folic acid)
- Transfusion reaction
- Hemodialysis

*Not all inclusive.

SAFETY ALERT
- A low-grade fever in neutropenic patients is of great significance because it may indicate infection and lead to septic shock and death unless treated promptly.
- Neutropenic fever (≥100.4° F [38° C] and a neutrophil count <500/μL) is a medical emergency.
- Blood cultures should be drawn STAT and antibiotics started within 1 hr.

When fever occurs in a neutropenic patient, it is assumed to be caused by infection and requires immediate attention. The immunocompromised, neutropenic patient has little or no ability to fight infection. Thus minor infections can lead rapidly to sepsis. The mucous membranes of the throat and mouth, the skin, the perineal area, and the pulmonary system are common entry points for pathogenic organisms in susceptible hosts.

Clinical manifestations related to infection at these sites include complaints of sore throat and dysphagia, ulcerative lesions of the pharyngeal and buccal mucosa, diarrhea, rectal tenderness, vaginal itching or discharge, shortness of breath, and nonproductive cough. Seriously consider any minor complaint of pain or any other symptom by the patient, and report it to the physician immediately. These seemingly minor complaints can progress to fever, chills, sepsis, and septic shock if not recognized and treated early.

DELEGATION DECISIONS

Caring for the Patient With Neutropenia

All members of the health care team have important roles in preventing infection in the patient with neutropenia. Careful hand washing is an important preventive measure and should be done before, during, and after patient care by everyone caring for the patient.

Role of Registered Nurse (RN)
- Determine the type of isolation precautions that need to be initiated, if any.
- Assess patient for subtle signs of infection such as confusion or fatigue.
- Screen visitors for infectious diseases.
- Communicate with nutrition services to eliminate undercooked meats from the patient diet.
- Instruct patient and visitors about hand washing.
- Teach patient and caregivers about how to avoid infection, including the need for skin care and oral hygiene.
- If the patient is managed as an outpatient, teach the patient and the caregivers about signs and symptoms of infection and to report promptly to a health care facility if they occur.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)
- Administer antibiotics and hematopoietic growth factors (consider state nurse practice act and agency policy for IV medications).
- Check the skin, oral mucosa, and perineal area for signs of infection.
- Monitor for signs and symptoms of infection and report them to the RN.

Role of Unlicensed Assistive Personnel (UAP)
- Obtain vital signs and report changes to the RN.
- Assist the patient with oral care and personal hygiene.

Systemic infections caused by bacterial, fungal, and viral organisms are common in patients with neutropenia. The patient's own flora (normally nonpathogenic) contributes significantly to life-threatening infections such as pneumonia. Organisms known to be common sources of infection include gram-positive coagulase-negative staphylococci and *Staphylococcus aureus* and gram-negative organisms such as *Escherichia coli* and *Pseudomonas aeruginosa*.[36,37] Fungi involved include *Candida* (usually *C. albicans*) and *Aspergillus* organisms. Viral infections caused by reactivation of herpes simplex and zoster are common after prolonged periods of neutropenia, such as in HSCT patients.

Diagnostic Studies

The primary diagnostic tests for assessing neutropenia are the peripheral WBC count and bone marrow aspiration and biopsy (Table 31-23). A total WBC count of less than 4000/μL (4×10^9/L) reflects leukopenia. However, only a differential count can confirm the presence of neutropenia (neutrophil count less than 1000/μL [1×10^9/L]). If the differential WBC count reflects an absolute neutropenia of 500 to 1000/μL (0.5 to 1.0×10^9/L), the patient is at moderate risk for a bacterial infection. An absolute neutropenia of less than 500/μL (0.5×10^9/L) places the patient at severe risk.

A peripheral blood smear is used to assess for immature forms of WBCs (e.g., bands). The hematocrit level, reticulocyte count, and platelet count are done to evaluate bone marrow function. Also review the patient's recent past and current drug

TABLE 31-23 COLLABORATIVE CARE

Neutropenia

Diagnostic

- History and physical examination
- WBC count with differential count
- WBC morphology
- Hct and Hgb values
- Reticulocyte and platelet count
- Bone marrow aspiration or biopsy
- Cultures of nose, throat, sputum, urine, stool, obvious lesions, blood (as indicated)
- Chest x-ray

Collaborative Therapy

- Identification and removal of cause of neutropenia (if possible)
- Identification of site of infection (if present) and causative organism
- Antibiotic therapy*
- Blood cultures drawn STAT, immediately before antibiotics
- Hematopoietic growth factors (G-CSF, GM-CSF, pegfilgrastim [Neulasta])
- Strict hand washing and patient hygiene (skin and oral care)
- Single-patient room, positive-pressure or high-efficiency particulate air (HEPA) filtration, depending on risk
- Community isolation and home precautions if outpatient

*Prompt initiation of empiric broad-spectrum antibiotic therapy at any sign of infection, even a low-grade fever (100.4°F [38°C]), is essential.
G-CSF, Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor.

history. If the cause of neutropenia is unknown, bone marrow aspirations and biopsies are done to examine cellularity and cell morphology. Additional studies may be done as indicated to assess spleen and liver function.

NURSING AND COLLABORATIVE MANAGEMENT
NEUTROPENIA

The factors involved in the nursing and collaborative care of neutropenia include (1) determining the cause of the neutropenia, (2) identifying the offending organisms if an infection has developed, (3) instituting antibiotic therapy, (4) administering hematopoietic growth factors, and (5) implementing protective environmental practices (e.g., strict hand washing)[38] (see Table 31-23).

Occasionally the cause of the neutropenia can be easily treated (e.g., nutritional deficiencies). However, neutropenia can also be a side effect that must be tolerated as a necessary step in therapy (e.g., chemotherapy, radiation therapy). In some situations the neutropenia resolves when the primary disease (e.g., tuberculosis) is treated.

Monitor the neutropenic patient for signs and symptoms of infection (e.g., any fever 100.4°F [38°C] or greater) and early septic shock. Early identification of a potentially infective organism depends on acquiring cultures from various sites. Serial blood cultures (at least two) or one from a peripheral site and one from a venous access device should be done promptly and antibiotics started immediately (within 1 hour). Communicate with the pharmacy regarding the urgency required for dispensing the medication. Cultures of sputum, throat, lesions, wounds, urine, and feces may also be ordered in the surveillance of the patient. Depending on the clinical situation, it may also be necessary to do a tracheal aspiration, bronchoscopy with bronchial brushings, or lung biopsy to diagnose the cause of pneumonic infiltrates. Invasive diagnostic studies are often contraindicated because of the concern of introducing infection and the fact that these patients are also often thrombocytopenic. Despite these many tests, the causative organism is identified in only approximately one half of neutropenic patients. Thus the priority is to obtain the blood cultures and administer the antibiotic STAT.

When a febrile episode occurs in a neutropenic patient, antibiotic therapy must be initiated immediately (within 1 hour) even before the determination of a specific causative organism by culture. Administration of broad-spectrum antibiotics is usually by the IV route because of the rapidly lethal effects of infection. However, some oral antibiotics are highly effective and routinely used for prophylaxis against infection in some neutropenic patients. The use of a third- or fourth-generation cephalosporin (e.g., cefepime [Maxipime], ceftazidime [Ceptaz]), a carbapenem (e.g., imipenem/cilastatin [Primaxin]), or a combination of an aminoglycoside plus an antipseudomonal offers broad-spectrum coverage for initial management.[37]

Regardless of the combination, you must initiate therapy promptly and observe the patient for side effects of antimicrobial agents. Side effects common to aminoglycosides include nephrotoxicity and ototoxicity. Side effects common to cephalosporins include rashes, fever, and pruritus. Additionally, ongoing febrile episodes or a change in the patient's assessment requires a call to the physician for additional cultures, diagnostic tests, or additional antimicrobial therapies.

The duration of the neutropenia also increases the patient's infection risk. The longer the neutropenia, the greater the risk of a fungal infection. Antifungal therapy is initiated whenever a culture is positive, or in patients who do not become afebrile with broad-spectrum antibiotic coverage.

Granulocyte colony-stimulating factor (G-CSF) (filgrastim [Neupogen], pegfilgrastim [Neulasta]), and granulocyte-macrophage colony-stimulating factor (GM-CSF) (sargramostim [Leukine, Prokine]) (see Table 16-14) can be used to prevent neutropenia or to reduce its severity and duration.[37] Once neutropenia has occurred, these agents are generally not as effective. G-CSF stimulates the production and function of neutrophils. GM-CSF stimulates the production and function of neutrophils and monocytes. These agents can be given IV or subcutaneously. Keratinocyte growth factor (palifermin [Kepivance]) may also be used to reduce the duration and severity of mucositis that may contribute to infection. (G-CSF, GM-CSF, and palifermin are discussed in Chapter 16.)

Determine the best means to protect the patient whose own defenses against infection are compromised. Keep the following principles in mind: (1) the patient's normal flora is the most common source of microbial colonization and infection; (2) transmission of organisms from humans most commonly occurs by direct contact with the hands; (3) air, food, water, and equipment provide additional opportunities for infection transmission; and (4) health care providers with transmissible illnesses and other patients with infections can also be sources of infection transmission under certain conditions.

Hand washing is the single most important preventive measure to minimize the risk of infection in the neutropenic patient. Strict hand washing by staff and visitors using an antiseptic hand wash, before and after contact, is the major method to prevent transmission of harmful pathogens.

TABLE 31-24 PATIENT & CAREGIVER TEACHING GUIDE

Neutropenia

Include the following instructions when teaching a patient or caregiver the precautions to take when the neutrophil count is low.

1. WASH YOUR HANDS frequently and make sure those around you wash their hands frequently, particularly if they help with your care. An antibacterial hand gel may also be used.
2. Notify your nurse or health care provider if you have any of the following:
   - Fever ≥100.4°F (38°C)*
   - Chills or feeling hot
   - Redness, swelling, discharge, or new pain on or in your body
   - Changes in urination or bowel movements
   - Cough, sore throat, mouth sores, or blisters
3. If you are at home, take your temperature as directed and follow instructions on what to do if you have a fever.
4. Avoid crowds and people with colds, flu, or infections. If you are in a public area, wear a mask and use hand sanitizing gel frequently.
5. Avoid uncooked meats, seafood, or eggs and unwashed fruits and vegetables. Ask your health care provider about specific dietary guidelines for you.
6. Bathe or shower daily. A moisturizer may be used to prevent skin from drying and cracking.
7. Brush your teeth with a soft toothbrush four times daily. You may floss once daily if it does not cause excessive pain or bleeding. Avoid alcohol-based mouthwashes.
8. Do not perform gardening or clean up after pets. Feeding and petting your dog or cat are fine as long as you wash your hands well after handling.

*Need to verify cut-off temperature with health care provider.

Separate immunocompromised patients from those who are infected or have conditions that increase the probability of transmitting infections (e.g., poor hygiene caused by lack of understanding or cognitive dysfunction). Often, patients can be managed on an outpatient basis if the patient and caregiver can astutely monitor for fevers and other signs of infection and then report promptly to a nearby health care facility (Table 31-24). If the patient is hospitalized, a private room should be used. High-efficiency particulate air (HEPA) filtration is an air-handling method with a high-flow filtering system that can reduce or eliminate the number of aerosolized pathogens in the environment. Although it is expensive to install, it is often used for a patient with severe prolonged neutropenia (e.g., bone marrow transplant patients). Care routines in a HEPA environment are essentially the same as care in any other private room. Additional neutropenic precaution guidelines may also be employed, such as prophylactic antibiotics and antifungals or the avoidance of uncooked meat. The nursing measures presented in eNursing Care Plan 31-2 (available on the website for this chapter) are important in the treatment of the patient with neutropenia.

Quality-of-life issues for the patient with neutropenia should not be overlooked. Fatigue, malaise, a decrease in functioning, and social isolation require appropriate interventions.

MYELODYSPLASTIC SYNDROME

Myelodysplastic syndrome (MDS) is a group of related hematologic disorders characterized by peripheral blood cytopenias (from ineffective blood cell production) and changes in the cellularity of the bone marrow with dysplastic changes. In MDS, *hematopoiesis* is disorderly and ineffective. It is estimated that 11,000 new cases of MDS are diagnosed each year in the United States. Although it can occur in all age-groups, the highest prevalence is in men over 80 years of age.[39,40]

INFORMATICS IN PRACTICE

Use of Internet to Access Information on Unfamiliar Diseases

- If you are assigned to take care of a patient with a disease or disorder that you are not familiar with, such as thalassemia, access the Internet and perform a quick search.
- Within minutes, you can learn the pathophysiology of thalassemia, treatment options, possible complications that you will need to monitor, and recommended medical and nursing interventions.
- Using this readily available information will help you deliver high-quality, evidence-based care.

Etiology and Pathophysiology

The etiology of MDS is unknown. People who have received radiation therapy, had chemotherapy with alkylating agents (e.g., chlorambucil, cyclophosphamide, melphalan), or been exposed to industrial solvents (e.g., benzene) have a higher risk of developing MDS than people who have not had these exposures. Rarely, genetic disorders are responsible for the disease. Nevertheless, in 60% to 70% of MDS patients, no specific cause can be identified.

MDS is referred to as a *clonal disorder* because some bone marrow stem cells continue to function normally, whereas others (a specific clone) do not. The abnormal clone of the stem cells is usually found in the bone marrow but eventually may be found in the circulation.

Occasionally one type of MDS transforms into another. In about 30% of cases, MDS progresses to acute myelogenous leukemia (AML).[41,42] In contrast to AML, in which the leukemic cells show little normal maturation, the clonal cells in MDS always display some degree of maturity. Disease progression is slower than in AML, and sometimes treatment is not required.

Clinical Manifestations

Manifestations result from neoplastic transformation of the pluripotent hematopoietic stem cells in the bone marrow. MDS commonly manifests as infection and bleeding caused by inadequate numbers of ineffectively functioning circulating granulocytes or platelets. MDS is often discovered in the older adult during testing for the symptoms of anemia, thrombocytopenia, or neutropenia. It may also be diagnosed incidentally from a routine CBC. During the advanced stage of MDS, life-threatening anemia, thrombocytopenia, and neutropenia occur.

Diagnostic Studies

Bone marrow biopsy with aspirate analysis is essential for both the diagnosis and the classification of the specific type of myelodysplasia. In MDS the patient has peripheral cytopenia and changes in the bone marrow (hypocellular or hypercellular). Laboratory data and bone marrow studies help rule out other causes of the dysplasia, such as nonmalignant disorders, cobalamin and folate deficiencies, and infections.[42,43]

NURSING AND COLLABORATIVE MANAGEMENT MYELODYSPLASTIC SYNDROME

Supportive treatment of MDS is based on the premise that the aggressiveness of treatment should match the aggressiveness of the disease. Supportive treatment consists of hematologic monitoring (serial bone marrow and peripheral blood examinations); antibiotic therapy; or transfusions with blood products, along with iron chelators to prevent iron overload.

Low-risk patients can often be treated with erythropoietin and G-CSF. Only about one third of high-risk patients are treated with intensive chemotherapy and/or HSCT. Azacitidine (Vidaza) and decitabine (Dacogen) are drugs that help restore normal growth control and differentiation of hematopoietic cells and reduce the frequency of transformation of MDS to acute leukemia. Side effects include myelosuppression, nausea, vomiting, constipation or diarrhea, renal dysfunction, and injection site erythema.

Lenalidomide (Revlimid) or thalidomide may also be used. Other treatments for MDS include cytarabine (Cytosar, Ara-C) with or without antitumor antibiotics (anthracyclines), antithymocyte globulin, and cyclosporine. High-dose chemotherapy and allogeneic HSCT have been used in an attempt to treat bone marrow dysfunction of MDS and restore it with normal hematopoiesis. However, because of the aggressiveness of this treatment, it is generally recommended for patients less than 55 years old.

Nursing care of a patient with MDS is similar to that of a patient with manifestations of anemia, thrombocytopenia, and neutropenia (see Nursing Care Plan 31-1 for the patient with anemia, and eNursing Care Plan 31-1 for the patient with thrombocytopenia, and eNursing Care Plan 31-2 for the patient with neutropenia. The eNCPs are available on the website for this chapter.)

LEUKEMIA

Leukemia is the general term used to describe a group of malignant disorders affecting the blood and blood-forming tissues of the bone marrow, lymph system, and spleen. Leukemia occurs in all age-groups. It results in an accumulation of dysfunctional cells because of a loss of regulation in cell division. It follows a progressive course that is eventually fatal if untreated. An estimated 43,000 new cases are diagnosed each year. Although often thought of as a disease of children, leukemia affects approximately 10 times more adults than children.[44]

Etiology and Pathophysiology

Regardless of the specific type, leukemia has no single cause. It is now known that all cancers, including leukemia, begin as a mutation in the DNA of certain cells. Most leukemias result from a combination of factors, including genetic and environmental influences. Abnormal genes *(oncogenes)* are capable of causing many types of cancers, including leukemias (see Chapter 16). Chemical agents (e.g., benzene), chemotherapeutic agents (e.g., alkylating agents), viruses, radiation, and immunologic deficiencies have all been associated with the development of leukemia. The incidence of leukemia is increased in radiologists, persons who have lived near nuclear bomb test sites or nuclear reactor accidents (e.g., Chernobyl), and persons previously treated with radiation therapy or chemotherapy.

Although ribonucleic acid (RNA) retroviruses cause a number of leukemias in animals, a viral cause for a human leukemia has been established only for some patients with adult T-cell leukemia. This form of leukemia is endemic in southwestern Japan and parts of the Caribbean and central Africa and is caused by the human T-cell leukemia virus type 1 (HTLV-1).[45]

Classification

Leukemia can be classified based on acute versus chronic disease and on the type of WBC involved. The terms *acute* and *chronic* refer to cell maturity and nature of disease onset. Acute leukemia is characterized by the clonal proliferation of immature hematopoietic cells. The leukemia develops after malignant transformation of a single type of immature hematopoietic cell, followed by cellular replication and expansion of that malignant clone. Chronic leukemias involve more mature forms of the WBC, and the disease onset is more gradual.

Leukemia can also be classified by identifying the type of leukocyte involved, whether it is of myelogenous or lymphocytic origin. By combining the acute and chronic categories with the cell type involved, one can identify four major types of leukemia: acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic myelogenous (granulocytic) leukemia (CML), and chronic lymphocytic leukemia (CLL). Other defining features of these leukemic subtypes are presented in Table 31-25.

Acute Myelogenous Leukemia. AML represents only one fourth of all leukemias, but it makes up approximately 80% of the acute leukemias in adults. Its onset is often abrupt and dramatic. A patient may have serious infections and abnormal bleeding from the onset of the disease.[44]

AML is characterized by uncontrolled proliferation of myeloblasts, the precursors of granulocytes. There is hyperplasia of the bone marrow. The clinical manifestations are usually related to replacement of normal hematopoietic cells in the marrow by leukemic myeloblasts and, to a lesser extent, to infiltration of other organs and tissue (see Table 31-25).

Acute Lymphocytic Leukemia. ALL is the most common type of leukemia in children and accounts for about 20% of acute leukemia cases in adults.[44] In ALL, immature small lymphocytes proliferate in the bone marrow; most are of B-cell origin. The majority of patients have fever at the time of diagnosis. Signs and symptoms may appear abruptly with bleeding or fever, or they may be insidious with progressive weakness, fatigue, bone and/or joint pain, and bleeding tendencies.

Central nervous system (CNS) manifestations are especially common in ALL and represent a serious problem. Leukemic meningitis caused by arachnoid infiltration occurs in many patients with ALL.

Chronic Myelogenous Leukemia. CML is caused by excessive development of mature neoplastic granulocytes in the bone marrow. The excess neoplastic granulocytes move into the peripheral blood in massive numbers and ultimately infiltrate the liver and spleen.

The natural history of CML is a chronic stable phase, followed by the development of a more acute, aggressive phase referred to as the *blastic phase.* The chronic phase of CML can last for several years and can usually be well controlled with treatment. Even with treatment, the chronic phase of the disease eventually progresses to the accelerated phase, ending in a blastic phase. Once CML transforms to an acute or blastic

TABLE 31-25 TYPES OF LEUKEMIA

Age of Onset	Clinical Manifestations	Diagnostic Findings
Acute Myelogenous Leukemia (AML)		
Most common cancer in children ages 0-7 yr. Increase in incidence with advancing age after 55 yr.	Fatigue and weakness, headache, mouth sores, anemia, bleeding, fever, infection, sternal tenderness, gingival hyperplasia, mild hepatosplenomegaly (one third of patients).	Low RBC count, Hgb, Hct, platelet count. Low to high WBC count with myeloblasts. High LDH. Hypercellular bone marrow with myeloblasts.
Acute Lymphocytic Leukemia (ALL)		
In children median age at diagnosis is 13 yr. Increases in incidence with advancing age after 60 yr.	Fever, pallor, bleeding, anorexia, fatigue and weakness. Bone, joint, and abdominal pain. Generalized lymphadenopathy, infections, weight loss, hepatosplenomegaly, headache, mouth sores, neurologic manifestations: CNS involvement, increased intracranial pressure (nausea, vomiting, lethargy, cranial nerve dysfunction) secondary to meningeal infiltration.	Low RBC count, Hgb, Hct, platelet count. Low, normal, or high WBC count. High LDH. Transverse lines of rarefaction at ends of metaphysis of long bones on x-ray. Hypercellular bone marrow with lymphoblasts. Lymphoblasts also possible in cerebrospinal fluid. Presence of Philadelphia chromosome (20%-25% of patients).
Chronic Myelogenous Leukemia (CML)		
Increase in incidence with advancing age after 55 yr.	No symptoms early in disease. Fatigue and weakness, fever, sternal tenderness, weight loss, joint pain, bone pain, massive splenomegaly, increase in sweating.	Low RBC count, Hgb, Hct. High platelet count early, lower count later. ↑ Neutrophils, normal number of lymphocytes, and normal or low number of monocytes. Low leukocyte alkaline phosphatase. Presence of Philadelphia chromosome in 90% of patients.
Chronic Lymphocytic Leukemia (CLL)		
Increase in incidence with advancing age after 50 yr, with predominance in men.	Frequently no symptoms. Detection of disease often during examination for unrelated condition, chronic fatigue, anorexia, splenomegaly and lymphadenopathy, hepatomegaly. May progress to fever, night sweats, weight loss, fatigue, and frequent infections.	Mild anemia and thrombocytopenia with disease progression. Total WBC count >100,000/μL. Increase in peripheral lymphocytes and lymphocytes in bone marrow. Hypogammaglobulinemia. May have autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura.

LDH, Lactate dehydrogenase.

phase, it needs to be treated more aggressively, similar to an acute leukemia.

Genetic Link

The *Philadelphia chromosome* originates from the translocation between the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The protein that is encoded by the newly created *BCR-ABL* gene on the Philadelphia chromosome interferes with normal cell cycle events, such as the regulation of cell proliferation.

The Philadelphia chromosome, which is present in 90% to 95% of patients with CML, is a diagnostic hallmark of CML. In addition, its presence is an important indicator of residual disease or relapse after treatment. However, the presence of the Philadelphia chromosome is not *specific* to diagnose CML, since it is also found in ALL and occasionally in AML.

Chronic Lymphocytic Leukemia. CLL is the most common leukemia in adults. CLL is characterized by the production and accumulation of functionally inactive but long-lived, small, mature-appearing lymphocytes. B cells are usually involved. The lymphocytes infiltrate the bone marrow, spleen, and liver. Lymph node enlargement (lymphadenopathy) is present throughout the body.

Complications are rare in early-stage CLL but may develop as the disease advances. Pressure on nerves from enlarged lymph nodes causes pain and even paralysis. Mediastinal node enlargement leads to pulmonary symptoms. Because CLL is usually a disease of older adults, treatment decisions must be made by considering the progression of the disease and the side effects of treatment. Many individuals in the early stages of CLL require no treatment. Others may be followed closely and receive treatment only when the disease progresses. Approximately one third require immediate intervention at the time of diagnosis.

Other Leukemias. Occasionally the subtype of leukemia cannot be identified. The malignant leukemic cells may have lymphoid, myeloid, or mixed characteristics. Frequently these patients do not respond to treatment and have a poor prognosis. Other rare types include hairy cell and biphenotypic (both abnormal myeloid and lymphoid clones) leukemias.

Overlap Between Leukemia and Lymphoma. Overlap exists between leukemia and non-Hodgkin's lymphoma (NHL) because both involve proliferation of lymphocytes or their precursors. A leukemia-like picture with peripheral lymphocytosis and bone marrow involvement may be present in about 20% of adults with some types of NHL. Although differentiation can be difficult, generally patients with more extensive nodal involvement (especially mediastinal), fewer circulating abnormal cells, and fewer blast forms in the marrow are considered to have lymphoma. A prominent leukemic phase is less common in aggressive lymphomas, except Burkitt's and lymphoblastic lymphomas.[45]

Clinical Manifestations

Although the clinical manifestations of leukemia are varied (see Table 31-25), they relate to problems caused by bone marrow failure and the formation of leukemic infiltrates (Fig. 31-12). Bone marrow failure results from (1) bone marrow overcrowding by abnormal cells and (2) inadequate production of normal marrow elements. The patient is predisposed to anemia, thrombocytopenia, and decreased number and function of WBCs.

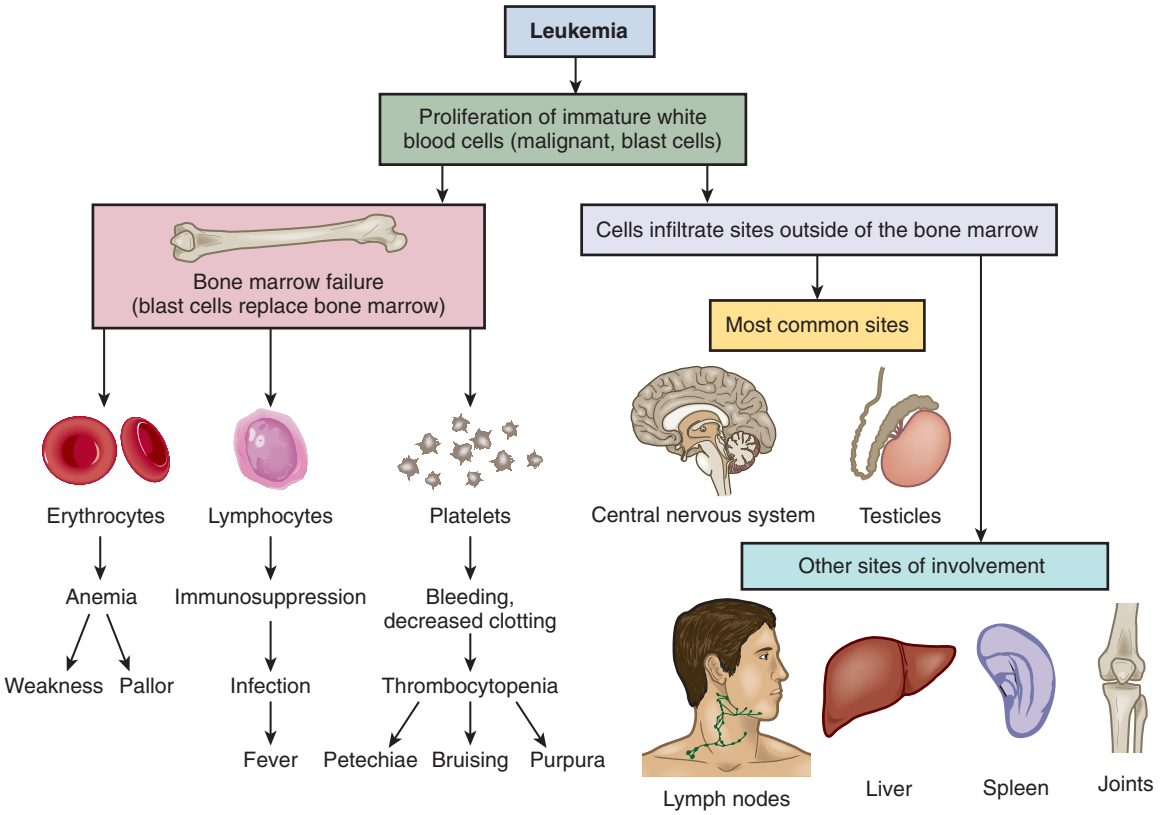

FIG. 31-12 Pathophysiology of leukemia.

As leukemia progresses, fewer normal blood cells are produced. The abnormal WBCs continue to accumulate because they do not go through the normal cell life cycle to death *(apoptosis)*. The leukemic cells may infiltrate the patient's organs, leading to problems such as splenomegaly, hepatomegaly, lymphadenopathy, bone pain, meningeal irritation, and oral lesions. Solid masses resulting from collections of leukemic cells called *chloromas* can also occur. A high leukemic white count in the peripheral blood (more than 100,000 cells/μL) can cause the blood to thicken and potentially block circulatory pathways. This is called *leukostasis* and can be life threatening.

Diagnostic Studies

Peripheral blood evaluation and bone marrow examination are the primary methods of diagnosing and classifying the types of leukemia. Morphologic, histochemical, immunologic, and cytogenetic methods are all used to identify leukemic cell types and stage of development. Identifying the type of leukemia is important because the various types have different prognoses and chemotherapeutic regimens. Other studies such as lumbar puncture and computed tomography (CT) scan can detect leukemic cells outside of the blood and bone marrow.

The malignant cells in most patients with leukemia have specific cytogenetic abnormalities that are associated with distinct subsets of the disease. These cytogenetic abnormalities have diagnostic, prognostic, and therapeutic importance. For example, in CML, the finding of the Philadelphia chromosome has a good prognostic significance, but not so in ALL.

Collaborative Care

Once a diagnosis of leukemia has been made, collaborative care is focused on the initial goal of attaining remission. Age and cytogenetic analysis often help form the basis of important treatment decisions. Because cytotoxic chemotherapy is the mainstay of the treatment, you need to understand the principles of cancer chemotherapy, including cellular kinetics, the use of multiple drugs rather than single agents, and the cell cycle. (See the section on chemotherapy in Chapter 16.)

In some cases, such as nonsymptomatic patients with CLL, watchful waiting with active supportive care may be appropriate. Although a patient may not be cured, attaining remission or disease control is a realistic option for the majority of patients. In some cases, cure is a realistic goal. In *complete remission* there is no evidence of overt disease on physical examination, and the bone marrow and peripheral blood appear normal. A lesser state of control is known as partial remission. *Minimal residual disease* is defined as tumor cells that cannot be detected by morphologic examination, but can be identified by molecular testing. *Partial remission* is characterized by a lack of symptoms and a normal peripheral blood smear, but still evidence of disease in the bone marrow. *Molecular remission* indicates that all molecular studies are negative for residual leukemia. The patient's prognosis is directly related to the ability to maintain a remission. The patient's prognosis becomes more unfavorable with each relapse. After each relapse, the succeeding remission may be more difficult to achieve and shorter in duration.

Sometimes patients have such a high WBC count (e.g., 100,000 cells/μL or more) that initial emergent treatment may include leukapheresis and hydroxyurea. The purpose of these treatments is to reduce the WBC count and risk of leukemia cell–induced thrombosis.

Stages of Chemotherapy. Chemotherapy is often divided into stages: induction, postinduction or postremission, and maintenance.

Induction Therapy. The first stage, *induction therapy,* is the attempt to bring about a remission. Induction is aggressive treatment that seeks to destroy leukemic cells in the tissues, peripheral blood, and bone marrow to eventually restore normal hematopoiesis on bone marrow recovery. During induction therapy, a patient may become critically ill because the bone marrow is severely depressed by the chemotherapeutic agents. Throughout the induction phase, nursing interventions focus on neutropenia, thrombocytopenia, and anemia, as well as providing psychosocial support to the patient and family. Common chemotherapy agents for induction of AML include cytarabine and an antitumor antibiotic (anthracycline) such as daunorubicin (Cerubidine), idarubicin (Idamycin), or mitoxantrone (Novantrone). After one course of induction therapy, approximately 70% of newly diagnosed patients achieve complete remission. It is generally assumed that leukemic cells persist undetected after induction therapy. This could lead to relapse within a few months if no further therapy is administered.[46]

Postinduction or Postremission Therapy. Terms used to describe postinduction or postremission chemotherapy include *intensification* and *consolidation. Intensification therapy,* or high-dose therapy, may be given immediately after induction therapy for several months. Other drugs that target the cell in a different way than those administered during induction may also be added.

Consolidation therapy is started after a remission is achieved. It may consist of one or two additional courses of the same drugs given during induction or involve high-dose therapy (intensive consolidation). The purpose of consolidation therapy is to eliminate remaining leukemic cells that may not be clinically or pathologically evident.

Maintenance Therapy. *Maintenance therapy* is treatment with lower doses of the same drugs used in induction or other drugs given every 3 to 4 weeks for a prolonged period. Like consolidation or intensification, the goal is to keep the body free of leukemic cells. Each type of leukemia requires different maintenance therapy. In AML, maintenance therapy is rarely effective and therefore rarely administered.

Drug Therapy Regimens. The therapeutic agents used to treat leukemia vary. Table 31-26 gives examples of treatment regimens used in various types of leukemia.[45-48]

Combination therapy is the mainstay of treatment for leukemia. The three purposes for using multiple drugs are to (1) decrease drug resistance, (2) minimize the drug toxicity to the patient by using multiple drugs with varying toxicities, and (3) interrupt cell growth at multiple points in the cell cycle.

Newer therapeutic drugs are aimed at small molecules that promote the growth and differentiation of leukemic cells. For example, arsenic trioxide (Trisenox), which is used to treat acute promyelocytic leukemia (a type of AML), causes DNA fragmentation and cell death. In addition, it inhibits cell proliferation and angiogenesis (new blood vessel growth). Imatinib targets the *BCR-ABL* protein (discussed above) that is present in nearly all patients with CML. Thus this drug kills only cancer cells, leaving healthy cells alone. (Targeted therapy is discussed in Chapter 16.)

The use of specific targeted therapy in the form of monoclonal antibodies is an important treatment modality in hematopoietic malignancies, but cures with these therapies alone are rare (see Table 16-13 and Fig. 16-16). Rituximab binds to the B-cell antigen (CD20) and has been used with CLL. Alemtuzumab (Campath) binds to CD52, a panlymphocyte antigen present on both T and B cells, and is used to treat CLL.

TABLE 31-26 DRUG THERAPY

Leukemia*

Drug Therapy	Other Therapy
Acute Myelogenous Leukemia	
cytarabine (Cytosar, Ara-C),† daunorubicin (Cerubidine),† idarubicin (Idamycin), 6-thioguanine (6-TG), mitoxantrone (Novantrone), arsenic trioxide (Trisenox),† tretinoin (Vesanoid),† etoposide (VePesid), clofarabine (Clolar), decitabine (Dacogen), fludarabine (Fludara) Combination chemotherapy of cytarabine and antitumor antibiotic (most common)	Autologous or allogeneic hematopoietic stem cell transplant (HSCT) (see Chapter 16)
Acute Lymphocytic Leukemia	
daunorubicin, doxorubicin (Adriamycin), vincristine (Oncovin), prednisone, dexamethasone (Decadron), L-asparaginase (Elspar), ponatinib (Iclusig), pegaspargase (Oncaspar), dasatinib (Sprycel), cyclophosphamide (Cytoxan), methotrexate, 6-mercaptopurine (Purinethol), cytarabine, nelarabine (Arranon), imatinib (Gleevec), clofarabine Combination chemotherapy of several agents is common over a prolonged time	Cranial radiation therapy, intrathecal methotrexate or cytarabine, allogeneic HSCT (see Chapter 16)
Chronic Myelogenous Leukemia	
bosutinib (Bosulif), imatinib, dasatinib, nilotinib (Tasigna), omacetaxine (Synribo), ponatinib, hydroxyurea (Hydrea) Combination chemotherapy including any of the following: cytarabine, thioguanine, daunorubicin, methotrexate, prednisone, vincristine, L-asparaginase, carmustine (BCNU), 6-mercaptopurine	Radiation, HSCT, α-interferon, leukapheresis
Chronic Lymphocytic Leukemia	
chlorambucil (Leukeran), cyclophosphamide, prednisone, vincristine, fludarabine, rituximab (Rituxan), alemtuzumab (Campath), pentostatin (Nipent), bendamustine (Treanda), oxaliplatin (Eloxatin), methotrexate, ofatumumab (Arzerra)	Radiation, splenectomy, colony-stimulating factors, allogeneic HSCT

*The classification and mechanisms of action of these drugs are presented in Table 16-7.
†Used for acute promyelocytic leukemia.

Other Treatments. In addition to chemotherapy, corticosteroids and radiation therapy can also have a role in the treatment of the patient with leukemia. Total body radiation may be used to prepare a patient for bone marrow transplantation, or radiation may be restricted to certain areas (fields) such as the liver and spleen or other organs affected by infiltrates. In ALL, prophylactic intrathecal methotrexate or cytarabine is given to decrease the chance of CNS involvement, which is common in this type of leukemia. When CNS leukemia does occur, cranial radiation may be given. Biologic and targeted therapy may be indicated for specific leukemias. (Biologic and targeted therapy is discussed in Chapter 16 and Table 16-13.)

Hematopoietic Stem Cell Transplantation. HSCT is another type of therapy used for patients with different forms of leukemia. The goal of HSCT is to totally eliminate leukemic cells

from the body using combinations of chemotherapy with or without total body irradiation. This treatment also eradicates the patient's hematopoietic stem cells, which are then replaced with those of an HLA-matched sibling or volunteer donor *(allogeneic)* or an identical twin *(syngeneic),* or with the patient's own *(autologous)* stem cells that were removed (harvested) before the intensive therapy. (HSCT is discussed in Chapter 16.)

The primary complications for patients with allogeneic HSCT are graft-versus-host disease (GVHD), relapse of leukemia (especially ALL), and infection (especially interstitial pneumonia). GVHD is discussed in Chapter 14. Because HSCT has serious associated risks, the patient must weigh the significant risks of treatment-related death or treatment failure (relapse) with the hope of cure.

NURSING MANAGEMENT
LEUKEMIA

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with leukemia are presented in Table 31-27.

NURSING DIAGNOSES

Nursing diagnoses for the patient with leukemia include those for anemia (see Nursing Care Plan 31-1), thrombocytopenia (eNursing Care Plan 31-1), and neutropenia (see eNursing Care Plan 31-2, available on the website for this chapter).

PLANNING

The overall goals are that the patient with leukemia will (1) understand and cooperate with the treatment plan; (2) experience minimal side effects and complications associated with both the disease and its treatment; and (3) feel hopeful and supported during periods of treatment, relapse, or remission.

NURSING IMPLEMENTATION

ACUTE INTERVENTION. The nursing role during acute phases of leukemia is extremely challenging because the patient has many physical and psychosocial needs. As with other forms of cancer, the diagnosis of leukemia can evoke great fear and be equated with death. It may be viewed as a hopeless, horrible disease with many painful and undesirable consequences. The treatment and prognosis of each patient with leukemia are driven by many factors, such as age and type of leukemia. Patients are not the same. Therefore it is important that you understand the patient's type of leukemia, the prognosis, the treatment plan, and the goals. By doing this, you can help the patient realize that, although the future may be uncertain, one can have a meaningful quality of life while in remission or with disease control, and that, in some cases, there is reasonable hope for cure.

The family also needs help adjusting to the stress of this abrupt onset of serious illness and the losses imposed by the sick role (e.g., dependence, withdrawal, changes in role responsibilities, alterations in body image). The diagnosis of leukemia often brings with it the need to make difficult decisions at a time of profound stress for the patient and family.

Patients may have co-morbid conditions that affect treatment decisions. Important nursing interventions include (1) maximizing the patient's physical functioning, (2) teaching patients that acute side effects of treatment are usually temporary, and (3) encouraging patients to discuss their quality-of-life issues. You are an important advocate in helping the patient and family understand the complexities of treatment decisions and manage the side effects and toxicities. A patient may require hospitalization or may need to temporarily relocate to an appropriate treatment center. This situation can lead a patient to feel deserted and isolated at a time when support is most needed. You have contact with a patient many hours a day and can help reverse feelings of abandonment and loneliness by balancing

TABLE 31-27 NURSING ASSESSMENT

Leukemia

Subjective Data

Important Health Information

Past health history: Exposure to chemical toxins (e.g., benzene, arsenic), radiation, or viruses (Epstein-Barr, HTLV-1); chromosome abnormalities (Down syndrome, Klinefelter syndrome, Fanconi syndrome), immunologic deficiencies; organ transplantation; frequent infections; bleeding tendencies

Medications: Use of phenylbutazone (Butazolidin), chloramphenicol, chemotherapy

Surgery or other treatments: Radiation exposure; prior radiation and chemotherapy for cancer

Functional Health Patterns

Health perception–health management: Family history of leukemia; malaise

Nutritional-metabolic: Mouth sores, weight loss; chills, night sweats; nausea, vomiting, anorexia, dysphagia, early satiety; easy bruising

Elimination: Hematuria, decreased urine output; diarrhea, dark or bloody stools

Activity-exercise: Fatigue with progressive weakness; dyspnea, epistaxis, cough

Cognitive-perceptual: Headache; muscle cramps; sore throat; generalized sternal tenderness, bone, joint, abdominal pain; paresthesias, numbness, tingling, visual disturbances

Sexuality-reproductive: Prolonged menses, menorrhagia, impotence

Objective Data

General

Fever, generalized lymphadenopathy, lethargy

Integumentary

Pallor or jaundice; petechiae, ecchymoses, purpura, reddish brown to purple cutaneous infiltrates, macules, and papules

Cardiovascular

Tachycardia, systolic murmurs

Gastrointestinal

Gingival bleeding and hyperplasia; oral ulcerations, herpes and Candida infections; perirectal irritation and infection; hepatomegaly, splenomegaly

Neurologic

Seizures, disorientation, confusion, decreased coordination, cranial nerve palsies, papilledema

Musculoskeletal

Muscle wasting, bone pain, joint pain

Possible Diagnostic Findings

Low, normal, or high WBC count with shift to the left (↑ blast cells); anemia, ↓ hematocrit and hemoglobin, thrombocytopenia, Philadelphia chromosome; hypercellular bone marrow aspirate or biopsy with myeloblasts, lymphoblasts, and markedly ↓ normal cells

HTLV-1, Human T-cell leukemia virus, type 1.

the demanding technical needs with a humanistic, caring approach. The needs of the patient with leukemia are best met by an interdisciplinary team (e.g., psychiatric and oncology clinical nurse specialists, case managers, dietitians, chaplains, and social workers).

From a physical care perspective, you are challenged to make astute assessments and plan care to help the patient manage the severe side effects of chemotherapy. The life-threatening results of bone marrow suppression (neutropenia, thrombocytopenia, and anemia) require aggressive nursing interventions. These patients may be at risk for oncologic emergencies such as tumor lysis syndrome, DIC, and leukostasis. Additional complications of chemotherapy may affect the patient's GI tract, nutritional status, skin and mucosa, cardiopulmonary status, liver, kidneys, and neurologic system. (Nursing interventions related to chemotherapy are discussed in Chapter 16.)

Review all drugs being administered, including the mechanism of action, purpose, routes of administration, usual doses, potential side effects, safe-handling considerations, and toxic effects. Assess laboratory data reflecting the effects of the drugs and sequelae of the disease. Unlike treatments for solid tumors, chemotherapy is administered to patients with leukemia even if they have severe myelosuppression, since the underlying disorder is causing the problem and will not resolve unless treated. Patient survival and comfort during aggressive chemotherapy are significantly affected by the quality of nursing care.

AMBULATORY AND HOME CARE. Ongoing care for the patient with leukemia is necessary to monitor for signs and symptoms of disease control or relapse. For a patient requiring long-term or maintenance chemotherapy, the fatigue of long-term chronic disease management can become arduous and discouraging. Therefore teach the patient and caregiver to understand the importance of continued diligence in disease management and the need for follow-up care. Also teach them about the drugs, self-care measures, and when to seek medical attention.

The goals of rehabilitation for long-term survivors of leukemia are to manage the physical, psychologic, social, and spiritual consequences and delayed effects from the disease and its treatment. (Delayed effects are discussed in Chapter 16.) Assistance may be needed to reestablish the various relationships that are a part of the patient's life. Involving the patient in survivor networks and support groups or services may help the patient adapt to living after a life-threatening illness. Exploring resources in the community (e.g., American Cancer Society, Leukemia & Lymphoma Society) may reduce the financial burden and the feelings of dependence. Also provide the resources for spiritual support.

Vigilant follow-up care helps to ensure that the cancer survivor's unique needs are recognized and treated. Often these needs may require a referral or consultation. For example, physical therapy personnel may be asked to develop an exercise program to prevent posttreatment deficits caused by drug-induced peripheral neuropathy. Most patients should receive the pneumococcal vaccine (Pneumovax) at diagnosis and every 5 years, and an annual influenza vaccine. These needs can also include other concerns such as vocational retraining and reproductive concerns for a patient of childbearing age.

EVALUATION

The expected outcomes are that the patient with leukemia will

- Cope effectively with the diagnosis, treatment regimen, and prognosis
- Experience no complications related to the disease or its treatment
- Feel comfortable and supported throughout treatment

TABLE 31-28 COMPARISON OF HODGKIN'S AND NON-HODGKIN'S LYMPHOMA

	Hodgkin's Lymphoma	Non-Hodgkin's Lymphoma
Cellular origin	B lymphocytes	B lymphocytes (85%) T or natural killer lymphocytes (15%)
Extent of disease	Localized to regional, but may be more widespread	Disseminated
B symptoms*	Common	40%
Extranodal involvement	Rare	Common

*B symptoms include fever (>100.4° F [38° C]), drenching night sweats, and weight loss (>10% from baseline within 6 mo).

LYMPHOMAS

Lymphomas are malignant neoplasms originating in the bone marrow and lymphatic structures resulting in the proliferation of lymphocytes. Lymphomas are the fifth most common type of cancer in the United States.[49] Two major types of lymphoma are Hodgkin's lymphoma and non-Hodgkin's lymphoma (NHL). A comparison of these two types of lymphoma is presented in Table 31-28.

HODGKIN'S LYMPHOMA

Hodgkin's lymphoma, also called Hodgkin's disease, makes up about 11% of all lymphomas. It is a malignant condition characterized by proliferation of abnormal giant, multinucleated cells, called *Reed-Sternberg cells,* which are located in lymph nodes. The disease has a bimodal age-specific incidence, occurring most frequently in persons from 15 to 35 years of age and above 50 years of age. In adults, it is twice as prevalent in men as in women. Each year, approximately 9060 new cases of Hodgkin's lymphoma are diagnosed and approximately 1200 deaths occur. However, long-term survival exceeds 85% for all stages.[50]

Etiology and Pathophysiology

Although the cause of Hodgkin's lymphoma remains unknown, several key factors are thought to play a role in its development. The main interacting factors include infection with Epstein-Barr virus (EBV), genetic predisposition, and exposure to occupational toxins. The incidence of Hodgkin's lymphoma is increased among patients who have HIV infection.[50]

Normally, the lymph nodes are composed of connective tissues that surround a fine mesh of reticular fibers and cells. In Hodgkin's lymphoma the normal structure of lymph nodes is destroyed by hyperplasia of monocytes and macrophages. The main diagnostic feature of Hodgkin's lymphoma is the presence of Reed-Sternberg cells in lymph node biopsy specimens. The disease is believed to arise in a single location (it originates in cervical lymph nodes in 70% of patients) and then spreads along adjacent lymphatics. However, in recurrent disease, it may be more diffuse and not necessarily contiguous. It eventually infiltrates other organs, especially lungs, spleen, and liver. When the

FIG. 31-13 Hodgkin's lymphoma (stage IIA). This patient has enlargement of the cervical lymph nodes.

disease begins above the diaphragm, it remains confined to lymph nodes for a variable time. Disease originating below the diaphragm frequently spreads to extralymphoid sites such as the liver.

Clinical Manifestations

The onset of symptoms in Hodgkin's lymphoma is usually insidious. The initial development is most often enlargement of cervical, axillary, or inguinal lymph nodes (Fig. 31-13); a mediastinal node mass is the second most common location. This lymphadenopathy affects discrete nodes that remain movable and nontender. The enlarged nodes are not painful unless they exert pressure on adjacent nerves.

The patient may notice weight loss, fatigue, weakness, fever, chills, tachycardia, or night sweats. A group of initial findings including fever (in excess of 100.4° F [38° C]), drenching night sweats, and weight loss (exceeding 10% in 6 months) are termed *B symptoms* and correlate with a worse prognosis. After the ingestion of even small amounts of alcohol, individuals with Hodgkin's lymphoma may complain of a rapid onset of pain at the site of disease. The cause for the alcohol-induced pain is unknown. Generalized pruritus without skin lesions may develop. Cough, dyspnea, stridor, and dysphagia may all reflect mediastinal node involvement.

In more advanced disease, there may be hepatomegaly and splenomegaly. Anemia results from increased destruction and decreased production of erythrocytes. Other physical signs vary depending on where the disease is located. For example, intrathoracic involvement may lead to superior vena cava syndrome, enlarged retroperitoneal nodes may cause palpable abdominal masses or interfere with renal function, jaundice may occur from liver involvement, spinal cord compression leading to paraplegia may occur with extradural involvement, and bone pain occurs as a result of bone involvement.

Diagnostic and Staging Studies

Peripheral blood analysis, excisional lymph node biopsy, bone marrow examination, and radiologic studies are important means of evaluating Hodgkin's lymphoma. Abnormalities in the CBC, such as a microcytic hypochromic anemia, are variable and not diagnostic. Leukopenia and thrombocytopenia may develop, but they are usually a consequence of treatment, advanced disease, or superimposed hypersplenism. Other blood studies may show hypoferremia caused by excessive iron uptake by the liver and the spleen, elevated leukocyte alkaline phosphatase from liver and bone involvement, hypercalcemia from bone involvement, and hypoalbuminemia from liver involvement.

Radiologic evaluation can help define all sites and determine the clinical stage of the disease. Positron emission tomography (PET) with or without CT scan is used to stage and then assess the response to therapy and to differentiate residual tumor from fibrotic masses after treatment. These scans may show increased uptake (by PET) and masses (by CT) such as mediastinal lymphadenopathy; renal displacement caused by retroperitoneal node enlargement; abdominal lymph node enlargement; and liver, spleen, bone, and brain infiltration.[50]

NURSING AND COLLABORATIVE MANAGEMENT HODGKIN'S LYMPHOMA

Using all of the information from the various diagnostic studies, one can determine a clinical stage of disease[50,51] (Fig. 31-14). The final staging is based on the clinical stage (extent of the disease) and the presence of B symptoms. Treatment depends on the nature and extent of the disease. The nomenclature used in staging involves an A or B classification, depending on whether symptoms are present when the disease is found, and a Roman numeral (I to IV) that reflects the location and extent of the disease. Additional features that may move an early stage (I or II) to an unfavorable prognosis, warranting more aggressive therapy, include an elevated sedimentation rate; age of 45 years or older; male gender; and the presence of a large mediastinal mass and low serum albumin, hemoglobin, and low or high lymphocyte counts.[51]

Once the stage of Hodgkin's lymphoma is established, management focuses on selecting a treatment plan. The standard for chemotherapy is the ABVD regimen: doxorubicin (**A**driamycin), **b**leomycin, **v**inblastine, and **d**acarbazine. Patients with favorable early-stage disease receive two to four cycles of chemotherapy. Patients with early-stage disease but unfavorable prognostic features (e.g., B symptoms) or intermediate-stage disease are treated with four to six cycles of chemotherapy. Advanced-stage Hodgkin's lymphoma is treated more aggressively using six to eight cycles of chemotherapy. A common regimen is BEACOPP (**b**leomycin, **e**toposide, doxorubicin (**A**driamycin), **c**yclophosphamide, vincristine (**O**ncovin), **p**rocarbazine, and **p**rednisone).[51] The role of radiation as a supplement to chemotherapy varies depending on sites of disease and the presence of resistant disease after chemotherapy. Response to therapy is determined by CT and PET scans and other diagnostic tests (e.g., bone marrow biopsy).

A variety of chemotherapy regimens and newer agents, such as brentuximab vedotin (Adcetris), are used to treat patients who have relapsed or refractory disease. Ideally, once remission is obtained, a hope for curative option may be intensive chemotherapy with the use of autologous or allogeneic HSCT.[51] HSCT has allowed patients to receive higher, potentially curative doses of chemotherapy while reducing life-threatening leukopenia (see Chapter 16). Combination chemotherapy works well because, as in leukemia, the drugs used have an additive antitumor effect without increasing side effects. As with leukemia, therapy must be aggressive. Therefore potentially life-threatening problems are encountered in an attempt to achieve a remission.

Maintenance chemotherapy does not contribute to increased survival once a complete remission is achieved. Occasionally, single drugs may be administered palliatively to patients who cannot tolerate intensive combination therapy. A serious consequence of the treatment for Hodgkin's lymphoma is the later

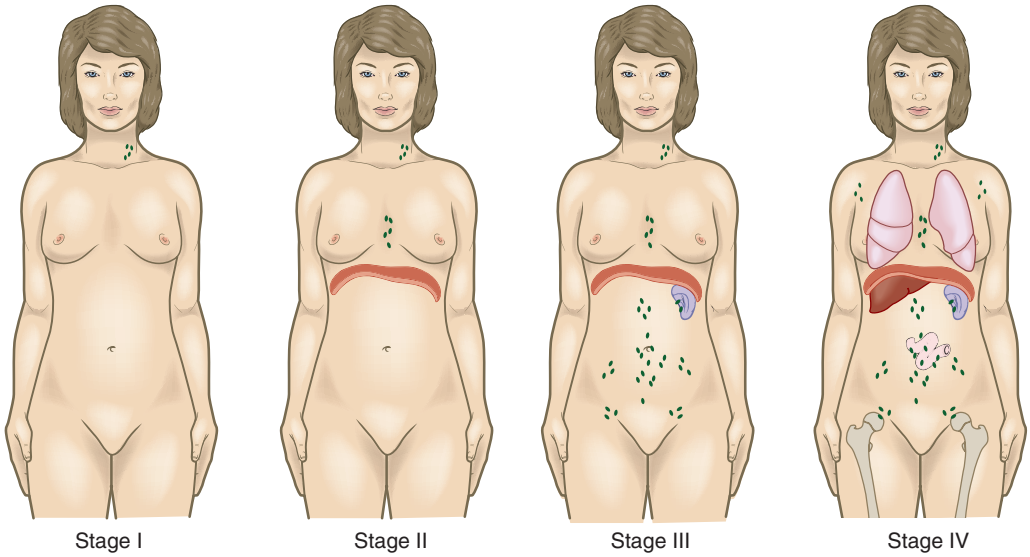

FIG. 31-14 Staging system for Hodgkin's lymphoma and non-Hodgkin's lymphoma. *Stage I,* involvement of single lymph node (e.g., cervical node). *Stage II,* involvement of two or more lymph nodes on one side of diaphragm. *Stage III,* lymph node involvement above and below the diaphragm. *Stage IV,* involvement outside of diaphragm (e.g., liver, bone marrow). The stage is followed by the letter *A* (absence) or *B* (presence) to indicate significant systemic symptoms (e.g., fever, night sweats, weight loss).

development of secondary malignancies (see Chapter 16), as well as potential long-term toxicities from the treatment, such as endocrine, cardiac, and pulmonary dysfunction.[50,51] The estimated risk of a secondary cancer is about 5% and generally occurs within the first 10 years after treatment for Hodgkin's lymphoma.[50] The most common secondary malignancies are AML, NHL, and solid tumors.

The nursing care for Hodgkin's lymphoma is largely based on managing problems related to the disease (e.g., pain caused by a tumor, superior vena cava syndrome), pancytopenia, and other side effects of therapy. Because the survival of patients with Hodgkin's lymphoma depends on their response to treatment, supporting the patient through the consequences of treatment is extremely important.

Psychosocial considerations are as important as they are with leukemia. However, the prognosis for Hodgkin's lymphoma is better than that for many forms of cancer or leukemia. The physical, psychologic, social, and spiritual consequences of the patient's disease must be addressed. Fertility issues may be of particular concern because this disease is frequently seen in adolescents and young adults. Help to ensure that these issues have been addressed soon after diagnosis. Evaluation of patients for long-term effects of therapy is important because delayed consequences of disease and treatment may not be apparent for many years. (Secondary malignancies and delayed effects are discussed in Chapter 16.)

NON-HODGKIN'S LYMPHOMA

Non-Hodgkin's lymphomas (NHLs) are a heterogeneous group of malignant neoplasms of primarily B-, T-, or natural killer (NK) cell origin affecting all ages. B-cell lymphomas constitute about 85% of all NHLs. They are categorized by the level of differentiation, cell of origin, and rate of cellular proliferation.[26] A variety of clinical presentations and courses are recognized, from indolent (slowly developing) to rapidly progressive disease. NHL is the most commonly occurring hematologic cancer and the fifth leading cause of cancer death. Each year approximately 66,360 new cases of NHL are diagnosed and approximately 19,320 deaths occur.[49]

Etiology and Pathophysiology

As with Hodgkin's lymphoma, the cause of NHL is usually unknown. NHLs may result from chromosomal translocations, infections, environmental factors, and immunodeficiency states. Chromosomal translocations have an important role in the pathogenesis of many NHLs. Some viruses and bacteria are implicated in the pathogenesis of NHL, including HTLV-1, EBV, human herpesvirus 8, hepatitis B and C, *Helicobacter pylori*, *Chlamydophila psittaci, Campylobacter jejuni,* and *Borrelia burgdorferi*. Environmental factors linked to the development of NHL include chemicals (e.g., pesticides, herbicides, solvents, organic chemicals, wood preservatives). NHL is also more common in individuals who have inherited immunodeficiency syndromes and who have used immunosuppressive medications (e.g., to prevent rejection after an organ transplant or to treat autoimmune disorders) or received chemotherapy or radiation therapy.

NHL does not have a hallmark feature that parallels the Reed-Sternberg cell of Hodgkin's lymphoma. However, all NHLs involve lymphocytes arrested in various stages of development and may mimic a leukemia. For example, small lymphocytic lymphoma (SLL) and chronic lymphocytic leukemia (CLL) result from malignant proliferation of small B lymphocytes, with CLL having the majority of disease within the bone marrow (versus the lymph nodes).[45] (The overlap among leukemia and NHLs is discussed on p. 665.) Diffuse large B-cell lymphoma, the most common aggressive lymphoma, is a neoplasm that originates in the lymph nodes, usually in the neck or abdomen. Burkitt's lymphoma is the most highly aggressive disease and is thought to originate from B-cell blasts in the lymph nodes.

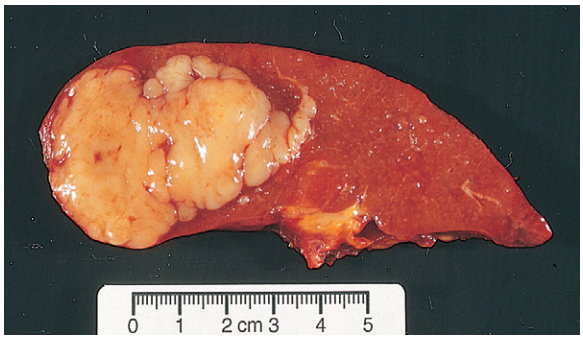

FIG. 31-15 Non-Hodgkin's lymphoma involving the spleen. The presence of an isolated mass is typical.

Clinical Manifestations

NHLs can originate outside the lymph nodes, the method of spread can be unpredictable, and the majority of patients have widely disseminated disease at the time of diagnosis (Fig. 31-15). The primary clinical manifestation is painless lymph node enlargement. The lymphadenopathy can wax and wane in indolent disease. Because the disease is usually disseminated when it is diagnosed, other symptoms are present depending on where the disease has spread (e.g., hepatomegaly with liver involvement, neurologic symptoms with CNS disease). NHL can also manifest in nonspecific ways, such as an airway obstruction, hyperuricemia and renal failure from tumor lysis syndrome, pericardial tamponade, and GI complaints.

Patients with high-grade lymphomas may have lymphadenopathy and constitutional symptoms (B symptoms) such as fever, night sweats, and weight loss. The peripheral blood is usually normal, but some lymphomas manifest in a "leukemic" phase.

Diagnostic and Staging Studies

Diagnostic studies used for NHL resemble those used for Hodgkin's lymphoma. However, because NHL is more often in extranodal sites, more diagnostic studies may be done, such as an MRI to rule out CNS or bone marrow infiltration, or a barium enema, upper endoscopy, or CT to visualize suspected GI involvement. Clinical staging, as described for Hodgkin's lymphoma, is used to help guide therapy (see Fig. 31-14), but establishment of the precise histologic subtype is extremely important. Lymph node excisional biopsy establishes the cell type and pattern. NHL is classified based on morphologic, genetic, immunophenotypic (cell surface antigens, CD20, CD52), and clinical features.

The World Health Organization has categorized more than 30 unique types of NHL. However, clinical studies have verified that different disease categories can be divided into one of two major categories: *indolent* (low grade) and *aggressive* (high grade), which is useful, along with gene expression patterns, in determining therapy[52] (Table 31-29). Additional factors, known as the International Prognostic Index (IPI), may be considered for each subtype to help select the appropriate treatment for these patients. Factors considered may include the clinical stage, number of extranodal sites, serum LDH, WBC count, hemoglobin, and patient's age and performance status. Immunologic, cytogenetic, and molecular studies are also useful for making therapeutic decisions and assessing prognosis. Other studies might include blood tests for tumor lysis (see Chapter 16); screening for hepatitis, HIV, and *H. pylori*; skin biopsies; bone marrow biopsies; and lumbar punctures. The prognosis for NHL is based on the histopathology.

TABLE 31-29 CLASSIFICATION OF NON-HODGKIN'S LYMPHOMA*

B-Cell Lymphomas

Precursor or Immature B-Cell Lymphomas
- Lymphoblastic lymphoma

Mature B-Cell Lymphomas
- Diffuse large B-cell lymphoma
- Follicular lymphoma
- Marginal zone B-cell lymphoma (MALT)
- Small lymphocytic lymphoma
- Mantle cell lymphoma
- Burkitt's lymphoma

T-Cell Lymphomas

Precursor or Immature T-Cell Lymphomas
- Lymphoblastic lymphoma

Mature T-Cell Lymphomas
- Peripheral T-cell lymphoma
- Mycosis fungoides and Sézary syndrome
- Anaplastic large T-cell lymphoma

Natural Killer Cell Lymphomas

*This is only a partial list.
MALT, Mucosa-associated lymphoid tissue.

NURSING AND COLLABORATIVE MANAGEMENT NON-HODGKIN'S LYMPHOMA

Treatment for NHL involves chemotherapy and sometimes radiation therapy (Table 31-30). Ironically, more aggressive lymphomas are more responsive to treatment and more likely to be cured. In contrast, indolent lymphomas have a naturally long course but are difficult to effectively treat.[52]

Patients with low-grade (indolent) lymphoma may live 10 years or more without treatment. However, some initial therapies can be well tolerated and have been shown to reduce the time to progression of the disease. Lymphomas that are infectious driven, such as *H. pylori* gastric lymphomas, may be treated with antibiotic or antiviral therapy. HSCT may have some benefit in certain subtypes of aggressive or refractory lymphomas.[45]

Rituximab, a monoclonal antibody against the CD20 antigen on the surface of normal and malignant B cells, is used to treat NHL. Once bound to the cells, rituximab causes lysis and cell death. Numerous chemotherapy combinations have been used to try to overcome the resistant nature of this disease (see Table 31-30). Complete remissions are uncommon, but the majority of patients respond with improvement in symptoms.

DRUG ALERT: Rituximab (Rituxan)
- Monitor patient for signs of severe hypersensitivity infusion reactions, especially with first infusion.
- Manifestations may include hypotension, bronchospasm, dysrhythmias, angioedema, and cardiogenic shock.
- Screen for history of hepatitis because the drug may reactivate hepatitis.

Other therapies for some types of NHL include the monoclonal antibodies ibritumomab tiuxetan (Zevalin) and tositumomab (Bexxar). These antibodies are linked to a radioactive isotope (yttrium-90 and iodine-131, respectively) (see Table 16-13). The monoclonal antibody targets the CD20 antigen, which is on the surface of mature B cells and B-cell tumors. This targeting allows for the delivery of radiation directly to the malignant cells. Side effects of this type of treatment include pancytopenia. Use radiation precautions in caring for these

TABLE 31-30 TREATMENT OF NON-HODGKIN'S LYMPHOMA*

Recommended Therapies	Common Chemotherapy Combinations
Indolent (Low Grade) (e.g., follicular lymphoma, marginal zone B-cell lymphoma [MALT])	
Observation until disease progression for asymptomatic patients with low-volume tumors and normal blood counts	**R-CHOP: r**ituximab, **c**yclophosphamide, doxorubicin **h**ydrochloride, vincristine (**O**ncovin), **p**rednisone
External beam irradiation for local, limited disease	**FMC: f**ludarabine, **m**itoxantrone, **c**yclophosphamide
Single-agent rituximab (Rituxan)	**R-CVP: r**ituximab, **c**yclophosphamide, **v**incristine, **p**rednisone
Single-agent chemotherapy (chlorambucil, cyclophosphamide, bendamustine) or alemtuzumab	**FND: f**ludarabine, mitoxantrone [**N**ovantrone], **d**examethasone ± rituximab
Rituximab with another agent (bendamustine, cyclophosphamide, fludarabine, cladribine, pentostatin, chlorambucil, denileukin diftitox)	**FC: f**ludarabine, **c**yclophosphamide
Combination chemotherapy (R-CHOP or other)	
Radioimmunotherapy	
Hematopoietic stem cell transplant (HSCT)	
Aggressive (Intermediate or High Grade) (e.g., mantle cell, diffuse large B-cell, Burkitt's, peripheral T-cell, natural killer cell lymphomas)	
Combination chemotherapy with localized radiation if needed	**R-CHOP** (see above)
Aggressive combination chemotherapy for 3-8 cycles with rituximab with local radiation if needed	**ICE** (or "RICE" with rituximab): **i**fosfamide, **c**yclophosphamide, **e**toposide
Intrathecal chemotherapy if needed	**R-EPOCH: r**ituximab, **e**toposide, **p**rednisone, vincristine (**O**ncovin), **c**yclophosphamide, doxorubicin **h**ydrochloride
HSCT	**ESHAP ± R: e**toposide, methylprednisolone (**S**olu-Medrol), **h**igh-dose cytarabine (**A**ra-C), cisplatin (**P**latinol), with or without rituximab
	Hyper-CVAD ± R: hyperfractionated **c**yclophosphamide, **v**incristine, doxorubicin (**A**driamycin), **d**examethasone alternating with high-dose methotrexate and cytarabine with or without rituximab
	DHAP ± R: dexamethasone, **h**igh-dose cytarabine (**A**ra-C), cisplatin (**P**latinol), with our without rituximab
	CODOX-M: cyclophosphamide, vincristine (**O**ncovin), **dox**orubicin, high-dose **m**ethotrexate, with or without rituximab (includes intrathecal methotrexate)
	FCR: fludarabine, **c**yclophosphamide, **r**ituximab
	SMILE: steroids, **m**ethotrexate, **i**fosfamide, **L**-asparaginase, **e**toposide
	High-dose cytarabine and high-dose methotrexate with leucovorin rescue

*Not all inclusive.
MALT, Mucosa-associated lymphoid tissue.

patients. Teach patients about safety issues and how to minimize the risk of radiation exposure to staff and others.

Peripheral T-cell lymphomas are treated similarly to intermediate-grade or high-grade B-cell lymphomas (without rituximab because they are generally not $CD20^+$). Cutaneous T-cell lymphomas may be treated with topical corticosteroids or topical chemotherapy for limited-stage disease. For more diffuse disease, treatment may include phototherapy, α-interferon, oral bexarotene (Targretin), vorinostat (Zolinza), or denileukin diftitox (Ontak), which is a fusion protein consisting of interleukin-2 and diphtheria toxin.[45,53] (Biologic and targeted therapy is discussed in Chapter 16.)

The nursing care for NHL is similar to that for Hodgkin's lymphoma. It is largely based on managing problems related to the disease (e.g., pain caused by the tumor, spinal cord compression, tumor lysis syndrome), pancytopenia, and other side effects of therapy. However, because NHL can be more extensive and involve specific organs (e.g., CNS, spleen, liver, GI tract, bone marrow), it is important to understand the subtype and extent of the disease. For example, a patient with known involvement of the colon may complain of acute abdominal pain. The patient most likely would have abdominal guarding and an enlarged and tympanic abdomen. This could indicate a bowel perforation and be considered a medical emergency. A patient with a Burkitt's NHL beginning chemotherapy would be at high risk for tumor lysis syndrome and would require frequent laboratory studies and monitoring, as well as strict documentation of intake and output. (Cancer-related therapies and side effects are discussed in Chapter 16.)

The patient undergoing external beam radiation therapy has special nursing needs. The skin in the radiation field requires attention. Concepts related to safety issues regarding radiation therapy are important in the plan of care (see Chapter 16).

Psychosocial considerations are important. Help the patient and family understand the disease, treatment, and expected and potential side effects. Fertility issues may be of concern in young patients. As in Hodgkin's lymphoma, evaluation of patients with NHL for long-term effects of therapy is important because the delayed consequences of disease and treatment may not become apparent for many years. (Secondary malignancies and delayed effects are discussed in Chapter 16.)

MULTIPLE MYELOMA

Multiple myeloma, or *plasma cell myeloma,* is a condition in which neoplastic plasma cells infiltrate the bone marrow and destroy bone. Multiple myeloma accounts for 1% of all malignancies and for about 10% of all hematologic malignancies.[49] The disease is twice as common in men as in women and usually develops after 40 years of age, with an average age of 65 years. Multiple myeloma occurs in African Americans more commonly than in whites. Although it was previously not considered curable, many patients are living 10 or more years because of the variety of treatments that can be provided throughout the course of the disease.[54]

Etiology and Pathophysiology

The cause of multiple myeloma is unknown. It is possible that exposure to radiation, organic chemicals (such as benzene), metals, herbicides, and insecticides may play a role. Genetic factors and viral infection may also influence the risk of developing multiple myeloma.

The disease process involves excessive production of plasma cells. Plasma cells are activated B cells, which produce immunoglobulins (antibodies) that normally serve to protect the body. However, in multiple myeloma instead of a variety of plasma cells producing antibodies to fight different infections, myeloma tumors produce monoclonal antibodies. *Monoclonal* means they are all of one kind, making them ineffective and even harmful. Not only do they not fight infections, but they also infiltrate the bone marrow. These monoclonal proteins (called M proteins) are made up of two light chains and two heavy chains. *Bence-Jones proteins* are the light chain part of these monoclonal antibodies. They show up in the urine in many patients with multiple myeloma.

Furthermore, plasma cell production of excessive and abnormal amounts of cytokines (interleukins [ILs]; IL-4, IL-5, and IL-6) also plays an important role in the pathologic process of bone destruction. As myeloma protein increases, normal plasma cells are reduced, which further compromises the body's normal immune response. Proliferation of malignant plasma cells and the overproduction of immunoglobulin and proteins result in the end-organ effects of myeloma on the bone marrow, bone, and kidneys and possibly the spleen, lymph nodes, liver, and even heart muscle.

Clinical Manifestations

Multiple myeloma develops slowly and insidiously. The patient often does not manifest symptoms until the disease is advanced, at which time skeletal pain is the major manifestation. Pain in the pelvis, spine, and ribs is particularly common and is triggered by movement. Diffuse osteoporosis develops as the myeloma protein destroys bone. Osteolytic lesions are seen in the skull, vertebrae, and ribs. Vertebral destruction can lead to collapse of vertebrae with ensuing compression of the spinal cord. Loss of bone integrity can lead to the development of pathologic fractures.

Bony degeneration also causes calcium to be lost from bones, eventually causing hypercalcemia. Hypercalcemia may cause renal, GI, or neurologic manifestations such as polyuria, anorexia, confusion, and ultimately seizures, coma, and cardiac problems. A serum "hyperviscosity syndrome" leading to cerebral, pulmonary, renal, and other organ dysfunction can occur in some patients. Even without hyperviscosity, high protein levels caused by the myeloma protein can result in renal tubular obstruction, interstitial nephritis, and renal failure. The patient may also display manifestations of anemia, thrombocytopenia, neutropenia, and immune dysfunction, all of which are related to the replacement of normal bone marrow with plasma cells. Neurologic abnormalities may be caused by regional myeloma cell growth compressing the spinal cord or cranial nerves, or by perineuronal or perivascular deposition.

Diagnostic Studies

Evaluating multiple myeloma involves laboratory, radiologic, and bone marrow examination. M protein is found in the blood and urine. Possible findings include pancytopenia, hypercalcemia, Bence Jones protein in the urine, and an elevated serum creatinine.

Skeletal bone surveys, MRI, and/or PET and CT scans show distinct lytic areas of bone erosions; generalized thinning of the bones; or fractures, especially in the vertebrae, ribs, pelvis, and bones of the thigh and upper arms. Bone marrow analysis shows significantly increased numbers of plasma cells in the bone marrow. The simplest measure of staging and prognosis in multiple myeloma is based on blood levels of two markers: β_2-microglobulin and albumin. In general, higher levels of β_2-microglobulin and lower levels of albumin are associated with a poorer prognosis.

Collaborative Care

Collaborative care involves managing both the disease and its symptoms. The current treatment options include watchful waiting (for early multiple myeloma, also called MGUS [monoclonal gammopathy of undetermined significance]), corticosteroids, chemotherapy, targeted therapy, and HSCT. Multiple myeloma is seldom cured, but treatment can relieve symptoms, produce remission, and prolong life. Ambulation and adequate hydration are used to treat hypercalcemia, dehydration, and potential renal damage. Weight bearing helps the bones resorb some calcium, and fluids dilute calcium and prevent protein precipitates from causing renal tubular obstruction. Control of pain and prevention of pathologic fractures are other goals of management. Analgesics, orthopedic supports, and localized radiation help reduce the skeletal pain.

Bisphosphonates, such as pamidronate (Aredia), zoledronic acid (Zometa), and etidronate (Didronel), inhibit bone breakdown and are used for the treatment of skeletal pain and hypercalcemia. They inhibit bone resorption without inhibiting bone formation and mineralization. They are given monthly by IV infusion. Radiation therapy is another important component of treatment, primarily because of its effect on localized lesions. Surgical procedures, such as vertebroplasty, may be done to support degenerative vertebrae.

DRUG ALERT: Zoledronic Acid (Zometa)

- Patient should be adequately rehydrated before administering drug.
- Renal toxicity may occur if IV infusion of drug is administered in less than 15 min.

Chemotherapy with corticosteroids is usually the first treatment recommended for multiple myeloma. It is used to reduce the number of plasma cells. Initial treatment depends on whether the patient is a future bone marrow transplant candidate and anticipated tolerance of therapy. The treatment usually includes a corticosteroid (dexamethasone or prednisone) plus one or two therapies, such as cyclophosphamide, lenalidomide, thalidomide, pomalidomide (Pomalyst), doxorubicin, or melphalan. High-dose chemotherapy followed by HSCT has evolved as the standard of care in eligible patients.[55]

Targeted therapy for multiple myeloma may include bortezomib (Velcade) and carfilzomib (Kyprolis). These drugs inhibit proteasomes, which are intracellular multienzyme complexes that degrade proteins. Proteasome inhibitors can cause these proteins to accumulate, thus leading to altered cell function. Normal cells are capable of recovering from proteasome inhibition, but cancer cells undergo death when proteasomes are inhibited.

Drugs may be used to treat complications of multiple myeloma. For example, allopurinol may be given to reduce hyperuricemia, and IV furosemide (Lasix) promotes renal excretion of calcium.

NURSING MANAGEMENT
MULTIPLE MYELOMA

A major focus of care relates to the bone involvement and sequelae from bone breakdown. Maintaining adequate hydra-

tion is a primary nursing consideration to minimize problems from hypercalcemia. IV fluids may be administered to attain a urine output of 1.5 to 2 L/day. Although tumor lysis is rare, once chemotherapy is initiated, allopurinol may be given to prevent any renal damage from uric acid accumulation (from cell breakdown). Because of the myeloma proteins, the patient is at additional risk of renal dysfunction and electrolyte and fluid imbalances.

Because of the potential for pathologic fractures, use caution when moving and ambulating the patient. A slight twist or strain in the wrong area (e.g., a weak area in the patient's bones) may be sufficient to cause a fracture. In addition, the development of peripheral neuropathy is common with several therapies for multiple myeloma and can contribute to discomfort, the inability to perform basic activities of daily living, and the risk of injury from falling. Pain medications and therapies can also lead to severe constipation.

Pain management requires innovative and knowledgeable nursing interventions. Analgesics, such as nonsteroidal antiinflammatory drugs, acetaminophen, or an acetaminophen/opioid combination, may be more effective than opioids alone in diminishing bone pain. Braces, especially for the spine, may also help control pain. As in any pain management situation, assess the patient and implement necessary measures to alleviate the pain. (Pain management is discussed in Chapter 9.) Patients may also be at risk for deep vein thrombosis related to chemotherapy and immobility and should have appropriate preventive measures employed.[55]

Assessment and prompt treatment of infection are important in the care of patients with multiple myeloma. These recurrent infections may be due to a decrease in the production of normal immunoglobulins, the ineffectiveness of the overproduced and abnormal immunoglobulins, corticosteroids, and/or neutropenia as a result of the bone marrow infiltration or side effects of treatment.

The patient's psychosocial needs require sensitive, skilled management. Help the patient and significant others adapt to changes fostered by chronic sickness and adjust to the losses related to the disease process, while helping to maximize functioning and quality of life.[56] The patient with multiple myeloma may experience remissions and exacerbations. Patients may be on dialysis because of myeloma-induced renal failure. Consequently acute care is needed at various times during the course of the illness. The final, acute phase is unresponsive to treatment and usually short in duration. The way in which patients and families confront death may be affected by the manner in which they have learned to accept and live with the chronic disease.

DISORDERS OF THE SPLEEN

The spleen can be affected by many illnesses, most of which can cause some degree of *splenomegaly* (enlarged spleen) (Table 31-31). The term *hypersplenism* refers to the occurrence of splenomegaly and peripheral cytopenias (anemia, leukopenia, and thrombocytopenia). The degree of splenic enlargement varies with the disease. For example, massive splenic enlargement occurs with infectious mononucleosis, chronic myelogenous leukemia, and thalassemia major. Mild splenic enlargement occurs with HF and systemic lupus erythematosus. The normal spleen contains 350 mL of blood, and about one third of the platelet mass is sequestered in the spleen.[57]

TABLE 31-31 CAUSES OF SPLENOMEGALY

Hereditary Hemolytic Anemias
- Sickle cell disease
- Thalassemia

Autoimmune Cytopenias
- Acquired hemolytic anemia
- Immune thrombocytopenia

Infections and Inflammations
- Bacterial infections: endocarditis, salmonella
- Mycobacterial infections: tuberculosis
- Spirochetes: syphilis, Lyme disease
- Viral infections: hepatitis, human immunodeficiency virus, cytomegalovirus, mononucleosis
- Parasitic infections: malaria, trypanosomiasis, schistosomiasis, leishmaniasis, toxoplasmosis
- Rickettsial infections: Rocky Mountain spotted fever, typhoid fever
- Fungal infections: histoplasmosis
- Autoimmune diseases: systemic lupus erythematosus, rheumatoid arthritis

Infiltrative Diseases
- Acute and chronic leukemia
- Lymphomas
- Polycythemia vera
- Multiple myeloma, amyloidosis
- Other primary or secondary neoplasms and cysts
- Sarcoidosis
- Gaucher disease

Congestion
- Cirrhosis of the liver
- Heart failure (portal hypertension)
- Portal or splenic vein thrombosis

When the spleen enlarges, its normal filtering and sequestering capacity increases. Consequently, there is often a reduction in the number of circulating blood cells as they engorge the spleen. In addition, there are unusual findings in the peripheral smear, such as pitted or pocked erythrocytes or Howell-Jolly bodies. These findings assist in diagnosing a malfunctioning spleen. A slight to moderate enlargement of the spleen is usually asymptomatic and found during routine examination of the abdomen. Even massive splenomegaly can be well tolerated, but the patient may complain of abdominal discomfort and early satiety. In addition to physical examination, other techniques to assess the size of the spleen include radionuclide colloid liver-spleen scan, CT or PET scan, MRI, and ultrasound scan.

Occasionally laparoscopy or open laparotomy and splenectomy are indicated in the evaluation or treatment of splenomegaly. Another major indication for splenectomy is splenic rupture. The spleen may rupture from trauma; inadvertent tearing during other surgical procedures; and diseases such as mononucleosis, malaria, and lymphoid neoplasms. After a splenectomy, there can be a dramatic increase in peripheral RBC, WBC, and platelet counts.

Nursing responsibilities for the patient with spleen disorders vary depending on the problem. Splenomegaly may be painful and may require analgesic administration; care in moving, turning, and positioning; and evaluation of lung expansion because spleen enlargement may impair diaphragmatic excursion. If anemia, thrombocytopenia, or leukopenia develops from splenic enlargement, institute nursing measures to support

the patient and prevent life-threatening complications. If splenectomy is performed, observe the patient for hemorrhage and shock.

After splenectomy, immunologic deficiencies may develop. IgM levels are reduced, while IgG and IgA values remain within normal limits. Postsplenectomy patients have a lifelong risk for infection, especially from encapsulated organisms such as *Pneumococcus* species. This risk is reduced by immunization with pneumococcal vaccine (e.g., Pneumovax).

BLOOD COMPONENT THERAPY

Blood component therapy is frequently used to manage hematologic diseases. Many therapeutic and surgical procedures depend on blood product support. However, blood component therapy only temporarily supports the patient until the underlying problem is resolved. Because transfusions are not free from hazards, they should be used only if necessary.

Avoid developing a complacent attitude about this common but potentially dangerous therapy. Make sure that the physician has discussed the risks, benefits, and alternatives with the patient and that this is documented in the patient's medical record.

Traditionally, the term *blood transfusion* meant the administration of whole blood. Blood transfusion now has a broader meaning because of the ability to administer specific components of blood such as platelets, packed red blood cells (PRBCs), or plasma. Usually a specific component is ordered, although whole blood may be rarely used with massive hemorrhage or for an exchange transfusion[58-60] (Table 31-32).

TABLE 31-32 BLOOD PRODUCTS*

Description	Special Considerations	Indications for Use
Packed RBCs		
Packed RBCs are prepared from whole blood by sedimentation or centrifugation. One unit contains 250-350 mL. They can be stored up to 35 days depending on processing.	Use of RBCs for treatment allows remaining components of blood (e.g., platelets, albumin, plasma) to be used for other purposes. There is less danger of fluid overload. Packed RBCs are preferred RBC source because they are more component specific. Leukocyte depletion (leukoreduction) by filtration, washing, or freezing frequently used. Decreases hemolytic febrile or mild allergic reactions in patients who receive frequent transfusions.	Severe or symptomatic anemia, acute blood loss. One unit of RBCs can be expected to increase Hgb by 1 g/dL or Hct by 3% in a typical adult. One unit of RBCs can replace a blood loss of 500 mL.
Frozen RBCs		
Frozen RBCs are prepared from RBCs using glycerol for protection and frozen. They can be stored for 10 yr.	Must be used within 24 hr of thawing. Successive washings with saline solution remove majority of WBCs and plasma proteins.	Autotransfusion. Stockpiling or rare donors for patients with alloantibodies.
Platelets		
Platelets are prepared from fresh whole blood. One donor unit contains 30-60 mL of platelet concentrate (from whole blood). Platelets also pooled from multiple donors. An apheresed single donation contains 200-400 mL of platelets.	Multiple units of platelets can be obtained from one donor by plateletpheresis. They can be kept at room temperature for 1-5 days depending on type of collection and storage bag used. Bag should be agitated periodically. For patients who receive frequent transfusions and become refractory, may give leukocyte reduced, HLA, or type specific to prevent alloimmunization to HLA antigens.	Bleeding caused by thrombocytopenia; may be contraindicated in thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia except in life-threatening hemorrhage. Expected increase is 10,000/μL/U. Failure to have an increase may be due to fever, sepsis, splenomegaly, or DIC or development of antibodies *(refractory).*
Fresh Frozen Plasma		
Liquid portion of whole blood is separated from cells and frozen. One unit contains 200-250 mL. Plasma is rich in clotting factors but contains no platelets. May be stored for ≥1 yr, depending on storage. Must be used within 24 hr after thawing.	Use of plasma in treating hypovolemic shock is being replaced by pure preparations such as albumin and plasma expanders.	Bleeding caused by deficiency in clotting factors (e.g., DIC, hemorrhage, massive transfusion, liver disease, vitamin K deficiency, excess warfarin).
Albumin		
Albumin is prepared from plasma. It can be stored for 5 yr. It is available in 5% or 25% solution.	Albumin 25 g/dL is osmotically equal to 500 mL of plasma. Hyperosmolar solution acts by moving water from extravascular to intravascular space. It is heat treated and does not transmit viruses.	Hypovolemic shock, hypoalbuminemia.
Cryoprecipitates and Commercial Concentrates		
Cryoprecipitate is prepared from fresh frozen plasma, with 10-20 mL/bag. It can be stored for 1 yr. Once thawed, must be used within 5 days.	See Table 31-19.	Replacement of clotting factors, especially factor VIII, von Willebrand factor, and fibrinogen.

*Component therapy has replaced the use of whole blood, which accounts for <10% of all transfusions. Granulocyte transfusions are not included here because they are rarely used.
DIC, Disseminated intravascular coagulation; *HLA,* human leukocyte antigen.

Administration Procedure

Blood components are usually administered with at least a 19-gauge needle, cannula, or catheter. Larger sizes (e.g., 18 or 16 gauge) may be preferred if rapid transfusions are given. Smaller needles can be used for platelets, albumin, and clotting factor replacement. Whatever type of venous access is used, verify its patency before requesting the blood component from the blood bank. Most blood product administration tubing is of a "Y type" with a microaggregate filter (filters out particulate), with one arm of the Y for the isotonic saline solution and the other arm of the Y for the blood product.

SAFETY ALERT

- Do not use dextrose solutions or lactated Ringer's solution for administering blood because they will cause RBC hemolysis.
- Do not give any additives (including medications) via the same tubing as the blood unless the tubing is first cleared with saline solution.

After obtaining the blood or blood components from the blood bank, make a positive identification of the donor blood and recipient. Improper product-to-patient identification is the most common cause of hemolytic transfusion reactions, thus placing a great responsibility on nurses to carry out the identification procedure appropriately. Follow the policy and procedures at your place of employment. Many institutions have implemented a dual-checking system with two licensed individuals checking the patient identification with the labeled blood component. The blood bank is responsible for typing and crossmatching the donor's blood with the recipient's blood. The result of the compatibility testing should be noted on the product bag or tag, if pertinent.

ABO compatibility is not a prerequisite for platelet transfusions. However, after multiple platelet transfusions, a patient may develop anti-HLA antibodies to the transfused platelets. With the use of lymphocyte typing to match HLA types of the donor and the recipient, multiple platelet transfusions can be given with fewer complications to those who develop antibodies to platelets. In addition, the patient may be premedicated with an antihistamine (e.g., diphenhydramine [Benadryl]) and hydrocortisone to decrease the possibility of reacting to platelet transfusions.

Take the patient's vital signs before beginning the transfusion so that you have a baseline measure. If the patient has abnormal vital signs (e.g., high fever), call the physician to clarify when the blood component may be administered. Administer the blood as soon as it is brought to the patient. Do not refrigerate it on the nursing unit. If the blood is not used within 30 minutes, return it to the blood bank. During the first 15 minutes or 50 mL of blood infusion, remain with the patient. If there are any untoward reactions, they are most likely to occur at this time. The rate of infusion during this period should be no more than 2 mL/minute. Do not infuse PRBCs quickly except in an emergency. Rapid infusion of cold blood may cause the patient to become chilled. If rapid replacement of large amounts of blood is necessary, a blood-warming device may be used. Other blood components, such as fresh frozen plasma and platelets, may be infused over 15 to 30 minutes. Refer to your institution's policy and procedure.

After the first 15 minutes, vital signs are usually retaken, and the rate of infusion is determined by the patient's clinical condition and the product being infused. Observe the patient periodically throughout the transfusion (e.g., every 30 minutes) and up to 1 hour after the transfusion. Most patients not in danger of fluid overload can tolerate the infusion of 1 unit of PRBCs over 2 hours. The transfusion should not take more than 4 hours to administer because of the increased risk of bacterial growth in the product once it is out of refrigeration. Blood that is unrefrigerated for 4 hours or longer should not be infused and should be returned to the blood bank.

ETHICAL/LEGAL DILEMMAS

Religious Beliefs

Situation

W.D., an 81-year-old woman with dementia, is transferred from a nursing home to a hospital because of gastrointestinal bleeding from an unknown cause. Some of her family members tell you that she is a Jehovah's Witness and must not receive blood products. If she does not have exploratory surgery and transfusions, the surgeon believes that she will die.

Ethical/Legal Points for Consideration

- Competent adults have the right to make health care decisions, including the right to refuse treatment, based on their religious beliefs.
- If the patient is determined to be incompetent and a guardian has been appointed, the guardian has the legal right to make the consent or refusal.
- If the health care professional believes that the treatment is essential to preserve life and health and there is no legal decision maker, a request is made for a legal determination of whether the patient is incapable of consent or refusal. If the judge agrees, the patient is made a ward of the court for this issue. Usually the physician is directed to make a decision based on the patient's best interests.
- Courts tend to defer to any past information coming directly from patients about their own personal desires, even if that information is not in valid advance directives.

Discussion Questions

1. What resources do you have available to consult about religious practices?
2. How could you make a determination if the family were acting in W.D.'s best interest or their own?
3. What nonblood alternatives are available for Jehovah's Witnesses?

DELEGATION DECISIONS

Blood Transfusions

Role of Registered Nurse (RN)

- Ensure that an IV line is being used with a large-bore needle, catheter, or cannula, preferably 19 gauge or larger.
- Double-check patient identification and blood product identification data with another licensed nurse (consider state nurse practice act and agency policy).
- Adjust infusion rate of transfusion according to patient needs.
- Evaluate patient for signs of transfusion reactions.
- Evaluate for therapeutic effect of blood product (improvement in complete blood count, increased blood pressure, improved patient color, decreased bleeding).
- Monitor for signs of circulatory overload (e.g., shortness of breath) if the transfusion must be given rapidly.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Assist with checking patient identification and blood product identification data with the RN (consider state nurse practice act and agency policy).
- Monitor blood transfusion rate (consider state nurse practice act and agency policy).

Role of Unlicensed Assistive Personnel (UAP)

- Obtain blood products from the blood bank as directed by the RN.
- Take vital signs before the transfusion and after the first 15 min.

Blood Transfusion Reactions

A *blood transfusion reaction* is an adverse reaction to blood transfusion therapy that can range in severity from mild symptoms to a life-threatening condition. Because complications of transfusion therapy may be significant, judicious evaluation of the patient is required. Blood transfusion reactions can be classified as acute or delayed (Tables 31-33 and 31-34).

If an acute transfusion reaction occurs, take the following steps: (1) stop the transfusion; (2) maintain a patent IV line with saline solution; (3) notify the blood bank and the health care provider immediately; (4) recheck identifying tags and numbers; (5) monitor vital signs and urine output; (6) treat symptoms per physician order; (7) save the blood bag and tubing and send them to the blood bank for examination;

TABLE 31-33 ACUTE TRANSFUSION REACTIONS

Cause	Manifestations	Management	Prevention
Acute Hemolytic Reaction			
Infusion of ABO-incompatible whole blood, RBCs, or components containing ≥10 mL of RBCs. Antibodies in the recipient's plasma attach to antigens on transfused RBCs, causing RBC destruction.	Reactions usually develop in first 15 min. Chills, fever, low back pain, flushing, tachycardia, dyspnea, tachypnea, hypotension, vascular collapse, hemoglobinuria, acute jaundice, dark urine, bleeding, acute kidney injury, shock, cardiac arrest, DIC, death.	Treat shock and DIC if present. Draw blood samples for serologic testing slowly to avoid hemolysis from the procedure. Send urine specimen to the laboratory. Maintain BP with IV colloid solutions. Give diuretics as prescribed to maintain urine flow. Insert indwelling urinary catheter or measure voided amounts to monitor hourly urine output. Dialysis may be required if renal failure occurs. Do not transfuse additional RBC-containing components until blood bank has provided newly crossmatched units.	Meticulously verify and document patient identification from sample collection to component infusion (e.g., visually compare label on sample collection and blood component with patient identification).
Febrile, Nonhemolytic Reaction (most common)			
Sensitization to donor WBCs (most common), platelets, or plasma proteins.	Sudden chills, rigors, and fever (rise in temperature of >1°C), headache, flushing, anxiety, vomiting, muscle pain.	Give antipyretics as prescribed (acetaminophen). Avoid aspirin in thrombocytopenic patients. Do not restart transfusion unless physician orders.	Consider leukocyte-reduced blood products (filtered, washed, or frozen) for patients with a history of two or more such reactions. Give acetaminophen or diphenhydramine (Benadryl) 30 min before transfusion.
Mild Allergic Reaction			
Sensitivity to foreign plasma proteins. More common in people with history of allergies.	Flushing, itching, pruritus, urticaria (hives).	Give antihistamine, corticosteroid, epinephrine, as ordered. If symptoms are mild and transient, transfusion may be restarted slowly with physician's order. Do not restart transfusion if fever or pulmonary symptoms develop.	Treat prophylactically with antihistamines. Consider washed RBCs and platelets.
Anaphylactic and Severe Allergic Reaction			
Sensitivity to donor plasma proteins. Infusion of IgA proteins to IgA-deficient recipient who has developed IgA antibody.	Anxiety, urticaria, dyspnea, wheezing, progressing to cyanosis, bronchospasm, hypotension, shock, and possible cardiac arrest.	Initiate CPR, if indicated. Have epinephrine ready for injection. Antihistamines, corticosteroids, β_2-agonists may also be prescribed. Do not restart transfusion.	Transfuse extensively washed RBC products from which all plasma has been removed. Use blood from IgA-deficient donor. Use autologous components.
Circulatory Overload Reaction			
Fluid administered faster than the circulation can accommodate. People with cardiac or renal disease at risk.	Cough, dyspnea, pulmonary congestion, adventitious breath sounds, headache, hypertension, tachycardia, distended neck veins.	Place patient upright with feet in dependent position. Obtain chest x-ray STAT if ordered. Administer prescribed diuretics, O_2, morphine. Phlebotomy may be indicated.	Adjust transfusion volume and flow rate based on patient size and clinical status. Have blood bank divide future units into smaller aliquots for better spacing of fluid input.
Sepsis Reaction			
Transfusion of bacterially infected blood components.	Rapid onset of chills, high fever, vomiting, diarrhea, marked hypotension, or shock.	Obtain culture of patient's blood and send bag with remaining blood and tubing to blood bank for further study. Treat septicemia as directed—antibiotics, IV fluids, vasopressors.	Collect, process, store, and transfuse blood products according to blood banking standards and infuse within 4 hr of starting time.

TABLE 31-33 ACUTE TRANSFUSION REACTIONS—cont'd

Cause	Manifestations	Management	Prevention
Transfusion-Related Acute Lung Injury (TRALI) Reaction			
Reaction between transfused antileukocyte antibodies and recipient's leukocytes, causing pulmonary inflammation and capillary leak.	Noncardiogenic pulmonary edema. Fever, hypotension, tachypnea, frothy sputum, dyspnea, hypoxemia, respiratory failure. Leading cause of transfusion-related deaths.	Send bag with remaining blood and tubing to blood bank. Draw blood for arterial blood gases and HLA or antileukocyte antibodies. Obtain chest x-ray STAT. Provide O_2 and administer corticosteroids (diuretics of no value) as ordered. Initiate CPR if needed, and provide ventilatory and BP support if needed.	Provide leukocyte-reduced products. Identify donors who are implicated in TRALI reactions and do not allow them to donate.
Massive Blood Transfusion Reaction			
Can occur when replacement of RBCs or blood exceeds the total blood volume within 24 hr. RBC transfusions do not contain clotting factors, albumin, and platelets.	Hypothermia and cardiac dysrhythmias (from rapid infusion of large quantities of cold blood). Citrate toxicity and hypocalcemia (from the use of citrate as a storage solution). Hypocalcemia (citrate binds calcium) manifested as muscle tremors and ECG changes. Hyperkalemia (from potassium leaking from stored RBCs). Manifested as muscle weakness, diarrhea, paresthesias, paralysis of the cardiac or respiratory muscles, and cardiac arrest.	When patients receive massive transfusions of blood products, monitor clotting status and electrolyte levels.	Use blood-warming equipment. Infusion of 10% calcium gluconate (10 mL with every 1 L of citrated blood).

DIC, Disseminated intravascular coagulation; *HLA,* human leukocyte antigen; *IgA,* immunoglobulin A.

TABLE 31-34 DELAYED TRANSFUSION REACTIONS

Manifestations	Prevention and Management
Delayed Hemolytic	
Fever, mild jaundice, decreased hemoglobin. Occurs as early as 3 days or as late as several mo, but usually 5-10 days posttransfusion as the result of destruction of transfused RBCs by alloantibodies not detected during crossmatch.	Generally, no acute treatment is required. But hemolysis may be severe enough to warrant further transfusions.
Hepatitis B*	
Elevated liver enzymes (AST and ALT), anorexia, malaise, nausea and vomiting, fever, dark urine, jaundice. Usually resolves spontaneously within 4-6 wk. Chronic carrier state can develop and result in permanent damage to the liver.	Hepatitis B virus can be detected in donated blood by the presence of hepatitis B surface antigen (HBsAg). Treat symptomatically (see Chapter 44).
Hepatitis C*	
Similar to hepatitis B, but symptoms are usually less severe. Chronic liver disease and cirrhosis may develop.	Before testing of anti-HCV in donated blood, accounted for 90%-95% of all posttransfusion hepatitis. Treat symptomatically (see Chapter 44).
Iron Overload	
Excess iron is deposited in heart, liver, pancreas, and joints, causing dysfunction. Heart failure, dysrhythmias, impaired thyroid and gonadal function, diabetes, arthritis, cirrhosis. Commonly occurs in patients receiving >100 units for chronic anemia (e.g., sickle cell anemia, β-thalassemia) over time.	Treat symptomatically. Deferoxamine (Desferal), which chelates and removes accumulated iron via the kidneys, administered IV or subcutaneously. Deferasirox (Exjade) and deferiprone (Ferriprox) are oral agents that chelate iron.
Other	
Cytomegalovirus (CMV), HIV, human herpesvirus type 6 (HSV-6), Epstein-Barr virus (EBV), human T cell leukemia virus, HTLV-1, and malaria. Most recent threats have been agents that primarily affect animals, but have been transmitted to the blood supply through the food supply, or vectors such as mosquitoes or ticks. These include *Plasmodium* species (malaria), dengue fever virus, West Nile virus, *Trypanosoma cruzi* (Chagas' disease), *Babesia* species (babesiosis), human herpesvirus 8 (KS virus), and variant Creutzfeldt-Jakob disease ("mad cow disease").	Treatment based on the cause. Ways of detecting some of these agents are now available and required, such as the nucleic acid test for West Nile virus and *T. cruzi.* Donor screening has been the only available method to reduce the risk of donor-contaminated blood for others.

*New cases of transfusion-related hepatitis B and C are not common.
ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *HCV,* hepatitis C virus; *HTLV-1,* human T-cell leukemia virus, type 1; *KS,* Kaposi sarcoma.

(8) collect required blood and urine specimens at intervals based on the hospital policy to evaluate for hemolysis; and (9) document on transfusion reaction form and patient chart. The blood bank and laboratory are responsible for identifying the type of reaction.

Acute Transfusion Reactions. The most common cause of hemolytic reactions is transfusion of ABO-incompatible blood (see Table 31-33). This is an example of a type II cytotoxic hypersensitivity reaction (see Chapter 14). Severe hemolytic reactions are rare. Mislabeling specimens and administering blood to the wrong individual cause most acute hemolytic reactions. This again points to the importance of using proper patient identifiers when drawing blood samples and when administering medications and blood products.

Delayed Transfusion Reactions. Delayed transfusion reactions include delayed hemolytic reactions (discussed previously), infections, and iron overload (see Table 31-34).

Autotransfusion

Autotransfusion, or autologous transfusion, involves removing whole blood from a person and transfusing that blood back into the same person. The problems of incompatibility, allergic reactions, and transmission of disease can be avoided. Methods of autotransfusion include the following:

- *Autologous donation* or *elective phlebotomy* (predeposit transfusion). A person donates blood before a planned surgical procedure. The blood can be frozen and stored for up to 10 years. Usually the blood is stored without being frozen and is given to the person within a few weeks of donation. This technique is especially beneficial to the patient with a rare blood type or for any patient who might be expected to require limited blood product support during a major surgical procedure (e.g., elective orthopedic surgery).
- *Autotransfusion.* A newer method for replacing blood volume involves safely and aseptically collecting, filtering, and returning the patient's own blood lost during a major surgical procedure or from a traumatic injury. This system was originally developed in response to patients' concerns about the safety of blood from blood products. However, today it provides an important way to safely replace volume and stabilize bleeding patients. Collection devices are most often used during surgeries. Some systems allow blood to be automatically and continuously reinfused. Others require collecting the blood for a time (usually no longer than 4 hours) and then reinfusing it.

Drainage after the first 24 hours or drainage that is suspected to contain pathogens should not be reinfused. Anticoagulants may or may not be added before reinfusion. Development of clots after blood is filtered through the collection system can sometimes prevent reinfusion of the blood. Sometimes blood that has been collected has become depleted of its normal coagulation factors. Therefore monitoring coagulation studies in the patient receiving an autotransfusion is important.

CASE STUDY

Leukemia

iStockphoto/Thinkstock

Patient Profile

J.J., a 28-year-old white man, had a bad fall while hiking in the nearby hills. He went to the emergency department because of severe bruising from the fall.

Subjective Data

- Complains of oral pain and white patches covering his tongue
- Has had a 2-month history of extreme fatigue, malaise, and flu symptoms
- Complains of shortness of breath and his heart bounding
- Has taken numerous prescribed antibiotics and increased rest and sleep in the past 2 months without relief of symptoms

Objective Data

Physical Examination

- Has bruises and ecchymoses from fall
- Gingiva has petechiae and patchy white spots
- Temperature 102.2° F (39° C), respiratory rate 26/min, pulse 110/min
- Has splenomegaly

Laboratory Results

- Hct 20%
- Hgb 6.9 g/dL
- WBC count 120,000/μL (120×10^9/L)
- Platelet count 25,000/μL (25×10^9/L)

Bone Marrow Biopsy

- Multiple myeloblasts (>50%)

Collaborative Care

- Consultation with a hematologist-oncologist
- Two units of packed red blood cells

Discussion Questions

1. What components of the laboratory test results suggest acute leukemia?
2. How is acute myelogenous leukemia treated?
3. What is J.J.'s prognosis?
4. What are the life-threatening problems that can occur as a result of this disease and treatment? How can you anticipate and assess for these problems?
5. ***Priority Decision:*** What are the priority nursing interventions?
6. ***Priority Decision:*** What are the priorities for patient teaching with a newly diagnosed young adult with leukemia?
7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Delegation Decision:*** What nursing interventions can the registered nurse (RN) delegate to unlicensed assistive personnel (UAP) while J.J. is getting his blood transfusions?
9. ***Evidence-Based Practice:*** J.J. becomes fatigued after starting chemotherapy. He wants to know if he can still exercise even if he is so fatigued. What is your best advice for him?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a severely anemic patient, the nurse would expect to find
   a. dyspnea and tachycardia.
   b. cyanosis and pulmonary edema.
   c. cardiomegaly and pulmonary fibrosis.
   d. ventricular dysrhythmias and wheezing.
2. When obtaining assessment data from a patient with a microcytic, hypochromic anemia, the nurse would question the patient about
   a. folic acid intake.
   b. dietary intake of iron.
   c. a history of gastric surgery.
   d. a history of sickle cell anemia.
3. Nursing interventions for a patient with severe anemia related to peptic ulcer disease include *(select all that apply)*
   a. monitoring stools for guaiac.
   b. instructions for high-iron diet.
   c. taking vital signs every 8 hours.
   d. teaching self-injection of erythropoietin.
   e. administration of cobalamin (vitamin B_{12}) injections.
4. The nursing management of a patient in sickle cell crisis includes *(select all that apply)*
   a. monitoring CBC.
   b. optimal pain management and O_2 therapy.
   c. blood transfusions if required and iron chelation.
   d. rest as needed and deep vein thrombosis prophylaxis.
   e. administration of IV iron and diet high in iron content.
5. A complication of the hyperviscosity of polycythemia is
   a. thrombosis.
   b. cardiomyopathy.
   c. pulmonary edema.
   d. disseminated intravascular coagulation (DIC).
6. When caring for a patient with thrombocytopenia, the nurse instructs the patient to
   a. dab his or her nose instead of blowing.
   b. be careful when shaving with a safety razor.
   c. continue with physical activities to stimulate thrombopoiesis.
   d. avoid aspirin because it may mask the fever that occurs with thrombocytopenia.
7. The nurse would anticipate that a patient with von Willebrand disease undergoing surgery would be treated with administration of vWF and
   a. thrombin.
   b. factor VI.
   c. factor VII.
   d. factor VIII.
8. DIC is a disorder in which
   a. the coagulation pathway is genetically altered, leading to thrombus formation in all major blood vessels.
   b. an underlying disease depletes hemolytic factors in the blood, leading to diffuse thrombotic episodes and infarcts.
   c. a disease process stimulates coagulation processes with resultant thrombosis, as well as depletion of clotting factors, leading to diffuse clotting and hemorrhage.
   d. an inherited predisposition causes a deficiency of clotting factors that leads to overstimulation of coagulation processes in the vasculature.
9. Priority nursing actions when caring for a hospitalized patient with a new-onset temperature of 102.2° F and severe neutropenia include *(select all that apply)*
   a. administering the prescribed antibiotic STAT.
   b. drawing peripheral and central line blood cultures.
   c. ongoing monitoring of the patient's vital signs for septic shock.
   d. taking a full set of vital signs and notifying the physician immediately.
   e. administering transfusions of WBCs treated to decrease immunogenicity.
10. Because myelodysplastic syndrome arises from the pluripotent hematopoietic stem cell in the bone marrow, laboratory results the nurse would expect to find include a(n)
    a. excess of T cells.
    b. excess of platelets.
    c. deficiency of granulocytes.
    d. deficiency of all cellular blood components.
11. The most common type of leukemia in older adults is
    a. acute myelocytic leukemia.
    b. acute lymphocytic leukemia.
    c. chronic myelocytic leukemia.
    d. chronic lymphocytic leukemia.
12. Multiple drugs are often used in combinations to treat leukemia and lymphoma because
    a. there are fewer toxic and side effects.
    b. the chance that one drug will be effective is increased.
    c. the drugs are more effective without causing side effects.
    d. the drugs work by different mechanisms to maximize killing of malignant cells.
13. The nurse is aware that a major difference between Hodgkin's lymphoma and non-Hodgkin's lymphoma is that
    a. Hodgkin's lymphoma occurs only in young adults.
    b. Hodgkin's lymphoma is considered potentially curable.
    c. non-Hodgkin's lymphoma can manifest in multiple organs.
    d. non-Hodgkin's lymphoma is treated only with radiation therapy.
14. A patient with multiple myeloma becomes confused and lethargic. The nurse would expect that these clinical manifestations may be explained by diagnostic results that indicate
    a. hyperkalemia.
    b. hyperuricemia.
    c. hypercalcemia.
    d. CNS myeloma.
15. When reviewing the patient's hematologic laboratory values after a splenectomy, the nurse would expect to find
    a. leukopenia.
    b. RBC abnormalities.
    c. decreased hemoglobin.
    d. increased platelet count.
16. Complications of transfusions that can be decreased by the use of leukocyte depletion or reduction of RBC transfusion are
    a. chills and hemolysis.
    b. leukostasis and neutrophilia.
    c. fluid overload and pulmonary edema.
    d. transmission of cytomegalovirus and fever.

1. a, 2. b, 3. a, b, 4. a, b, c, d, 5. a, 6. a, 7. d, 8. c, 9. a, b, c, d, 10. d, 11. d, 12. d, 13. c, 14. c, 15. d, 16. d

CASE STUDY

Managing Multiple Patients

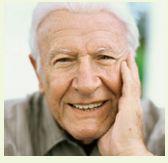
Introduction

You are working on the oncology unit and have been assigned to care for the following four patients. You have one UAP who is assigned to help you and there are two other RNs on your clinical unit.

Patients

iStockphoto/Thinkstock

A.J. is a 90-year-old white woman who is admitted with severe anemia (Hgb 5.9 g/dL and Hct 18.2%). She prefers to take care of herself with "natural therapy" and has not seen a health care provider for 10 years. A.J. is having difficulty performing ADLs without having to stop and catch her breath. She received 2 units of RBCs and is undergoing further workup to determine the cause of her anemia.



iStockphoto/Thinkstock

J.J. is a 28-year-old white man newly diagnosed with acute myeloblastic leukemia (AML). His most recent vital signs are BP 100/70, temperature 102.2° F (39° C), respiratory rate 26/min, pulse 110. Lab results reveal hematocrit 20%, Hgb 6.9 g/dL, WBC count 120,000/μL (120 × 10^9/L), and platelet count 25,000/μL (25 × 10^9/L). He is admitted for blood transfusions and induction therapy.

iStockphoto/Thinkstock

P.H. is a 45-year-old woman who is currently receiving chemotherapy for treatment of ovarian cancer. She is admitted with fever and chills. Her WBC count is 2200/μL (2.2 × 10^9/L) with an absolute neutrophil count of 400/μL (0.4 × 10^9/L). She is admitted for IV antibiotic therapy and is in protective isolation. Her most recent vital signs are BP 118/60, temperature 99.2° F (37.3° C), respiratory rate 20/min, pulse 98.

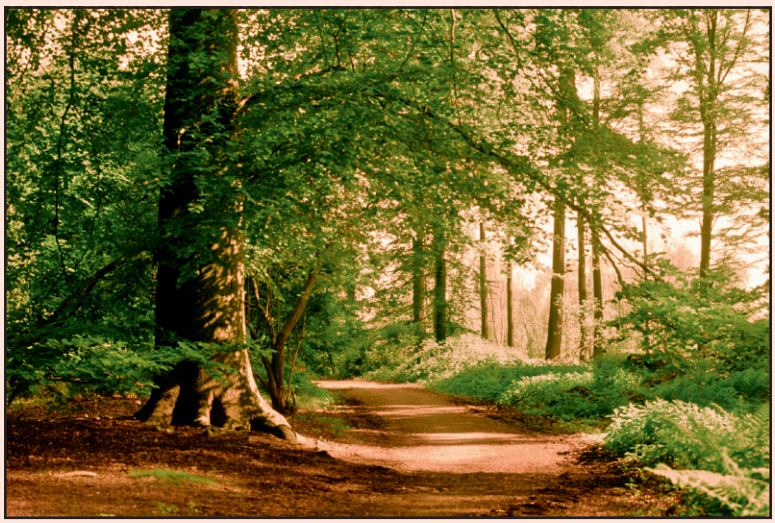
iStockphoto/Thinkstock

G.L. is a 70-year-old man who came to the emergency department yesterday evening with complaints of abdominal pain. A CT scan of the abdomen revealed several masses in his lymphatic system. The physician suspects non-Hodgkin's lymphoma and admits him for a diagnostic workup. He currently rates his pain as a 3 on a scale of 0-10.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale for your decision.
2. ***Delegation Decision:*** Which task could you delegate to the UAP *(select all that apply)?*
   - a. Assist A.J. to a chair after completing her AM care.
   - b. Obtain the first unit of blood for J.J. from the blood bank.
   - c. Explain the importance of protective isolation to P.H. and her family.
   - d. Ask A.J. why she has not been willing to get any medical care for 10 years.
   - e. Ask G.L. about the presence of additional clinical manifestations of non-Hodgkin's lymphoma.
3. ***Priority and Delegation Decision:*** When you enter J.J.'s room, you find him somewhat confused and lethargic. His family states he had just had a severe coughing episode. What initial action would be the most appropriate?
   - a. Perform a focused neurologic examination.
   - b. Call respiratory therapy to give him a breathing treatment.
   - c. Ask his family members if they have a copy of his living will.
   - d. Have the UAP stay with J.J. while you page the health care provider STAT.

Case Study Progression



J.J.'s health care provider orders a repeat CBC and an emergency CT scan of the head. Your supervisor makes arrangements for another RN to accompany J.J. to the CT scan while you prepare to administer the first unit of RBCs.

4. A.J. is diagnosed with iron-deficiency anemia. The physician orders ferrous sulfate 325 mg TID. You teach A.J. to take her iron *(select all that apply)*
   - a. at breakfast time in the morning.
   - b. with orange juice to increase absorption.
   - c. 1 hour before meals to facilitate absorption.
   - d. 2 hours after eating to minimize side effects.
   - e. whenever she feels tired or is short of breath with activity.
5. When teaching P.H.'s family about neutropenic precautions, you emphasize that the most important intervention to prevent infection is
   - a. hand washing.
   - b. wearing a mask.
   - c. keeping P.H. in a private room.
   - d. limiting the number of visitors in her room.
6. G.L. asks you to explain the diagnostic testing he can expect to undergo related to the suspected lymphoma. Which tests will you explain to him *(select all that apply)?*
   - a. PET scan
   - b. Bone marrow biopsy
   - c. Peripheral blood smear
   - d. Excisional lymph node biopsy
   - e. Lymphangiography of internal lymph nodes
7. ***Management Decision:*** An RN from the float pool arrives to accompany J.J. to CT scan at the same time the UAP arrives with his first unit of RBCs. Which intervention would be most appropriate?
   - a. Put the unit of RBCs in the refrigerator to start when J.J. returns to the floor.
   - b. Ask the RN to verify the correct unit of RBCs with you and start the infusion.
   - c. Give the RN a SBAR report on J.J. and ask her to start the blood on route to CT scan.
   - d. Ask the RN if she would prefer to give the blood or hold it for J.J.'s return to the unit.

LEARNING OUTCOMES

1. Differentiate the anatomic location and function of the following cardiac structures: pericardial layers, atria, ventricles, semilunar valves, and atrioventricular valves.
2. Relate the coronary circulation to the areas of heart muscle supplied by the major coronary arteries.
3. Differentiate the structure and function of arteries, veins, capillaries, and endothelium.
4. Describe the mechanisms involved in the regulation of blood pressure.
5. Relate the various waveforms on a normal electrocardiogram to the associated cardiac events.
6. Select essential assessment data related to the cardiovascular system that should be obtained from a patient and/or caregiver.
7. Select appropriate techniques to use in the physical assessment of the cardiovascular system.
8. Differentiate normal from abnormal findings of a physical assessment of the cardiovascular system.
9. Link the age-related changes of the cardiovascular system to the differences in assessment findings.
10. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the cardiovascular system.

STRUCTURES AND FUNCTIONS OF CARDIOVASCULAR SYSTEM

Heart

Structure. The heart is a four-chambered hollow muscular organ normally about the size of a fist. It lies within the thorax in the mediastinal space that separates the right and left pleural cavities. The heart is composed of three layers: a thin inner lining, the *endocardium;* a layer of muscle, the *myocardium;* and an outer layer, the *epicardium.* The heart is covered by a fibroserous sac called the *pericardium.* This sac consists of two layers: the inside *(visceral)* layer of the pericardium (part of the epicardium) and the outer *(parietal)* layer. A small amount of pericardial fluid (approximately 10 to 15 mL) lubricates the space between the pericardial layers *(pericardial space)* and prevents friction between the surfaces as the heart contracts.[1]

The heart is divided vertically by the septum. The interatrial septum creates a right and left atrium, and the interventricular septum creates a right and left ventricle. The thickness of the wall of each chamber is different. The atrial myocardium is thinner than that of the ventricles, and the left ventricular wall is two or three times thicker than the right ventricular wall.[1] The thickness of the left ventricle is necessary to produce the force needed to pump the blood into the systemic circulation.

Blood Flow Through Heart. The blood flow through the heart is illustrated in Fig. 32-1.

Cardiac Valves. The four valves of the heart serve to keep blood flowing in a forward direction. The cusps of the mitral and tricuspid valves are attached to thin strands of fibrous tissue termed *chordae tendineae* (Fig. 32-2). Chordae are anchored in the papillary muscles of the ventricles. This support system prevents the eversion of the leaflets into the atria during ventricular contraction. The pulmonic and aortic valves (also known as *semilunar valves*) prevent blood from regurgitating into the ventricles at the end of each ventricular contraction.

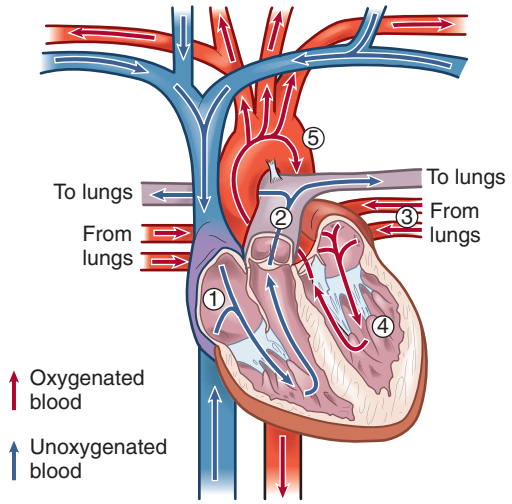

FIG. 32-1 Schematic representation of blood flow through the heart. *Arrows* indicate direction of flow. *1,* The right atrium receives venous blood from the inferior and superior venae cavae and the coronary sinus. The blood then passes through the tricuspid valve into the right ventricle. *2,* With each contraction, the right ventricle pumps blood through the pulmonic valve into the pulmonary artery and to the lungs. *3,* Oxygenated blood flows from the lungs to the left atrium by way of the pulmonary veins. *4,* It then passes through the mitral valve and into the left ventricle. *5,* As the heart contracts, blood is ejected through the aortic valve into the aorta and thus enters the systemic circulation.

Blood Supply to Myocardium. The myocardium has its own blood supply, the *coronary circulation* (Fig. 32-3). Blood flow into the two major coronary arteries occurs primarily during **diastole** (relaxation of the myocardium). The left coronary artery arises from the aorta and divides into two main branches: the left anterior descending artery and the left circumflex artery. These arteries supply the left atrium, the left ventricle, the interventricular septum, and a portion of the right ventricle. The right coronary artery also arises from the aorta, and its branches supply the right atrium, the right ventricle, and a portion of the posterior wall of the left ventricle. In 90% of people the atrioventricular (AV) node and the bundle of His receive blood supply from the right coronary artery. For this reason, blockage of this artery often causes serious defects in cardiac conduction.

The divisions of coronary veins parallel the coronary arteries. Most of the blood from the coronary system drains into the coronary sinus (a large channel), which empties into the right atrium near the entrance of the inferior vena cava.

Conduction System. The conduction system is specialized nerve tissue responsible for creating and transporting the electrical impulse, or **action potential.** This impulse starts depolarization and subsequently cardiac contraction (Fig. 32-4, *A*). The electrical impulse is normally started by the sinoatrial (SA) node (the pacemaker of the heart). Each impulse coming from the SA node travels through interatrial pathways to depolarize the atria, resulting in a contraction.

The electrical impulse travels from the atria to the AV node through internodal pathways. The excitation then moves through the bundle of His and the left and right bundle branches. The left bundle branch has two fascicles (divisions): anterior and posterior. The action potential moves through the walls of both ventricles by means of *Purkinje fibers.* The ventricular conduction system delivers the impulse within 0.12 second. This triggers a synchronized right and left ventricular contraction.

The result of the cardiac cycle is the ejection of blood into the pulmonary and systemic circulations. It ends with repolarization when the contractile fiber cells and the conduction pathway cells regain their resting polarized condition. Cardiac

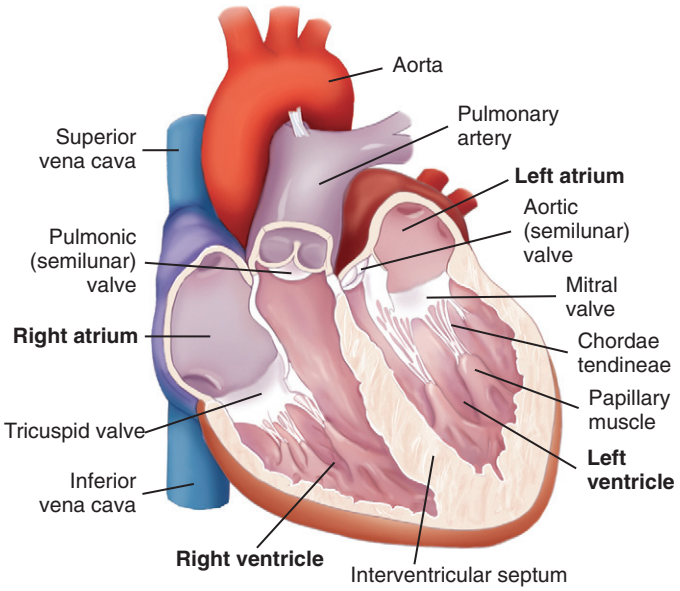

FIG. 32-2 Anatomic structures of the heart and heart valves.

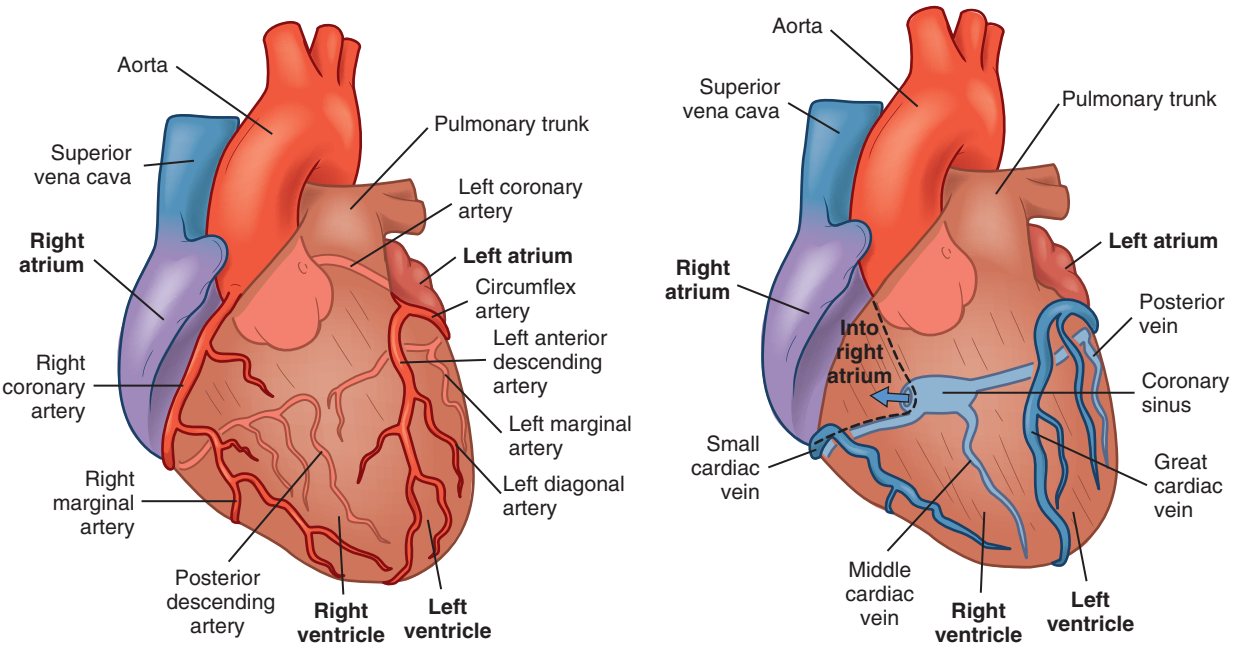

FIG. 32-3 Coronary arteries and veins.

muscle cells have a compensatory mechanism that makes them unresponsive or refractory to restimulation during the action potential. During ventricular contraction, there is an *absolute refractory period* during which cardiac muscle does not respond to any stimuli. After this period, cardiac muscle gradually recovers its excitability, and a *relative refractory period* occurs by early diastole.

Electrocardiogram. The electrical activity of the heart can be detected on the body surface using electrodes and is recorded on an electrocardiogram (ECG). The letters P, QRS, T, and U are used to identify the separate waveforms (Fig. 32-4, *B*). The first wave, P, begins with the firing of the SA node and represents depolarization of the atria. The QRS complex represents depolarization from the AV node throughout the ventricles. There is a delay of impulse transmission through the AV node that accounts for the time between the beginning of the P wave and the beginning of the QRS wave. The T wave represents repolarization of the ventricles. The U wave, if seen, may repre-

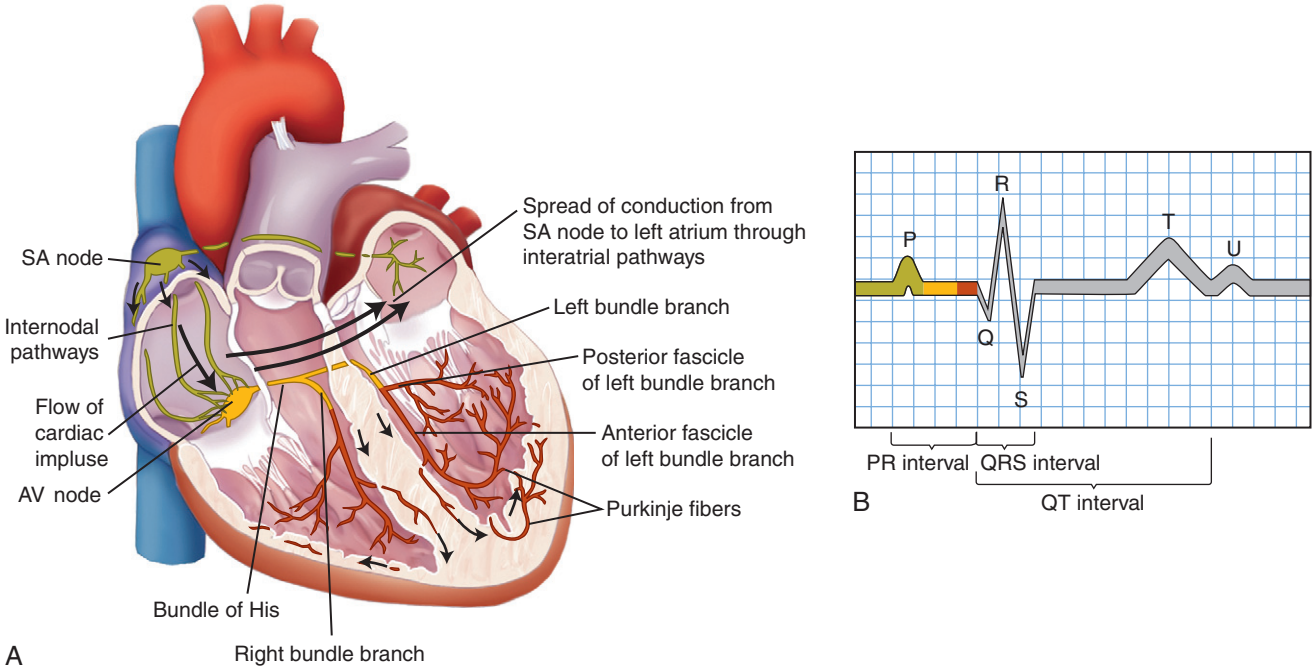

FIG. 32-4 **A,** Conduction system of the heart. *AV,* Atrioventricular; *SA,* sinoatrial. **B,** The normal electrocardiogram (ECG) pattern. The P wave represents depolarization of the atria. The QRS complex indicates depolarization of the ventricles. The T wave represents repolarization of the ventricles. The U wave, if present, may represent repolarization of the Purkinje fibers, or it may be associated with hypokalemia. The PR, QRS, and QT intervals reflect the time it takes for the impulse to travel from one area of the heart to another.

sent repolarization of the Purkinje fibers, or it may be associated with hypokalemia.[2]

Intervals between these waves (PR, QRS, and QT intervals) reflect the time it takes for the impulse to travel from one area of the heart to another. These time intervals can be measured, and changes from these time references often indicate pathologic conditions. (See Chapter 36 for a complete discussion of ECG monitoring.)

Mechanical System. *Depolarization* triggers mechanical activity. **Systole,** contraction of the myocardium, results in ejection of blood from the ventricles. Relaxation of the myocardium, *diastole*, allows for filling of the ventricles. **Cardiac output (CO)** is the amount of blood pumped by each ventricle in 1 minute. It is calculated by multiplying the amount of blood ejected from the ventricle with each heartbeat—the *stroke volume* (SV)—by the heart rate (HR) per minute:

$$CO = SV \times HR$$

For the normal adult at rest, CO is maintained in the range of 4 to 8 L/min. **Cardiac index (CI)** is the CO divided by the body surface area (BSA). The CI adjusts the CO to the body size. The normal CI is 2.8 to 4.2 L per minute per meter squared ($L/min/m^2$).

Factors Affecting Cardiac Output. Numerous factors can affect either the HR or the SV, and thus the CO. The HR, which is controlled primarily by the autonomic nervous system, can reach as high as 180 beats/minute for short periods without harmful effects. The factors affecting the SV are preload, contractility, and afterload. Increasing preload, contractility, and afterload increases the workload of the myocardium, resulting in increased oxygen demand.

Frank-Starling law states that, to a point, the more the myocardial fibers are stretched, the greater their force of contraction. The volume of blood in the ventricles at the end of diastole, before the next contraction, is called **preload.** Preload determines the amount of stretch placed on myocardial fibers. Preload can be increased by a number of conditions such as myocardial infarction, aortic stenosis, and hypervolemia.[3] Contractility can be increased by epinephrine and norepinephrine released by the sympathetic nervous system. Increasing contractility raises the SV by increasing ventricular emptying.

Afterload is the peripheral resistance against which the left ventricle must pump. Afterload is affected by the size of the ventricle, wall tension, and arterial blood pressure (BP). If the arterial BP is elevated, the ventricles meet increased resistance to ejection of blood, increasing the work demand. Eventually this results in *ventricular hypertrophy,* an enlargement of the cardiac muscle tissue without an increase in CO or the size of chambers (see Fig. 35-1, *B*).

Cardiac Reserve. The cardiovascular system must respond to numerous situations in health and illness (e.g., exercise, stress, hypovolemia). The ability to respond to these demands by altering CO is termed **cardiac reserve.**

Vascular System

Blood Vessels. The three major types of blood vessels in the vascular system are the arteries, veins, and capillaries. Arteries, except for the pulmonary artery, carry oxygenated blood away from the heart. Veins, except for the pulmonary veins, carry deoxygenated blood toward the heart. Small branches of arteries and veins are arterioles and venules, respectively. Blood circulates from the left side of the heart into arteries, arterioles, capillaries, venules, and veins, and then back to the right side of the heart.

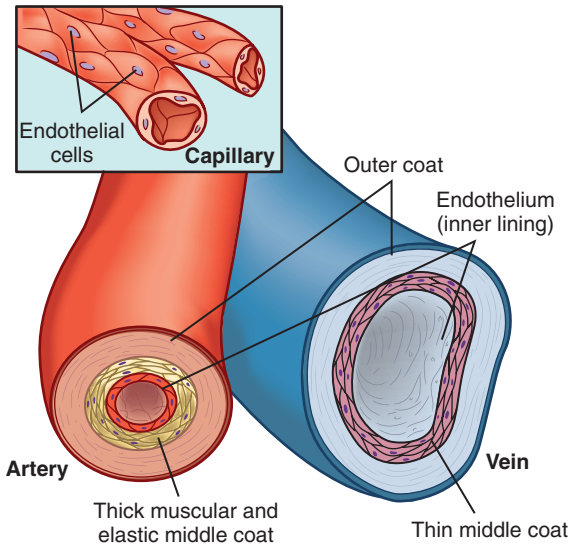

FIG. 32-5 Comparative thickness of layers of the artery, vein, and capillary.

Arteries and Arterioles. The arterial system differs from the venous system by the amount and type of tissue that make up arterial walls (Fig. 32-5). The large arteries have thick walls composed mainly of elastic tissue. This elastic property cushions the impact of the pressure created by ventricular contraction and provides recoil that propels blood forward into the circulation. Large arteries also contain some smooth muscle. Examples of large arteries are the aorta and the pulmonary artery.

Arterioles have relatively little elastic tissue and more smooth muscle. Arterioles serve as the major control of arterial BP and distribution of blood flow. They respond readily to local conditions such as low oxygen (O_2) and increasing levels of carbon dioxide (CO_2) by dilating or constricting.

The innermost lining of the arteries is the endothelium. The endothelium serves to maintain hemostasis, promote blood flow, and, under normal conditions, inhibit blood coagulation. When the endothelial surface is disrupted (e.g., rupture of an atherosclerotic plaque), the coagulation cascade is initiated and results in the formation of a fibrin clot.

Capillaries. The thin capillary wall is made up of endothelial cells, with no elastic or muscle tissue (see Fig. 32-5). The exchange of cellular nutrients and metabolic end products takes place through these thin-walled vessels. Capillaries connect the arterioles and venules.

Veins and Venules. Veins are large-diameter, thin-walled vessels that return blood to the right atrium (see Fig. 32-5). The venous system is a low-pressure, high-volume system. The larger veins contain semilunar valves at intervals to maintain the blood flow toward the heart and to prevent backward flow. The amount of blood in the venous system is affected by a number of factors, including arterial flow, compression of veins by skeletal muscles, alterations in thoracic and abdominal pressures, and right atrial pressure.

The largest veins are the *superior vena cava,* which returns blood to the heart from the head, neck, and arms, and the *inferior vena cava,* which returns blood to the heart from the lower part of the body. These large-diameter vessels are affected by the

pressure in the right side of the heart. Elevated right atrial pressure can cause distended neck veins or liver engorgement as a result of resistance to blood flow.

Venules are relatively small vessels made up of a small amount of muscle and connective tissue. Venules collect blood from the capillary beds and channel it to the larger veins.

Regulation of Cardiovascular System

Autonomic Nervous System. The autonomic nervous system consists of the sympathetic nervous system and the parasympathetic nervous system (see Chapter 56).

Effect on Heart. Stimulation of the sympathetic nervous system increases the HR, the speed of impulse conduction through the AV node, and the force of atrial and ventricular contractions. This effect is mediated by specific sites in the heart called beta (β)-adrenergic receptors, which are receptors for norepinephrine and epinephrine.

In contrast, stimulation of the parasympathetic system (mediated by the vagus nerve) slows the HR by decreasing the impulses from the SA node, and thus conduction through the AV node.

Effect on Blood Vessels. The source of neural control of blood vessels is the sympathetic nervous system. The alpha$_1$ (α_1)-adrenergic receptors are located in vascular smooth muscles. Stimulation of α_1-adrenergic receptors results in vasoconstriction. Decreased stimulation to α_1-adrenergic receptors causes vasodilation. (Sympathetic nervous system receptors that influence BP are presented in Table 33-1.)

The parasympathetic nerves have selective distribution in the blood vessels. For example, blood vessels in skeletal muscle do not receive parasympathetic input.

Baroreceptors. *Baroreceptors* in the aortic arch and carotid sinus (at the origin of the internal carotid artery) are sensitive to stretch or pressure within the arterial system. Stimulation of these receptors (e.g., volume overload) sends information to the vasomotor center in the brainstem. This results in temporary inhibition of the sympathetic nervous system and enhancement of the parasympathetic influence, causing a decreased HR and peripheral vasodilation. Decreased arterial pressure causes the opposite effect.

Chemoreceptors. *Chemoreceptors* are located in the aortic and carotid bodies and the medulla. They are capable of causing changes in respiratory rate and BP in response to increased arterial CO_2 pressure (hypercapnia) and, to a lesser degree, decreased plasma pH (acidosis) and arterial O_2 pressure (hypoxia). When the chemoreceptors in the medulla are triggered, they stimulate the vasomotor center to increase BP.[4]

Blood Pressure

The **arterial blood pressure** is a measure of the pressure exerted by blood against the walls of the arterial system. The **systolic blood pressure (SBP)** is the peak pressure exerted against the arteries when the heart contracts. The **diastolic blood pressure (DBP)** is the residual pressure in the arterial system during ventricular relaxation (or filling). BP is usually expressed as the ratio of systolic to diastolic pressure.

The two main factors influencing BP are *cardiac output* (CO) and *systemic vascular resistance* (SVR):

$$BP = CO \times SVR$$

SVR is the force opposing the movement of blood. This force is created primarily in small arteries and arterioles. Normal blood pressure is SBP less than 120 mm Hg and DBP less than 80 mm Hg[5] (see Chapter 33).

Measurement of Arterial Blood Pressure. BP can be measured by invasive and noninvasive techniques. The invasive technique consists of catheter insertion into an artery. The catheter is attached to a transducer, and the pressure is measured directly (see Chapter 66).

Noninvasive, indirect measurement of BP can be done with a sphygmomanometer and a stethoscope. The sphygmomanometer consists of an inflatable cuff and a pressure gauge. The BP is measured by auscultating for sounds of turbulent blood flow through a compressed artery (termed **Korotkoff sounds**). The brachial artery is the recommended site for taking a BP.

After placing the appropriate size cuff on the upper arm, inflate the cuff to a pressure 20 to 30 mm Hg above the SBP. This causes blood flow in the artery to cease. If the SBP is not known, estimate the pressure by palpating the brachial pulse and inflating the cuff until the pulse ceases. The pressure noted at this time is the estimated SBP. Inflate the BP cuff 20 to 30 mm Hg above this number.

As the pressure in the cuff is lowered, auscultate the artery for Korotkoff sounds. There are five phases of Korotkoff sounds. The first phase is a tapping sound caused by the spurt of blood into the constricted artery as the pressure in the cuff is gradually deflated. This sound is noted as the SBP. The fifth phase occurs when the sound disappears, which is noted as the DBP.[6] BP is recorded as SBP/DBP (e.g., 120/80 mm Hg). Sometimes, an *auscultatory gap* occurs, which is a loss of sound between the SBP and the DBP. Proper BP technique (e.g., using the correct cuff size, positioning arm at heart level) is essential for accurate readings[6] (see Table 33-11).

Another noninvasive way to measure BP indirectly is an automated device that uses oscillometric measurements to assess BP. Though this method does not involve auscultation, the same attention to proper technique is essential for accuracy. Finally, SBP (and pulse) can be assessed using a Doppler ultrasonic flowmeter. The hand-held transducer is positioned over the artery (identified by audible, pulsatile sounds). The cuff is applied above the artery, inflated until the sounds disappear, and then another 20 to 30 mm Hg beyond that point. The cuff is then slowly deflated until sounds return. This point is the SBP.[6]

Pulse Pressure and Mean Arterial Pressure. **Pulse pressure** is the difference between the SBP and DBP. It is normally about one third of the SBP. If the BP is 120/80 mm Hg, the pulse pressure is 40 mm Hg. An increased pulse pressure due to an increased SBP may occur during exercise or in individuals with atherosclerosis of the larger arteries. A decreased pulse pressure may be found in heart failure or hypovolemia.

Another measurement related to BP is **mean arterial pressure (MAP).** The MAP refers to the average pressure within the arterial system that is felt by organs in the body. It is not the average of the diastolic and systolic pressures because the length of diastole exceeds that of systole at normal HRs. MAP is calculated as follows:

$$MAP = (SBP + 2\,DBP) \div 3$$

A person with a BP of 120/60 mm Hg has an estimated MAP of 80 mm Hg. In patients with invasive BP monitoring, this value is automatically calculated and takes the patient's HR into consideration (see Chapter 66).

An MAP greater than 60 mm Hg is needed to adequately perfuse and sustain the vital organs of an average person under most conditions. When the MAP falls below this number for a period of time, vital organs are underperfused and will become ischemic.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON THE CARDIOVASCULAR SYSTEM

One of the greatest risk factors for cardiovascular disease (CVD) is age. CVD remains the leading cause of death in adults older than age 85. It is the most common cause of hospitalization and the second leading cause of death in adults younger than age 85. The most common cardiovascular problem is coronary artery disease (CAD) secondary to atherosclerosis. It is difficult to separate normal aging changes from the pathophysiologic changes of atherosclerosis. Many of the physiologic changes in the cardiovascular system of older adults are a result of the combined effects of the aging process, disease, environmental factors, and lifetime health behaviors rather than just age alone.[7]

Age-related changes in the cardiovascular system and differences in assessment findings are presented in Table 32-1. With increased age, the amount of collagen in the heart increases and elastin decreases. These changes affect the myocardium's ability to stretch and contract. One of the major changes in the cardiovascular system is the response to physical or emotional stress. In times of increased stress, CO and SV decrease due to reduced contractility and HR response. The resting supine HR is not markedly affected by aging. When the patient changes positions (e.g., sits upright), the sympathetic nerve pathway may be affected by fibrous tissue and fatty deposits, resulting in a blunted HR response.[7]

Cardiac valves become thicker and stiffer from lipid accumulation, degeneration of collagen, and fibrosis. The aortic and mitral valves are most frequently affected. These changes result in either regurgitation of blood when the valve should be closed or narrowing of the orifice of the valve (stenosis) when the valve should be open. The turbulent blood flow across the affected valve results in a **murmur.**

The number of pacemaker cells in the SA node decreases with age. By age 75, a person may have only 10% of the normal number of pacemaker cells. Although this is compatible with adequate SA node function, it may account for the frequency of some sinus dysrhythmias in older adults. Similar decreases also occur in the number of conduction cells in the internodal tracts, bundle of His, and bundle branches. These changes contribute to the development of atrial dysrhythmias and heart blocks. About 50% of older adults have an abnormal resting ECG that shows increases in the PR, QRS, and/or QT intervals.[8]

The autonomic nervous system control of the cardiovascular system changes with aging. The number and function of β-adrenergic receptors in the heart decrease with age. So the older adult not only has a decreased response to physical and emotional stress, but also is less sensitive to β-adrenergic agonist drugs. The lower maximum HR during exercise results in only a twofold increase in CO compared with the three or four times increase seen in younger adults.

Arterial and venous blood vessels thicken and become less elastic with age.[9] Arteries increase their sensitivity to vasopressin (antidiuretic hormone). With aging both of these changes contribute to a progressive increase in SBP and a decrease or no change in DBP. Thus an increase in the pulse pressure is found. Hypertension is not a normal consequence of aging, and should be treated. Valves in the large veins in the lower extremities have a reduced ability to return the blood to the heart, often resulting in dependent edema.

Orthostatic hypotension, which is estimated to be present in more than 30% of patients over age 70 with systolic hypertension, may be related to medications and/or decreased baroreceptor function.[8] *Postprandial hypotension* (decrease in BP of at least 20 mm Hg that occurs within 75 minutes after eating) may also occur in about a third of otherwise healthy older adults. Both orthostatic and postprandial hypotension may be related to falls in older adults. Despite the changes associated with aging, the heart is able to function adequately under most circumstances.

TABLE 32-1 GERONTOLOGIC ASSESSMENT DIFFERENCES

Cardiovascular System

Changes	Differences in Assessment Findings
Chest Wall	
Kyphosis	Altered chest landmarks for palpation, percussion, and auscultation. Distant heart sounds.
Heart	
Myocardial hypertrophy, ↑ collagen and scarring, ↓ elastin	↓ Cardiac reserve, heart failure.
Downward displacement	Difficulty in isolating apical pulse
↓ CO, HR, SV in response to exercise or stress	↓ Response to exercise and stress. Slowed recovery from activity.
Cellular aging and fibrosis of conduction system	↓ Amplitude of QRS complex and slight. lengthening of PR, QRS, and QT intervals. Irregular cardiac rhythms, ↓ maximal HR, ↓ HR variability.
Valvular rigidity from calcification, sclerosis, or fibrosis, impeding complete closure of valves	Systolic murmur (aortic or mitral) possible without an indication of cardiovascular disease.
Blood Vessels	
Arterial stiffening caused by loss of elastin in arterial walls, thickening of intima of arteries, and progressive fibrosis of media	↑ In systolic BP and possible ↑ or ↓ in diastolic BP. Possible widened pulse pressure. Pedal pulses diminished. ↑ In intermittent claudication.
Venous tortuosity increased	Inflamed, painful, or cordlike varicosities. Dependent edema.

ASSESSMENT OF CARDIOVASCULAR SYSTEM

Subjective Data

A careful health history and physical examination will help you distinguish symptoms that reflect a cardiovascular problem from problems of other body systems. Explore and document all cues that alert you to the possibility of underlying cardiovascular problems.

Important Health Information

History of Present Illness. Ask the patient what problem has brought him or her to the health care facility or provider.

CASE STUDY

Patient Introduction

Jupiterimages/Banana-Stock/Thinkstock

L.P., a 63-year-old Asian American man, is brought to the emergency department by ambulance at 6 AM after calling 911 with complaints of chest pain, shortness of breath (SOB), palpitations, and dizziness. The paramedics have started an IV and oxygen at 2 L/min via nasal cannula. They also administered four chewable baby ASA and a nitroglycerin tablet, and they obtained a 12-lead ECG. L.P. is pain free on arrival but still complains of palpitations and dizziness.

Critical Thinking

As you read through this assessment chapter, think about L.P.'s symptoms with the following questions in mind:

1. What are the possible causes of L.P.'s chest pain, SOB, palpitations, and dizziness?
2. What would be your major focus when assessing L.P.?
3. What questions would you ask L.P.?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies would you expect to be ordered?

Evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Fully explore all symptoms the patient is experiencing (see Table 32-1).

Past Health History. Many illnesses affect the cardiovascular system directly or indirectly. Ask the patient about a history of chest pain, shortness of breath, fatigue, alcohol and tobacco use, anemia, rheumatic fever, streptococcal throat infections, congenital heart disease, stroke, palpitations, dizziness with position changes, syncope, hypertension, thrombophlebitis, intermittent claudication, varicosities, and edema.

Medications. Assess the patient's current and past use of medications. This includes over-the-counter (OTC) drugs, herbal supplements, and prescription drugs. For example, aspirin prolongs the blood clotting time, and is found in many drugs used to treat cold symptoms. List all of the patient's drugs. Include dosage, time of last dose, and the patient's understanding of the drug's purpose and side effects. Many noncardiac drugs can adversely affect the cardiovascular system and should be assessed (Table 32-2).

Surgery or Other Treatments. Ask the patient about specific treatments, past surgeries, or hospital admissions related to cardiovascular problems. Explore any admissions or outpatient procedures for diagnostic workups or cardiovascular symptoms. Note whether an ECG or a chest x-ray has been done for baseline data.

Functional Health Patterns. The strong correlation between components of a patient's lifestyle and cardiovascular health supports the need to review each functional health pattern. Key questions to ask a person with a cardiovascular problem are listed in Table 32-3.

Health Perception–Health Management Pattern. Ask the patient about the presence of major cardiovascular risk factors. These include abnormal serum lipids, hypertension, sedentary lifestyle, diabetes mellitus, obesity, and tobacco use. If a patient uses tobacco, estimate the number of pack-years of tobacco use (number of packs smoked per day multiplied by the number of years the patient has smoked). Document the patient's attitude about tobacco use and attempts and methods used to stop. Record any alcohol use. This information should include type of alcohol, amount, frequency, and any changes in the reaction to it. Also note any use of habit-forming drugs, including recreational drugs.

Question the patient about any allergies, including food and environmental allergies. Determine whether the patient has ever experienced a drug reaction or an allergic or anaphylactic reaction. Ask specifically about any allergic reaction to contrast media if there is a chance that a cardiac catheterization may be needed.

TABLE 32-2 CARDIOVASCULAR EFFECTS OF NONCARDIAC DRUGS*

Drug Classification	Examples	Cardiovascular Effects
Anticancer agents	daunorubicin (Cerubidine) doxorubicin (Adriamycin)	Dysrhythmias, cardiomyopathy
Antipsychotics	chlorpromazine (Thorazine) haloperidol (Haldol)	Dysrhythmias, orthostatic hypotension
Corticosteroids	cortisone (Cortone) prednisone (Orasone)	Hypotension, edema, potassium depletion
Hormone therapy, oral contraceptives	estrogen + progestin (Ortho-Novum, Prempro, Tri-Norinyl)	Myocardial infarction, thromboembolism, stroke, hypertension
Nonsteroidal antiinflammatory drugs (NSAIDs) †	ibuprofen (Motrin) celecoxib (Celebrex)	Hypertension, myocardial infarction, stroke
Psychostimulants	cocaine amphetamines	Tachycardia, angina, myocardial infarction, hypertension, dysrhythmias
Tricyclic antidepressants	amitriptyline (Elavil) doxepin (Sinequan)	Dysrhythmias, orthostatic hypotension

*List is not all-inclusive.
†Second-generation NSAIDs, known as COX-2 inhibitors, have been linked to an increased risk of serious adverse cardiovascular events.

GENETIC RISK ALERT

Coronary Artery Disease

- Specific genetic links, especially related to lipoprotein genes, have been identified for some families with CAD.
- The clustering of CAD in families is strong if there is early age of onset affecting several relatives.

Cardiomyopathy

- Hypertrophic cardiomyopathy can be caused by autosomal dominant mutations.
- Dilated cardiomyopathy can be caused by autosomal and X-linked dominant mutations.

Hypertension

- Hypertension results from a complex interplay between genetic and environmental factors.
- Lifestyle choices (e.g., smoking, lack of exercise) may trigger genetic tendencies to hypertension.

Confirmed illnesses of blood relatives can highlight any genetic or familial tendencies toward CAD, peripheral vascular disease, hypertension, bleeding, cardiac disorders, diabetes mellitus, atherosclerosis, and stroke. Note any family members who developed cardiac disease younger than age 55. In addition, disorders affecting the vascular system, such as intermittent claudication and varicosities, may be familial. Finally, assess any family health history of noncardiac problems such as asthma,

TABLE 32-3 HEALTH HISTORY

Cardiovascular System

Health Perception–Health Management
- Do you practice any preventive measures to decrease risk factors for heart disease?*
- Have you noticed an increase in heart symptoms such as chest pain or dyspnea?*
- Does your heart problem cause you to be less able to care for yourself?*
- Do you foresee any potential self-care problems because of your heart problem?*
- Have you ever used tobacco? If yes, in what form, how much, and for how long? Have you tried to quit? If yes, what methods have you tried? Are you interested in more information about quitting?
- How often and how much alcohol do you drink?

Nutritional-Metabolic
- Describe your usual daily diet, including salt, fat, and liquid intake.
- What is your present weight? What was your weight 1 year ago? If different, explain.
- Does eating cause fatigue or shortness of breath?*

Elimination
- Do your feet or ankles ever swell?* If yes, how far up your legs? Does it go away after sleeping all night?
- Have you ever taken medication to help you get rid of excess fluid or to relieve constipation?*
- Are you having any problems related to urination?*
- Do you ever strain to have a bowel movement?

Activity-Exercise
- Are your daily activities or exercise limited because of your heart problem?*
- When were you last able to comfortably perform your usual activities or exercise?
- Do you experience any discomfort or side effects as a result of exercise or any activity?*
- Can you comfortably walk and talk at the same time?
- How often do you attend activities outside your home?
- What was your most strenuous activity in the last few weeks compared with 6 months ago?

Sleep-Rest
- How many pillows do you sleep on at night? Has this changed recently?*
- Do you ever wake up suddenly and feel as if you cannot catch your breath?*
- Do you have a history of sleep apnea?*
- How many times a night do you awaken to urinate?

Cognitive-Perceptual
- Do you ever experience dizziness or fainting?*
- Do you ever find it difficult to verbally express yourself or to remember things?*
- Do you experience any pain (e.g., chest pain, leg pain with activity) as a result of your heart problem?*

Self-Perception–Self-Concept
- Have your perceptions of yourself changed since you were diagnosed with a heart disease?*
- How has your heart disease affected the quality of your life?

Role-Relationship
- Has this illness affected any of the roles that you play in your daily life?*
- How have your significant others been affected by your heart disease?

Sexuality-Reproductive
- Has your heart disease caused a change in your sexual activity?*
- Do you experience any heart-related symptoms during sexual activity?*
- Do any of your medications affect your ability to participate in sexual activities?*
- Females: Are you currently taking oral contraceptives, hormonal therapy, or drug therapy for breast cancer?

Coping–Stress Tolerance
- Describe your normal coping mechanisms during times of stress or anxiety.
- To whom or where would you turn during a time of stress? Are these people or services helping you now?*
- Do you practice any stress reduction techniques?*
- Do you have a history of depression?*
- Do you feel capable of handling your present health situation?
- Do you experience any heart symptoms (e.g., chest pain, palpitations) during times of stress or anger?*

Values-Beliefs
- What influence have your values or beliefs had during your illness?
- Do you feel any conflicts between your values or beliefs and the plan of care?*
- Describe any cultural or religious beliefs that may influence the management of your heart problem.

*If yes, describe.

renal disease, liver disease, and obesity because they can affect the cardiovascular system.

Nutritional-Metabolic Pattern. Being underweight or overweight may indicate potential cardiovascular problems. Thus it is important to assess the patient's weight history (e.g., over the past year) in relation to height. Determine the amount of salt and saturated fats in the patient's typical diet. In addition to actual food habits, which may be influenced by culture, investigate the patient's attitudes and plans relative to diet and weight management.

Elimination Pattern. The patient on diuretics may report increased voiding and/or nocturia. Investigate any history of incontinence or constipation, including any use of medications (prescribed and OTC) for constipation. Teach patients with cardiovascular problems to avoid straining during a bowel movement (Valsalva maneuver). Ask patients if they have any swelling of the lower extremities and if it resolves when their feet are elevated or after an overnight sleep.

Activity-Exercise Pattern. The benefit of exercise for cardiovascular health is clear, with aerobic exercise being most beneficial. Record the types of exercise done and the duration, intensity, and frequency of each. Ask about and note the occurrence of any symptoms during exercise (e.g., chest pain, shortness of breath, claudication) that may indicate a cardiovascular problem.

Sleep-Rest Pattern. Cardiovascular problems often disrupt sleep. *Paroxysmal nocturnal dyspnea* (attacks of shortness of breath, especially ones at night that awaken the patient) and Cheyne-Stokes respiration are associated with heart failure. Many patients with heart failure need to sleep with their head

elevated on pillows or in a chair. Note the number of pillows needed to sleep or the need to sleep upright *(orthopnea)* and whether this has changed recently.

Sleep apnea has been associated with an increased risk of life-threatening dysrhythmias, especially in patients with heart failure. Nocturia, a common finding with cardiovascular patients, also interrupts normal sleep patterns. Fully explore both conditions.

Cognitive-Perceptual Pattern. It is important to ask both the patient and the caregiver about cognitive-perceptual problems. Cardiovascular problems such as dysrhythmias, hypertension, and stroke may cause problems with syncope, language, and memory. Report any pain associated with the cardiovascular system (e.g., chest pain, claudication).

Self-Perception–Self-Concept Pattern. If a cardiovascular event is acute, the patient's self-perception may be affected. Invasive diagnostic procedures often lead to body image concerns for the patient. When CVD is chronic, the patient may not be able to identify the cause but can often describe the inability to "keep up" previous levels of activity. This may also affect the patient's quality of life, so inquire about the effects of the illness on the patient.

Role-Relationship Pattern. The patient's gender, race, and age are all related to cardiovascular health. In addition, the patient's marital status, role in the household, employment status, number of children and their ages, living environment, and caregivers help you to identify strengths and support systems in the patient's life. Assess the patient's level of satisfaction or dissatisfaction with life roles, since this may alert you to possible areas of stress or conflict.

Sexuality-Reproductive Pattern. Ask the patient about the effect of the cardiovascular problem on sexual activity. Because older patients often fear sudden death during sexual intercourse, it may lead to changes in their sexual behavior. Fatigue, chest pain, or shortness of breath may also limit sexual activity. Erectile dysfunction (ED) may be a symptom of peripheral vascular disease and/or a side effect of some medications used to treat CVD (e.g., β-adrenergic blockers [beta blockers], diuretics). Ask about the use of drugs for ED (e.g., sildenafil [Viagra]). These drugs are contraindicated if the patient is also taking a nitrate because the combination of ED drugs and nitrates can cause significant hypotension.[10] Determine whether counseling may be helpful.

Ask female patients if they use oral contraceptives, hormone therapy (HT) for symptoms of menopause, or drug therapy for breast cancer. Women who smoke and use oral contraceptives are at increased risk for blood clots (e.g., venous thromboembolism). Similarly, there is an increased risk for CVD with the use of HT and selective estrogen-receptor modulators (e.g., tamoxifen [Novaldex]).[11]

Coping–Stress Tolerance Pattern. Ask the patient to identify areas that cause stress and the usual methods of coping with stress. Potentially stressful areas include health concerns, marital relationships, family and friends, occupation, and finances.

Work-related stress, depression, and inadequate social support are risk factors for CVD and cardiac events.[4] Ask the patient about each of these factors. Information about support systems such as family, extended family and friends, counselors, or religious groups can provide vital insight when planning care.

Values-Belief Pattern. Individual values and beliefs, which are greatly affected by culture, may play a significant role in the real or potential conflict a patient faces when dealing with a diagnosis of CVD. Some patients may attribute their illness to punishment from God; others may think that a "higher power" may assist them. Information about a patient's values and beliefs will help you intervene during periods of crisis.

CASE STUDY—cont'd

Subjective Data

Jupiterimages/Banana-Stock/Thinkstock

A focused subjective assessment of L.P. revealed the following information:

- ***PMH:*** History of hypertension, mitral valve prolapse with mild regurgitation, heart failure, and type 2 diabetes mellitus.
- ***Medications:*** Lisinopril (Prinivil) 10 mg/day PO, metoprolol (Lopressor) 50 mg PO BID, ASA 325 mg/day PO, furosemide (Lasix) 40 mg/day PO, and glipizide (Glucotrol) 5 mg/day PO.
- ***Health Perception–Health Management:*** L.P. denies any previous history of chest pain or CAD. He was feeling fine until this morning when he awoke and experienced SOB, chest pain, palpitations, and dizziness while walking to the bathroom. He became frightened that he was having a heart attack so called 911. Denies smoking or alcohol intake. SOB and chest pain are now gone, but he continues to feel palpitations and dizziness when he sits up.
- ***Elimination:*** Denies any edema. States takes Lasix in the morning and typically "pees until lunchtime." Denies nocturia.

Objective Data

Physical Examination

Vital Signs. After you observe the patient's general appearance, obtain vital signs. Measure BP bilaterally. These readings normally vary from 5 to 15 mm Hg. Use the arm with the highest BP for subsequent BP measurements. Take orthostatic (postural) BPs and HRs while the patient is supine, sitting with legs dangling, and standing. SBP should not decrease more than 20 mm Hg from the supine to the standing position. HR should not increase more than 20 beats/minute from the supine to the standing position.

Peripheral Vascular System

Inspection. Inspect the skin for color, hair distribution, and venous pattern. Inspect the extremities for conditions such as edema, dependent rubor, clubbing of the nail beds, varicosities, and lesions such as stasis ulcers. Edema in the extremities can be caused by gravity, interruption of venous return, or right-sided heart failure.

Inspect the large veins in the neck (internal and external jugular) while the patient is gradually elevated from a supine position to an upright (30 to 45 degrees) position. Distention and prominent pulsations of these neck veins, referred to as *jugular venous distention,* can be caused by right-sided heart failure.

Palpation. Palpate the upper and lower extremities for temperature, moisture, pulses, and edema bilaterally to assess for symmetry. Look for edema by depressing the skin over the tibia or medial malleolus for 5 seconds. Normally, there is no depression after releasing pressure. If pitting edema is present, grade it from 1+ (mild pitting, slight brief indentation) to 4+ (very deep pitting, indentation that lasts a long time).[6]

Palpate the pulses in the neck and extremities for information on arterial blood flow. Assess the rhythm (e.g., regular, irregular) and force. It is important to palpate each carotid pulse separately to avoid vagal stimulation and possible dysrhyth-

mias. Compare the characteristics of the arteries on the right and left extremities simultaneously to determine symmetry.

When palpating the arteries identified in Fig. 32-6, rate the force of the pulse using the following scale[6]:

0 = Absent
1+ = Weak
2+ = Normal
3+ = Increased, full, bounding

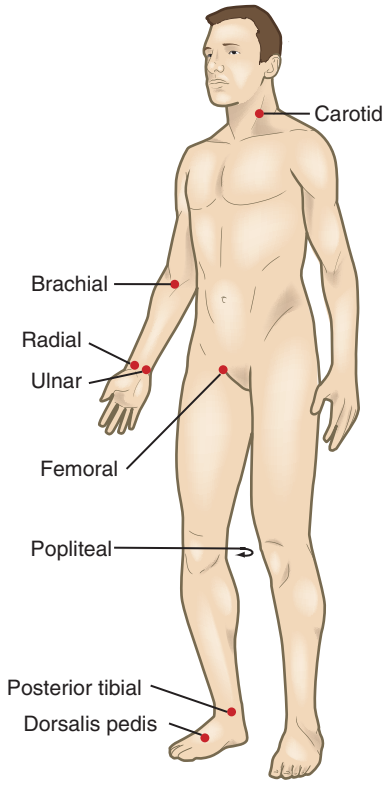

FIG. 32-6 Common sites for palpating arteries.

The rigidity (hardness) of the vessel should also be noted. The normal pulse feels like a tap, whereas a vessel wall that is narrowed or bulging vibrates. The term for a palpable vibration is *thrill.*

Capillary refill is used to assess arterial flow to the extremities. Position the patient's hands near the level of the heart and squeeze a nail bed to produce blanching. Observe for the return of color. This should occur in less than 2 seconds with normal peripheral perfusion and CO.

Auscultation. An artery that is narrowed or has a bulging wall may create turbulent blood flow. This abnormal flow can create a buzzing or humming termed a *bruit.* This is heard with a stethoscope placed over the vessel. Auscultation of major arteries such as the carotid arteries, abdominal aorta, and femoral arteries should be part of the initial cardiovascular assessment. Abnormalities of the cardiovascular system are described in Table 32-4.

Thorax

Inspection and Palpation. An overall inspection and palpation of the bony structures of the thorax are the initial steps in the examination. Next, inspect and palpate the areas where the cardiac valves project their sounds by identifying the intercostal spaces (ICSs). The raised notch, the *angle of Louis,* is where the manubrium and the body of the sternum are joined, and is located at the level of the second rib. It is palpable in the midline of the sternum. It is used to count ICSs and locate specific auscultatory areas (Fig. 32-7).

Locate the following auscultatory areas: the aortic area in the second ICS to the right of the sternum, the pulmonic area in the second ICS to the left of the sternum, the tricuspid area in the fifth left ICS close to the sternum, and the mitral area in the left midclavicular line at the fifth ICS. A fifth auscultatory area is *Erb's point,* located at the third left ICS near the sternum. Normally, no pulsations are felt in these areas unless the patient has a thin chest wall.

A valvular disorder may be suspected if abnormal pulsations or thrills are felt. Next, inspect and palpate the epigastric area, which lies on either side of the midline just below the xiphoid

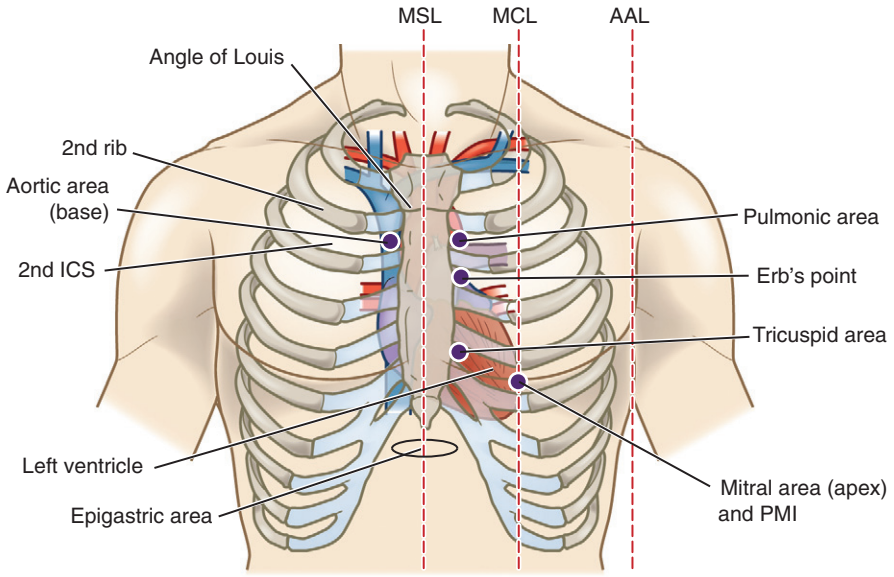

FIG. 32-7 Orientation of the heart within the thorax and cardiac auscultatory areas. *Red lines* indicate the midsternal line *(MSL),* midclavicular line *(MCL),* and anterior axillary line *(AAL). ICS,* Intercostal space; *PMI,* point of maximal impulse.

TABLE 32-4 ASSESSMENT ABNORMALITIES

Cardiovascular System

Finding*	Description	Possible Etiology* and Significance
Inspection		
Jugular venous distention	Distended neck (jugular) veins with patient sitting at 30- to 45-degree angle	Elevated right atrial pressure, right-sided heart failure
Central cyanosis	Bluish or purplish tinge in central areas such as tongue, conjunctivae, inner surface of lips	Inadequate O_2 saturation of arterial blood because of pulmonary or cardiac disorders (e.g., congenital defects)
Peripheral cyanosis	Bluish or purplish tinge in extremities or in nose and ears	Reduced blood flow because of heart failure, vasoconstriction, cold environment
Splinter hemorrhages	Small red to black streaks under fingernails	Infective endocarditis (infection of endocardium, usually in area of cardiac valves)
Clubbing of nail beds	Obliteration of normal angle between base of nail and skin	Endocarditis, congenital defects, prolonged O_2 deficiency
Color changes in extremities with postural change	Pallor, cyanosis, mottling of skin after limb elevation. Dependent rubor (reddish blue discoloration). Glossy skin	Chronic decreased arterial perfusion
Ulcers	*Venous:* Necrotic crater-like lesion usually found on lower leg at medial malleolus. Characterized by slow wound healing *Arterial:* Pale ischemic base, well-defined edges usually found on toes, heels, lateral malleoli	Poor venous return, varicose veins, incompetent venous valves. Arteriosclerosis, diabetes
Varicose veins	Visible dilated, discolored, tortuous vessels in lower extremities	Incompetent valves in vein
Palpation		
Pulse		
Bounding	Sharp, brisk, pounding pulse	Hyperkinetic states (e.g., anxiety, fever), anemia, hyperthyroidism
Thready	Weak, slowly rising pulse easily obliterated by pressure	Blood loss, decreased cardiac output, aortic valve disease, peripheral arterial disease
Irregular	Regularly irregular or irregularly irregular. Skipped beats	Cardiac dysrhythmias
Pulsus alternans	Regular rhythm, but strength of pulse varies with each beat	Heart failure, cardiac tamponade
Absent	Lack of pulse	Atherosclerosis, trauma, embolus
Thrill	Vibration of vessel or chest wall	Aneurysm, aortic regurgitation, arteriovenous fistula
Rigidity	Stiffness or inflexibility of vessel wall	Atherosclerosis
>100 beats/min	Tachycardia	Exercise, anxiety, shock, need for increased cardiac output, hyperthyroidism
<60 beats/min	Bradycardia	Rest or sleeping, SA or AV node damage, athletic conditioning, side effect of drugs (e.g., β-adrenergic blockers), hypothyroidism
Displaced point of maximal impulse (apical pulse)	Point of maximal impulse is palpated (or auscultated) below the fifth ICS and to the left of the MCL	Cardiac enlargement as a result of coronary artery disease, heart failure, cardiomyopathy
Extremities		
Unusually warm extremities	Hands and feet warmer than normal	Possible thyrotoxicosis
Cold extremities	Hands and/or feet cold to touch. External covering necessary for comfort	Intermittent claudication, peripheral arterial disease, low cardiac output, severe anemia
Pitting edema of lower extremities or sacral area	Visible finger indentation after application of firm pressure, weight gain, tightening of clothing, including shoes, marks or indentations from constricting garments	Interruption of venous return to heart, right-sided heart failure
Abnormal capillary refill	Blanching of nail bed for ≥2 sec after release of pressure	Possible reduced arterial capillary perfusion, anemia
Asymmetry in limb circumference	Measurable swelling of involved limb	Venous thromboembolism, varicose veins, lymphedema
Auscultation		
Pulse deficit	Apical heart rate exceeding peripheral pulse rate	Cardiac dysrhythmias, most often atrial fibrillation/flutter or premature ventricular contractions
Arterial bruit	Turbulent flow sound in peripheral artery	Arterial obstruction or aneurysm
Third heart sound (S_3)	Extra heart sound, low pitched, heard in early diastole. Similar to sound of a gallop	Left ventricular failure. Volume overload. Mitral, aortic, or tricuspid regurgitation. Hypertension (possible)
Fourth heart sound (S_4)	Extra heart sound, low pitched, heard in late diastole. Similar to sound of a gallop	Forceful atrial contraction from resistance to ventricular filling (e.g., in left ventricular hypertrophy, aortic stenosis, hypertension, coronary artery disease)
Cardiac murmurs	Turbulent sounds occurring between normal heart sounds. Characterized by loudness, pitch, shape, quality, duration, timing	Cardiac valve disorder, abnormal blood flow patterns
Pericardial friction rub	High-pitched, scratchy sound heard during S_1 and/or S_2 at the apex. Heard best with patient sitting and leaning forward, and at the end of expiration	Pericarditis

*Limited to common assessment findings and etiologic factors. (Further discussion of conditions listed may be found in Chapters 33 to 38, 66, and 67.)

process. In a thin person, you may see the pulsation of the abdominal aorta. Normally, you can palpate it here. Next, inspect the precordium, which is located over the heart, for heaves. **Heaves** are sustained lifts of the chest wall in the precordial area that can be seen or palpated. They may be caused by left ventricular hypertrophy. Normally no pulsations are seen or felt here.

When the patient is supine, palpate the mitral valve area for the **point of maximal impulse (PMI)** (also called the *apical pulse*). This reflects the pulsation of the apex of the heart. The PMI lies medial to the midclavicular line in the fourth or fifth ICS. If the PMI is palpable, record its position in relation to the midclavicular line and ICSs. When the PMI is below the fifth ICS and left of the midclavicular line, the heart may be enlarged.

Auscultation. Normal heart sounds are produced by the movement of blood through the cardiac valves. These sounds can be heard through a stethoscope placed on the chest wall. The first heart sound (S_1) is associated with closure of the tricuspid and mitral valves. It has a soft lubb sound. The second heart sound (S_2) is associated with closure of the aortic and pulmonic valves. It has a sharp dupp sound. S_1 signals the beginning of systole. S_2 signals the beginning of diastole (Fig. 32-8). Listen to the auscultatory areas in sequence (see Fig. 32-7).

S_1 and S_2 are heard best with the diaphragm of the stethoscope because they are high pitched. Extra heart sounds (S_3 or S_4), if present, are heard best with the bell of the stethoscope because they are low pitched. Have the patient lean forward while sitting to enhance the sounds from the second ICSs (aortic and pulmonic areas). Place the patient in a left side-lying position to enhance the sounds at the mitral area.

When auscultating the apical area, simultaneously palpate the radial pulse. Determine whether the rhythm is regular or irregular while listening and feeling. If the apical and radial pulses are not equivalent, count the apical pulse while a second person simultaneously counts the radial pulse for 1 full minute. The difference between the two numbers is called a *pulse deficit* and can indicate cardiac dysrhythmias.

Normally no sound is heard between S_1 and S_2 during the periods of systole and diastole. Sounds that are heard during these periods may represent abnormalities and should be described. An exception to this is a normal splitting of S_2, which is best heard at the pulmonic area during inspiration. Splitting of this heart sound can be abnormal if it is heard during expiration or if it is constant (fixed) during the respiratory cycle.

The S_3 heart sound is a low-intensity vibration of the ventricular walls usually associated with decreased compliance of the ventricles during filling. An S_3 heart sound may be normal (physiologic) in young adults. It is pathologic in patients with left-sided heart failure or mitral valve regurgitation. S_3 is heard closely after S_2 and is known as a *ventricular gallop*. The S_4 heart sound is a low-frequency vibration caused by atrial contraction. It precedes S_1 of the next cycle, and is known as an *atrial gallop*. An S_4 heart sound may be normal in older adults with no evidence of heart disease. It is pathologic in patients with CAD, cardiomyopathy, left ventricular hypertrophy, or aortic stenosis.[6]

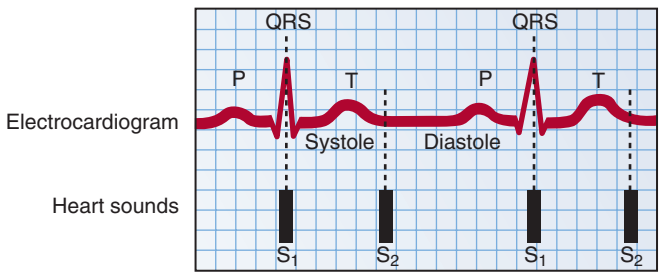

FIG. 32-8 Relationship of electrocardiogram, cardiac cycle, and heart sounds.

CASE STUDY—cont'd

Objective Data: Physical Examination

Jupiterimages/Banana-Stock/Thinkstock

Physical examination findings of L.P. are as follows:

- BP 98/70, apical pulse 164, pulse irregular, respiratory rate 20, temperature 98.2°F (36.8°C), O_2 saturation 93% on room air
- Awake, alert, and oriented ×3
- Lungs clear on auscultation; systolic murmur present
- Cardiac monitor shows atrial fibrillation with a rapid ventricular response
- +1 pedal pulses bilaterally
- No peripheral edema, jugular venous distention, or heaves noted

As you continue reading this chapter, consider diagnostic studies you would anticipate being ordered for L.P.

Murmurs, produced by turbulent blood flow across diseased heart valves, are graded on a six-point Roman numeral scale of loudness and recorded as a ratio. I/VI indicates a murmur that is barely audible with the stethoscope, heard only in a quiet room and then not easily. VI/VI indicates a murmur that can be heard with the stethoscope lifted just off the chest wall.[6]

Pericardial friction rubs are sounds caused by friction that occurs when inflamed surfaces of the pericardium (pericarditis) move against each other. They are high-pitched, scratchy sounds that may be transient or intermittent and may last several hours to days. Friction rubs are usually heard best at the apex, with the patient upright and leaning forward, and following expiration.[6]

Document any abnormal sounds. This includes the timing (during systole or diastole), location (the anatomic site on the chest where it is heard the loudest), position (heard best when the patient is supine, sitting and leaning forward, or in the left side-lying position), and any other abnormal findings (irregular apical pulse or palpable chest wall heaves) associated with the sound.

Abnormal assessment findings are described in Table 32-4. A method of recording data from the cardiovascular assessment is presented in Table 32-5.

TABLE 32-5 NORMAL PHYSICAL ASSESSMENT OF CARDIOVASCULAR SYSTEM

Inspection	Skin warm, normal color. Capillary refill <2 sec. PMI not visible. No JVD with patient at 45-degree angle.
Palpation	PMI palpable in fourth ICS at left MCL. No thrills or heaves. Slight palpable pulsations of abdominal aorta in epigastric area. Carotid and extremity pulses 2+ and equal bilaterally. No pedal edema.
Auscultation	S_1 and S_2 heard. Apical-radial pulse rate equal, 72, and regular. No murmurs or extra heart sounds.

ICS, Intercostal space; *JVD,* jugular venous distention; *MCL,* midclavicular line; *PMI,* point of maximal impulse.

FOCUSED ASSESSMENT

Cardiovascular System

Use this checklist to make certain the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Chest pain	Y	N
Palpitations	Y	N
Shortness of breath (especially when lying down or at rest)	Y	N
Edema in legs or any part of body	Y	N
Leg pain during exercise	Y	N
Excess urination at night	Y	N

Objective: Diagnostic

Check the following for critical values or changes.

Cardiac biomarkers (troponin, CK-MB)	✓
Hematocrit and hemoglobin	✓
Electrocardiogram	✓

Objective: Physical Examination

Inspect and Palpate

Anterior chest wall for pulsations and heaves	✓
Pulses for symmetry, quality, and rhythm	✓

Auscultate

Blood pressure	✓
Heart for rate, rhythm, and sounds	✓

CK-MB, Creatine kinase–MB.

A *focused assessment* is used to evaluate the status of previously identified cardiovascular problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the cardiovascular system is presented in the box above.

DIAGNOSTIC STUDIES OF CARDIOVASCULAR SYSTEM

Numerous diagnostic studies are available to assess the cardiovascular system. Table 32-6 identifies the most common studies. Select studies are described in more detail below.

Blood Studies

Many blood studies provide information about the cardiovascular system. For example, some reflect the O_2-carrying capacity (red blood cell count and hemoglobin) and coagulation properties (clotting times) of the blood. (See Chapter 30 and Tables 30-6 and 30-7 for hematology studies.)

Cardiac Biomarkers. When cells are injured, they release their contents, including enzymes and other proteins, into the circulation. These *biomarkers* are useful in the diagnosis of myocardial injury and infarction.

Cardiac-specific troponin is a myocardial muscle protein released into circulation after injury or infarction. Two subtypes, cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI), are specific to myocardial tissue. Normally the level in the blood is very low, so a rise in level is diagnostic of myocardial injury. cTnT and cTnI are detectable within hours (on average 4 to 6 hours) of myocardial injury, peak at 10 to 24 hours, and can be detected for up to 10 to 14 days (see Fig. 34-11). Troponin is the biomarker of choice in the diagnosis of myocardial infarction (MI). Recent development of high-sensitivity troponin (hs-cTnT, hs-cTnI) assays may provide even earlier detection of a cardiac event.[12]

Creatine kinase (CK) enzymes are found in a variety of organs and tissues and occur as three isozymes. These isozymes are specific to skeletal muscle (CK-MM), brain and nervous tissue (CK-BB), and the heart (CK-MB). CK-MB elevation is specific for myocardial injury or infarction. CK-MB levels begin to rise 3 to 6 hours after symptom onset, peak in 12 to 24 hours, and return to baseline within 12 to 48 hours after MI.[13] The peak level and return to normal can be delayed in a person who has had a large MI. Levels drop more rapidly in patients who are quickly and successfully treated for an MI. (Fig. 34-11 depicts the changes in cardiac markers related to an MI.)

Myoglobin is a low-molecular-weight heme protein found in cardiac and skeletal muscle. Myoglobin elevation is a sensitive indicator of very early myocardial injury but lacks specificity for MI. Its usefulness in diagnosing MI is limited.[13]

Correct interpretation of diagnostic tests requires consideration of the time from onset of symptoms and the time of the expected presence and elevation of the biomarkers. Additional data (patient symptoms, history, and ECG changes) complete the diagnostic picture for the patient with suspected myocardial injury or MI.

C-Reactive Protein. C-reactive protein (CRP) is a protein produced by the liver during periods of acute inflammation. CRP can be measured using a high-sensitivity test (hs-CRP). An increased level of CRP is an independent risk factor for CAD. The level of CRP may also predict the risk for future cardiac events in patients with unstable angina and MI, but studies have produced conflicting results.[14]

Homocysteine. Homocysteine (Hcy) is an amino acid that is produced during protein catabolism. Elevated Hcy levels can be either hereditary or acquired from dietary deficiencies of vitamin B_6, vitamin B_{12}, or folate. Elevated levels of Hcy have been linked to a higher risk of CAD, peripheral vascular disease, and stroke. It is recommended that Hcy testing be performed in those patients with a familial predisposition for early CVD or a history of CVD in the absence of other common risk factors.[15]

Cardiac Natriuretic Peptide Markers. There are three natriuretic peptides: (1) atrial natriuretic peptide (ANP) from the atrium, (2) b-type natriuretic peptide (BNP) from the ventricles, and (3) c-type natriuretic peptide from endothelial and renal epithelial cells. BNP is the marker of choice for distinguishing a cardiac or respiratory cause of dyspnea. N-terminal pro-brain natriuretic peptide (NT-pro-BNP) is also secreted in the ventricles and is more sensitive but less specific than BNP as a diagnostic marker of heart failure.[13] When diastolic blood pressure increases (e.g., heart failure), BNP and NT-pro-BNP are released and increase natriuresis (excretion of sodium in the urine). (ANP and BNP are also discussed in Chapter 33 on p. 711 and in Chapter 35 on p. 768.)

Serum Lipids. Serum lipids consist of triglycerides, cholesterol, and phospholipids. They circulate in the blood bound to protein. Thus they are often referred to as *lipoproteins.* (Types of serum lipids are depicted in eFig. 32-1, available on the website for this chapter.)

Triglycerides are the main storage form of lipids and make up about 95% of fatty tissue. Cholesterol, a structural component of cell membranes and plasma lipoproteins, is a precursor

of corticosteroids, sex hormones, and bile salts. In addition to being absorbed from food in the gastrointestinal tract, cholesterol can also be synthesized in the liver. Phospholipids contain glycerol, fatty acids, phosphates, and a nitrogenous compound. Although formed in most cells, phospholipids usually enter the circulation as lipoproteins synthesized by the liver. Apoproteins are water-soluble proteins that combine with most lipids to form lipoproteins.

Different classes of lipoproteins contain varying amounts of the naturally occurring lipids. These include the following:

1. *Chylomicrons:* primarily exogenous triglycerides from dietary fat
2. *Low-density lipoproteins (LDLs):* mostly cholesterol with moderate amounts of phospholipids
3. *High-density lipoproteins (HDLs):* about 50% protein and 50% phospholipids and cholesterol
4. *Very-low-density lipoproteins (VLDLs):* primarily endogenous triglycerides with moderate amounts of phospholipids and cholesterol

Text continued on p. 704

TABLE 32-6 DIAGNOSTIC STUDIES

Cardiovascular System

Study	Description and Purpose	Nursing Responsibility
Blood Studies*		
Troponin (cardiac)	Contractile proteins that are released after an MI. Both troponin T and troponin I are highly specific to cardiac tissue. *Reference intervals:* ***Troponin I (cTnI)*** Negative: <0.5 ng/mL (<0.5 mcg/L) Indeterminate or suspicious for injury to myocardium: 0.5-2.3 ng/mL (0.5-2.3 mcg/L) Positive for myocardial injury: >2.3 ng/mL (>2.3 mcg/L) ***Troponin T (cTnT)*** <0.1 ng/mL (<0.1 mcg/L)	Rapid point-of-care (bedside) assays are available. Explain to patient the purpose of serial sampling (e.g., q6-8hr × 3) in conjunction with CK-MB and serial ECGs.
CK-MB	Cardiospecific isozyme that is released in the presence of myocardial tissue injury. Concentrations >4%-6% of total creatine kinase (CK) are highly indicative of MI. Serum levels increase within 4-6 hr after MI.	Serial sampling often done in conjunction with troponin and ECGs.
Myoglobin	Low-molecular-weight protein that is 99%-100% sensitive for myocardial injury. Serum concentrations rise 30-60 min after MI. *Reference interval:* *Male:* 15.2-91.2 mcg/L *Female:* 11.1-57.5 mcg/L	Cleared from the circulation rapidly, limited use in the diagnosis of cardiac injury/infarction.
C-reactive protein (CRP)	Marker of inflammation that can predict risk of cardiac disease and cardiac events, even in patients with normal lipid values. High-sensitivity (hs) CRP assay used. *Lowest risk:* <1 mg/L *Moderate risk:* 1-3 mg/L *High risk:* >3 mg/L	Stable levels that can be measured nonfasting and any time during the day. May be more predictive risk factor of cardiovascular disease than LDLs for women. The average of two assays obtained 2 wk apart provides a more stable measurement than one single measurement.
Homocysteine	Amino acid produced during protein catabolism that has been identified as a risk factor for cardiovascular disease. Homocysteine may cause damage to the endothelium or have a role in formation of thrombi. *Reference interval:* *Male:* 5.2-12.9 μmol/L *Female:* 3.7-10.4 μmol/L	Hyperhomocysteinemia resulting from dietary deficiencies is treated with folic acid, vitamin B_6, and vitamin B_{12} supplements.
b-Type natriuretic peptide (BNP)	Peptide that causes natriuresis. Elevation helps to distinguish cardiac vs. respiratory cause of dyspnea. *Reference interval:* *BNP* (diagnostic for heart failure) >100 pg/mL (28.8 pmol/L)	Infusion of nesiritide (Natrecor) elevates levels temporarily.
NT-Pro-BNP	Aids in assessing the severity of heart failure in symptomatic and asymptomatic patients. *Reference interval:* *≤74 yr:* 124 pg/mL *>75 yr:* 449 pg/mL	In patients with renal insufficiency, NT-pro-BNP concentrations may increase and may not correlate with New York Heart Association functional classification of heart failure.
Serum Lipids		
Cholesterol	A blood lipid. Elevated cholesterol is considered a risk factor for cardiovascular heart disease. *Reference interval:* <200 mg/dL (<5.18 mmol/L) (varies with age and gender)	Cholesterol levels can be obtained in a nonfasting state.

*Reference ranges for the laboratory tests vary by institution because of differences in equipment and reagents used.

Continued

TABLE 32-6 DIAGNOSTIC STUDIES—cont'd

Cardiovascular System

Study	Description and Purpose	Nursing Responsibility
Serum Lipids—cont'd		
Triglycerides	Mixtures of fatty acids. Elevations are associated with cardiovascular disease and diabetes. *Reference interval:* <150 mg/dL (<1.7 mmol/L) (varies with age)	Triglyceride and lipoprotein levels must be obtained in a fasting state (at least 12 hr, except for water). Alcohol should be withheld for 24 hr before testing.
Lipoproteins† (HDL, LDL)	Electrophoresis is done to separate lipoproteins into HDL and LDL. There are marked day-to-day fluctuations in serum lipid levels. More than one determination is needed for accurate diagnosis and treatment. *Reference intervals* (vary with age): **HDL** *Recommended* *Male:* >40 mg/dL (>1.04 mmol/L) *Female:* >50 mg/dL (>1.3 mmol/L) *Low risk for CAD:* ≥60 mg/dL (>1.55 mmol/L) *High risk for CAD:* <40 mg/dL (<1.04 mmol/L) **LDL** *Recommended:* <100 mg/dL (<2.6 mmol/L) *Near optimal:* 100-129 mg/dL (2.6-3.34 mmol/L) *Moderate risk for CAD:* 130-159 mg/dL (3.37-4.12 mmol/L) *High risk for CAD:* >160 mg/dL (>4.14 mmol/L)	Risk for cardiac disease is assessed by dividing the total cholesterol level by the HDL level and obtaining a ratio. *Low risk:* Ratio <3 *Average risk:* Ratio 3-5 *Increased risk:* Ratio >5
Lipoprotein (a) [Lp(a)]	Increased levels are associated with an increased risk of premature CAD and stroke. *Reference interval:* <30 mg/dL (<0.3 g/L)	Lp(a) levels can be obtained in a nonfasting state.
Lipoprotein-associated phospholipase A_2 (Lp-PLA_2)	Elevated levels of Lp-PLA_2 are associated with vascular inflammation and increased risk for CAD. Serum levels of Lp-PLA_2 are measured by the PLAC test. *Reference interval:* *Male:* 131-376 ng/mL *Female:* 120-342 ng/mL	Lp-PLA_2 levels can be obtained in a nonfasting state.
Chest X-Ray	Patient is placed in two upright positions to examine the lung fields and heart size. The two common positions are posteroanterior (PA) and lateral. Normal heart size and contour for the individual's age, sex, and size are noted.	Inquire about frequency of recent x-rays and possibility of pregnancy. Provide lead shielding to areas not being viewed. Remove any jewelry or metal objects that may obstruct the view of the heart and lungs.
12-Lead ECG	Electrodes are placed on the chest and extremities, allowing the ECG machine to record cardiac electrical activity from 12 different views. A resting 12-lead ECG can identify conduction problems, dysrhythmias, position of heart, cardiac hypertrophy, pericarditis, myocardial ischemia or infarction, pacemaker activity, and effectiveness of drug therapy at one point in time.	Prepare skin and apply electrodes and leads. Position patient supine (or with head of bed elevated, if short of breath). Inform patient that no discomfort is involved and to lie still to decrease motion artifact.
Signal-averaged ECG (SAECG)	A high-resolution ECG that can identify electrical activity called late potentials, indicating a patient is at risk for developing ventricular dysrhythmias (e.g., ventricular tachycardia).	Same as for 12-lead ECG.
Ambulatory ECG Monitoring		
Holter monitoring	Recording of ECG rhythm for 24-48 hr and then correlating rhythm changes with symptoms and activities recorded in diary. Normal patient activity is encouraged to simulate conditions that produce symptoms. Electrodes are placed on chest, and a recorder is used to store information until it is recalled, printed, and analyzed for any rhythm disturbance. It can be performed on an inpatient or outpatient basis.	Prepare skin and apply electrodes and leads. Explain importance of keeping an accurate diary of activities and symptoms. Tell patient that no bath or shower can be taken during monitoring. Skin irritation may develop from electrodes.
Event monitor or loop recorder	Records rhythm disturbances that are not frequent enough to be recorded in one 24-hr period. It allows more freedom than a regular Holter monitor. Some units have electrodes that are attached to the chest and have a loop of memory that captures the onset and end of an event. Other types are placed directly on patient's wrist, chest, or fingers and have no loop of memory, but record the patient's ECG in real time. Recordings may be transmitted over the phone to a receiving unit.	Instruct in the use of equipment for recording and transmitting (if appropriate) of transient events. Teach patient about skin preparation for lead placement or steady skin contact for units not requiring electrodes. This will ensure the reception of optimal ECG tracings for analysis. Instruct patient to initiate recording as soon as symptoms begin or as soon thereafter as possible.

TABLE 32-6 DIAGNOSTIC STUDIES—cont'd

Cardiovascular System

Study	Description and Purpose	Nursing Responsibility
Exercise or Stress Testing	Various protocols are used to evaluate the effect of exercise tolerance on cardiovascular function. A common protocol uses 3-min stages at set speeds and elevation of the treadmill belt. The patient can exercise to either predicted peak HR (calculated by subtracting the person's age from 220) or to peak exercise tolerance, at which time the test is terminated. The test is also terminated for chest discomfort, significant increase or decrease in vital signs from baseline, or significant ECG changes indicating cardiac ischemia. Vital signs and ECG are monitored. The ECG is monitored after exercise for rhythm disturbances or, if ECG changes occurred with exercise, for return to baseline. Continual monitoring of vital signs and ECG rhythms for ischemic changes is important in the diagnosis of CAD. An exercise bike may be used if the patient is unable to walk on the treadmill.	Instruct patient to wear comfortable clothes and shoes that can be used for walking and running. Instruct patient about procedure and importance of reporting any symptoms that occur. Monitor vital signs and obtain 12-lead ECG before exercise, during each stage of exercise, and after exercise until all vital signs and ECG changes have returned to normal. Monitor patient's response throughout procedure. Contraindications include any reasons patient is unable to reach peak exercise tolerance. β-Adrenergic blockers may be held 24 hr before the test because they blunt the HR and limit the patient's ability to achieve maximal HR. Caffeine-containing food and fluids are held for 24 hr. Patients must refrain from smoking and strenuous exercise for 3 hr before test.
6-Minute walk test	Distance patient is able to walk on a flat surface in 6 min. Used to measure response to treatments and determine functional capacity for activities of daily living. Useful in people who are unable to perform treadmill or exercise bike testing. May be a better measure of fitness for older adults than exercise testing.	Instruct patient to wear comfortable shoes. Inform patient to carry or pull oxygen if used routinely. Encourage patient to walk as quickly as possible.
Echocardiogram • Contrast • M-mode • Two-dimensional • Color-flow imaging (duplex) • Real-time three-dimensional	Transducer that emits and receives ultrasound waves is placed in four positions on the chest above the heart. Transducer records sound waves that are bounced off the heart. Also records direction and flow of blood through the heart and transforms it to audio and graphic data that measure valvular abnormalities, congenital cardiac defects, wall motion, EF, and cardiac function. IV contrast agent may be used to enhance images.	Place patient in a left side-lying position facing equipment. Instruct patient about procedure and sensations (pressure and mechanical movement from head of transducer). No contraindications to procedure exist.
Stress echocardiogram	Combination of exercise test and echocardiogram. Resting images of the heart are taken with ultrasound, and then the patient exercises. Postexercise images are taken within 1 min of stopping exercise. Differences in left ventricular wall motion and thickening before and after exercise are evaluated.	Instruct and prepare patient for treadmill or exercise bicycle. Inform patient of importance of timely return to examination table for imaging after exercise. Contraindications include any reasons patient is unable to reach peak exercise tolerance.
Pharmacologic echocardiogram	Used as a substitute for the exercise stress test in individuals unable to exercise. IV dobutamine or dipyridamole is infused, and dosage is increased in 5-min intervals while echocardiogram is performed to detect wall motion abnormalities at each stage.	Start IV infusion. Administer medication per protocol. Monitor vital signs before, during, and after test until baseline achieved. Monitor patient for signs and symptoms of distress during procedure. Observe patient for side effects (e.g., shortness of breath, dizziness, nausea). Aminophylline may be given to prevent or reverse side effects of dipyridamole. Contraindications include any known allergies to medications.
Transesophageal echocardiogram (TEE)	A probe with an ultrasound transducer at the tip is swallowed while the physician controls angle and depth. As it passes down the esophagus, it sends back clear images of heart size, wall motion, valvular abnormalities, endocarditis vegetation, and possible source of thrombi without interference from lungs or chest ribs. A contrast medium may be injected IV for evaluating direction of blood flow if an atrial or ventricular septal defect is suspected. Doppler ultrasound and color-flow imaging can also be used concurrently.	Instruct patient to be NPO for at least 6 hr before test. Remove dentures. IV sedation is administered and throat locally anesthetized. A bite block is placed in the mouth. A designated driver is needed if done in the outpatient department. Monitor vital signs and oxygen saturation levels and perform suctioning as needed during procedure. Assist patient to relax. Patient may not eat or drink until gag reflex returns. Sore throat is temporary.
Nuclear Cardiology	Study involves IV injection of radioactive isotopes (^{99m}technetium-sestamibi [Cardiolite]). Radioactive uptake is counted over the heart by scintillation camera. It supplies information about myocardial contractility, myocardial perfusion, and acute cell injury.	Explain procedure to patient. Women should not wear bras to decrease breast attenuation. Establish IV line for injection of isotopes. Explain that radioactive isotope used is a small, diagnostic amount and will lose most of its radioactivity in a few hours. Inform the patient that he or she will be lying still on back with arms extended overhead for 20 min. Repeat scans are performed within a few minutes to hours after the injection.

Continued

TABLE 32-6 DIAGNOSTIC STUDIES—cont'd

Cardiovascular System

Study	Description and Purpose	Nursing Responsibility
Multigated acquisition (MUGA) (cardiac blood pool) scan	A small amount of the patient's blood is removed, mixed with a radioactive isotope (e.g., ^{99m}technetium-sestamibi), and reinjected IV. With the ECG used for timing, images are acquired during the cardiac cycle. Indicated for patients with MI, heart failure, or valvular heart disease. Can be used to evaluate the effect of various cardiac or cardiotoxic medications on the heart.	Explain procedure to patient. Establish IV line for removal of blood sample and reinjection of isotope. Establish ECG monitoring. Inform patient that procedure involves little risk.
Single-photon emission computed tomography (SPECT)	Used to determine size or risk of infarction and to determine infarction size. Small amounts of a radioactive isotope (e.g., ^{99m}technetium-tetrofosmin [Myoview], thallium-201) are injected IV and recordings are made of the radioactivity emitted over a specific area of the body. Circulation of the isotope can be used to detect coronary artery blood flow, intracardiac shunts, motion of ventricles, EF, and size of the heart chambers.	Explain procedure to patient. Establish IV line for injection of isotope. Establish ECG monitoring. Inform patient that procedure involves little risk.
Exercise (stress) nuclear imaging	Nuclear imaging images are taken at rest and after exercise. The injection is given at maximum HR (usually 85% of age-predicted maximum) on bicycle or treadmill. Patient is then required to continue exercise for 1 min to circulate the radioactive isotope. Scanning is done 15-60 min after exercise. A resting scan is performed 60-90 min after initial infusion or 24 hr later.	Explain procedure to patient. Instruct patient to eat only a light meal between scans. Certain medications may need to be held for 1-2 days before the scan. Patients should not have caffeine 12 hr prior. If targeted maximum HR is not achieved with exercise, test may be changed to pharmacologic imaging.
Pharmacologic nuclear imaging	Dipyridamole or adenosine is used to produce vasodilation when patients are unable to tolerate exercise. Vasodilation increases blood flow to well-perfused coronary arteries. Scanning procedure is same. Aminophylline may be given to prevent or reverse side effects of dipyridamole (e.g., shortness of breath, dizziness, nausea). Dobutamine is used if vasodilators are contraindicated.	Explain procedure to patient. Instruct patient to hold all caffeine products for 12 hr before procedure. Calcium channel blockers and β-adrenergic blockers should be held 24 hr before the test. Observe patient for side effects (e.g., shortness of breath, dizziness, nausea).
Positron emission tomography (PET)	Highly sensitive in distinguishing viable and nonviable myocardial tissue. Uses two radionuclides. Nitrogen-13-ammonia is injected IV first and scanned to evaluate myocardial perfusion. A second radioactive isotope, fluoro-18-deoxyglucose, is then injected and scanned to show myocardial metabolic function. In the normal heart, both scans match, but in an ischemic or damaged heart, they differ. The patient may or may not be stressed. A baseline resting scan is usually obtained for comparison.	Instruct patient on procedure. Explain that patient will be scanned by a machine and will need to stay still for a time. Patient's glucose level must be between 60-140 mg/dL (3.3-7.8 μmol/L) for accurate glucose metabolic activity. If exercise is included as part of testing, patient needs to be NPO and refrain from tobacco and caffeine for 24 hr before test.
Cardiovascular Magnetic Resonance Imaging (CMRI)	Noninvasive imaging technique obtains information about cardiac tissue integrity, aneurysms, EF, cardiac output, and patency of proximal coronary arteries. It does not involve ionizing radiation and is an extremely safe procedure. It provides images in multiple planes with uniformly good resolution.	Explain procedure to patient. Inform patient that the small diameter of the cylinder, along with loud noise of the procedure, may cause panic or anxiety. Antianxiety drugs and distraction strategies (e.g., music) may be recommended. Patient must lie still during test. Contraindicated for persons with implanted metallic devices or other metal fragments unless noted to be MRI safe. Discuss any implants before scan.
Magnetic resonance angiography (MRA)	Used for imaging vascular occlusive disease and abdominal aortic aneurysms. Same as MRI but with use of gadolinium as IV contrast medium.	Contraindications include any known allergies to contrast medium and persons with implanted metallic devices or other metal fragments.
Cardiac Computed Tomography (CT)	Cardiac CT is heart-specific CT imaging technology with or without IV contrast medium used to visualize heart anatomy, coronary circulation, and blood vessels.	
Coronary CT angiography (CTA)	Use of CT with injected IV contrast medium to obtain images of blood vessels and diagnose CAD.	Explain procedure to patient. Metal objects should be removed before examination. Patients should have a regular heart rhythm to allow for accurate testing. A β-adrenergic blocker may need to be administered before the test to control HR. The patient may need to be NPO for several hours before the procedure.

TABLE 32-6 DIAGNOSTIC STUDIES—cont'd

Cardiovascular System

Study	Description and Purpose	Nursing Responsibility
Calcium-scoring CT scan • Electron beam computed tomography (EBCT)	EBCT, also known as ultrafast CT, uses a scanning electron beam to quantify calcification in coronary arteries and heart valves (see Fig. 32-11). Primarily used for risk assessment in asymptomatic patients and to assess for heart disease in patients with atypical symptoms potentially related to cardiac causes.	Explain procedure to patient. Inform patient that procedure is quick and involves little or no risk.
Cardiac Catheterization	Involves insertion of catheter into heart to obtain information about O_2 levels and pressure readings within heart chambers. Contrast medium is injected to assist in seeing structures and motion of heart. Procedure is done by insertion of catheter into a vein (for right side of heart) and/or an artery (for left side of heart).	Check for sensitivity to contrast media. Withhold food and fluids for 6-12 hr before procedure. Give sedative and other drugs, if ordered. Inform patient about use of local anesthesia, insertion of catheter, feeling of warmth when dye is injected, and possible fluttering sensation of heart as catheter is passed. Note that patient may be instructed to cough or take a deep breath when dye is injected and that patient is monitored by ECG throughout procedure. After procedure, frequently assess circulation to extremity used for catheter insertion. Check peripheral pulses, color, and sensation of extremity per agency protocol. Observe puncture site for hematoma and bleeding. Place compression device over arterial site to achieve hemostasis, if indicated. Monitor vital signs and ECG. Assess for hypotension or hypertension, dysrhythmias, and signs of pulmonary emboli (e.g., respiratory difficulty).
Coronary angiography	During a cardiac catheterization, contrast medium is injected directly into coronary arteries. Used to evaluate patency of coronary arteries and collateral circulation.	Same as for cardiac catheterization.
Intracoronary ultrasound (ISUS)	During cardiac catheterization a small ultrasound probe is introduced into coronary arteries. Data are used to assess size and consistency of plaque, arterial walls, and effectiveness of intracoronary artery treatment.	Same as for cardiac catheterization.
Fractional flow reserve (FFR)	During cardiac catheterization a special wire is inserted into coronary arteries to measure pressure and flow. Information is used to determine need for angioplasty or stenting on nonsignificant blockages.	Same as for cardiac catheterization.
Electrophysiology Study (EPS)	Invasive study used to record intracardiac electrical activity using catheters (with multiple electrodes) inserted via the femoral and jugular veins into the right side of the heart. The catheter electrodes record the electrical activity in different cardiac structures. In addition, dysrhythmias can be induced and terminated.	Antidysrhythmic medications may be discontinued several days before study. Keep patient NPO 6-8 hr before test. Give premedication to promote relaxation if ordered. IV sedation often used during procedure. Patient must have frequent vital signs and continuous ECG monitoring after the procedure.
Peripheral Arteriography and Venography	Peripheral vessel blood flow is assessed by injecting contrast media into the appropriate arteries or veins (arteriography and venography). Serial x-ray studies taken to detect and visualize any atherosclerotic plaques, occlusion, aneurysms, venous abnormalities, or traumatic injury.	Check for allergy to contrast media. Give mild sedative, if ordered. Check extremity with puncture site for pulsation, warmth, color, and motion after procedure. Inspect insertion site for bleeding or swelling. Observe patient for allergic reactions to contrast media. See Table 38-9 for additional peripheral vascular diagnostic studies.
Hemodynamic Monitoring	Invasive and minimally invasive bedside hemodynamic monitoring is done using intraarterial, pulmonary artery, and central vein catheters to monitor arterial BP, stroke volume variation, pulmonary artery pressure, pulmonary artery wedge pressure, cardiac output, and central venous pressure. Used to evaluate cardiovascular status and response to treatment.	Patients requiring hemodynamic monitoring are critically ill and are monitored in intensive care units. See Chapter 66 for complete information on hemodynamic monitoring.

A lipid panel usually measures cholesterol, triglyceride, LDL, and HDL. Elevations in triglycerides and LDL are strongly associated with CAD. An increased HDL level is associated with a decreased risk of CAD.[4] High levels of HDLs serve a protective role by mobilizing cholesterol from tissues. (This is shown in eFig. 32-2, available on the website for this chapter.)

Although an association exists between elevated serum cholesterol levels and CAD, a measure of total cholesterol alone is not sufficient for an assessment of CAD. A risk assessment is calculated by comparing the total cholesterol to HDL ratio over time. An increase in the ratio indicates increased risk. This provides more information than either value alone. The patient must fast before blood is drawn for a lipid panel so food intake does not affect the results.

Plasma levels of apolipoprotein A-I (apo A-I) (the major HDL protein) and the ratio of apo A-I to apolipoprotein B (apo B) (the major LDL protein) are stronger predictors of CAD than the HDL cholesterol level alone. Measurements of these lipoproteins can be useful in identifying patients at risk for CAD.[13]

Lipoprotein (a), or Lp(a), has been studied for its role as a risk factor for CAD. Increased levels of Lp(a), especially with increased levels of lactate dehydrogenase (LDH), have been linked with the progression of atherosclerosis, especially in women.[4]

Lipoprotein-Associated Phospholipase A_2. Lipoprotein-associated phospholipase A_2 (Lp-PLA_2) is an inflammatory enzyme expressed in atherosclerotic plaques. Elevated levels of Lp-PLA_2 are related to an increased risk of CAD.[16]

Chest X-Ray

A radiographic picture of the chest can show cardiac contours, heart size, and anatomic changes in individual chambers (Fig. 32-9). The chest x-ray records any displacement or enlargement of the heart, extra fluid around the heart (pericardial effusion), and pulmonary congestion.

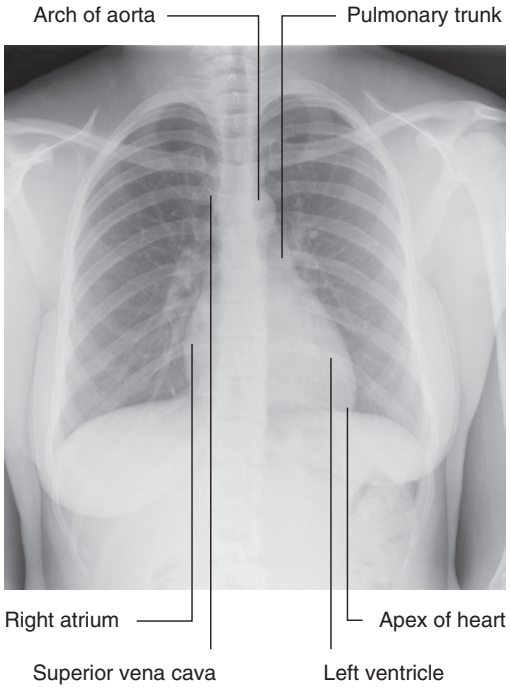

FIG. 32-9 Chest x-ray: standard posterior-anterior view.

Electrocardiogram

The basic P, QRS, and T waveforms (see Fig. 32-4, *B*) are used to assess cardiac activity. Deviations from the normal sinus rhythm can indicate problems in heart function. There are many types of ECG monitoring, including a resting 12-lead ECG, ambulatory ECG monitoring, and exercise or stress testing (see Table 32-6). Continuous ambulatory ECG (Holter monitoring) provides diagnostic information over a period of time. (See Chapter 36 for a complete discussion of ECG monitoring.)

Event Monitor or Loop Recorder. An event monitor or loop recorder is used to document less frequent ECG events. An event monitor is a portable unit that uses electrodes to store ECG data once triggered by the patient. A disadvantage of this type of monitoring is that, if symptoms occur for only a brief time, they may be over before the patient puts on the device and triggers it to record. Likewise, if patients are extremely symptomatic (e.g., syncopal), they may not be physically able to trigger the ECG recording. These devices can be used for routine pacemaker checks over the phone to the health care provider's office.[17]

An implantable loop recorder is used for patients who may have serious yet infrequent dysrhythmias. This small recorder is implanted though a small incision into the chest wall. It is activated to record either by the patient using a remote device or automatically if the HR exceeds or goes below a set rate. External loop recorders are worn for a month, and require electrodes continuously placed on the skin. This device only records when activated by the patient when symptoms occur.

Exercise or Stress Testing

Cardiac symptoms frequently occur only with activity because of the demand on the coronary arteries to provide more oxygen. Exercise testing is used to evaluate the heart's response to physical stress. This helps to assess CVD and set limits for exercise programs. Exercise testing is used for individuals who do not have restrictions related to walking or using a bicycle. It is also helpful for those with normal ECGs that limit diagnostic interpretation (e.g., pacemakers) (see Table 32-6).

Echocardiogram

The echocardiogram uses ultrasound (US) waves to record the movement of the structures of the heart. In the normal heart, ultrasonic sound waves directed at the heart are reflected back in typical configurations. *Contrast echocardiography* involves the addition of an IV contrast agent (e.g., albumin microbubbles, agitated saline) to assist in defining the images, especially in technically difficult patients (e.g., obese).

The echocardiogram provides information about abnormalities of (1) valvular structures and motion, (2) cardiac chamber size and contents, (3) ventricular and septal motion and thickness, (4) pericardial sac, and (5) ascending aorta. The **ejection fraction (EF),** or the percentage of end-diastolic blood volume that is ejected during systole, can also be measured. The EF provides information about the function of the left ventricle during systole.

Two commonly used types of echocardiograms are the *motion-mode (M-mode) echocardiogram* and the *two-dimensional (2-D) echocardiogram.* In the M-mode type, a single ultrasound beam is directed toward the heart, recording the motion of the intracardiac structures and detecting wall thickness and chamber size. The 2-D echocardiogram sweeps

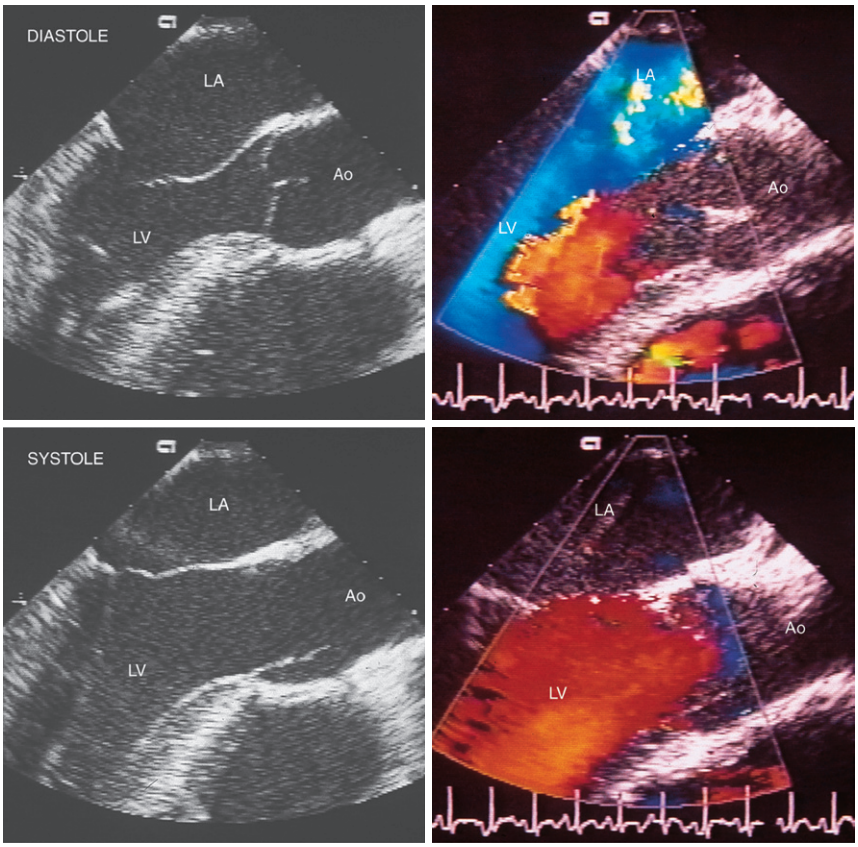

FIG. 32-10 Long-axis images of the aortic and mitral valve with the depth adjusted to optimize evaluation of valve anatomy and motion. The 2-D images *(left)* in diastole *(top)* and systole *(bottom)* show normal aortic and mitral opening and closure. The color flow images *(right)* show normal left ventricular inflow with no aortic regurgitation in diastole *(top)* and normal antegrade flow in the left ventricular outflow tract and no mitral regurgitation in systole *(bottom)*.

the ultrasound beam through an arc, producing a cross-sectional view. This shows correct spatial relationships among the structures.

Doppler technology allows for sound evaluation of the flow or motion of the scanned object (heart valves, ventricular walls, blood flow). *Color-flow imaging (duplex)* is the combination of 2-D echocardiography and Doppler technology (Fig. 32-10). It uses color changes to demonstrate the speed and direction of blood flow. Pathologic conditions, such as valvular leaks and congenital defects, can be diagnosed more effectively.

Real-time three-dimensional (3-D) ultrasound is a technology that uses multiple 2-D echo images with computer technology to provide a reconstruction of the heart. This technique produces information about the structures of the heart and how these structures change during the cardiac cycle.

Stress echocardiography, a combination of treadmill test and ultrasound images, evaluates wall motion abnormalities. By using a digital computer to compare images before and after exercise, wall motion and function are revealed. This test provides the information of an exercise stress test with the information from an echocardiogram. For those individuals unable to exercise, an IV drug (e.g., dobutamine [Dobutrex], dipyridamole [Persantine]) is used to produce pharmacologic stress on the heart while the patient is at rest.

Transesophageal echocardiography (TEE) provides more precise echocardiography of the heart than surface 2-D echocardiography by removing interference from the chest wall and lungs. The TEE uses a flexible endoscope probe with a ultrasound transducer in the tip for imaging of the heart and great vessels. The probe is passed into the esophagus to the level of the heart, and M-mode, 2-D, Doppler, and color-flow imaging can be obtained.

TEE is used frequently in an outpatient setting for evaluation of mitral valve disease and for identification of endocarditis vegetation, thrombus before cardioversion, or the source of cardiac emboli. In addition, TEE is used in the operating room to assess intraoperative cardiac function and in the emergency department to detect suspected aortic dissection.

The risks of TEE are low. However, complications may include perforation or tearing of the esophagus, hemorrhage, dysrhythmias, vasovagal reactions, and transient hypoxemia. TEE is contraindicated if the patient has a history of esophageal disorders, dysphagia, or radiation therapy to the chest wall. Patients require sedation during a TEE.

Nuclear Cardiology

One of the most common nuclear imaging tests is the multigated acquisition (MUGA) or cardiac blood pool scan. This test provides information on wall motion during systole and diastole, cardiac valves, and EF (see Table 32-6).

Perfusion imaging is also used with exercise testing to determine whether the coronary blood flow changes with increased activity. Stress perfusion imaging may show an abnormality even when a resting image is normal. This procedure is used to

diagnose CAD, make a prognosis in existing CAD, differentiate viable myocardium from scar tissue, and determine the potential for success of various interventions (e.g., coronary artery bypass surgery, percutaneous coronary intervention)[18] (see Chapter 34).

Exercise stress perfusion imaging is always preferred but, if a patient cannot exercise, IV dipyridamole or adenosine (Adenocard) can be given to dilate the coronary arteries and simulate the effect of exercise. After the drug takes effect, the isotope is injected and the imaging is done.

Cardiovascular Magnetic Resonance Imaging

Cardiovascular magnetic resonance imaging (CMRI) can detect and find areas of MI in a 3-D view. It is sensitive enough to find even small MIs that are not apparent with single-photon emission computed tomography imaging. CMRI aids in the final diagnosis of MI and the assessment of EF. It also plays a role in prediction of recovery from MI and in the diagnosis of congenital heart and aortic disorders and CAD.[19]

One major advantage of CMRI is that it does not require any radiation to the patient. In general, the use of CMRI in patients with pacemakers and ICDs is discouraged because the magnets can alter the function of the devices. When there is a strong clinical need and the benefits outweigh the risks, CMRI should only be performed in these patients at experienced centers.[19] Some newer models of these devices are approved for use with MRI.

Cardiac Computed Tomography

Cardiac computed tomography (CT) is a heart-imaging test that uses CT technology with or without IV contrast (dye) to see the heart anatomy, coronary circulation, and great blood vessels (e.g., aorta, pulmonary veins, artery). This technology is often called multidetector CT (MDCT) scanning. Types of CT scans used to diagnosis heart disease include coronary CT angiography (CTA) and calcium-scoring CT scan (see Table 32-6).

Coronary CTA is a noninvasive test. It can be done faster than a cardiac catheterization with less risk and discomfort to the patient.[20] Although the use of coronary CTA is increasing, cardiac catheterization (discussed in the next section) remains the gold standard to diagnose coronary artery stenosis. Further, when a cardiac catheterization is done, interventions (e.g., angioplasty, stent placement) can be performed if coronary blockages are found.

The calcium-scoring CT scan is used to find calcium deposits in plaque in the coronary arteries. The most common method used is the electron beam CT (EBCT) (Fig. 32-11). It can detect early coronary calcification before symptoms develop. The amount of coronary calcium is a predictor of future cardiac events.

Cardiac Catheterization

Cardiac catheterization is a common outpatient procedure. It provides information about CAD, coronary spasm, congenital and valvular heart disease, and ventricular function. Cardiac catheterization is also used to measure intracardiac pressures and O_2 levels, as well as CO and EF. With injection of contrast media and fluoroscopy, the coronary arteries can be seen, chambers of the heart can be outlined, and wall motion can be observed.

Cardiac catheterization is done by inserting a radiopaque catheter into the right and/or left side of the heart. For the right side of the heart, a catheter is inserted through an arm vein (basilic or cephalic) or a leg vein (femoral). Pressures are recorded as the catheter is moved into the vena cava, the right atrium, the right ventricle, and the pulmonary artery. The catheter is then moved until it is wedged or lodged in position. This blocks the blood flow and pressure from the right side of the heart and looks ahead through the pulmonary capillary bed to the pressure in the left side of the heart *(pulmonary artery wedge pressure)*. This pressure is used to assess the function of the left side of the heart.

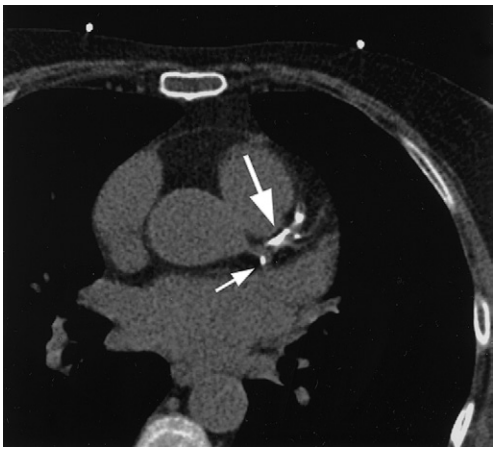

FIG. 32-11 Examples of coronary calcification of the left anterior descending coronary artery *(large arrow)* and left circumflex artery *(small arrow)* as seen on electron beam computed tomography.

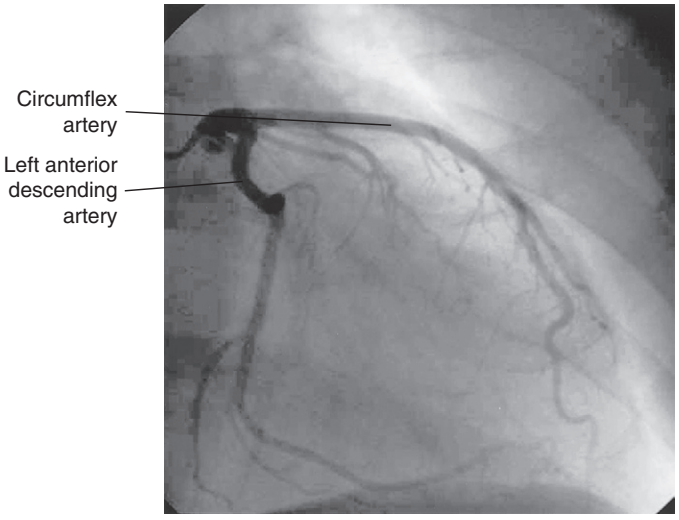

FIG. 32-12 Normal left coronary artery angiogram.

Left-sided heart catheterization is done by inserting a catheter into a femoral, brachial, or radial artery. The catheter is passed in a retrograde manner up to the aorta, across the aortic valve, and into the left ventricle.

Coronary angiography is done with a left-sided heart catheterization. The catheter is positioned at the origin of the coronary arteries (see Fig. 32-3), and contrast medium is injected into the arteries. Patients often feel a temporary flushed sensation with dye injection. The images identify the location and severity of any coronary blockages (see Figs. 32-12 and 34-7). Complications of cardiac catheterization include bleeding or hematoma at the puncture site; allergic reactions to the contrast

media; looping or kinking of the catheter; infection; thrombus formation; aortic dissection; dysrhythmias; MI; stroke; and puncture of the ventricles, cardiac septum, or lung tissue.

Intracoronary Ultrasound. Intracoronary ultrasound (ICUS), also known as intravascular ultrasound (IVUS), is an invasive procedure performed in the catheterization laboratory with coronary angiography. The 2-D or 3-D ultrasound images provide a cross-sectional view of the arterial walls of the coronary arteries. In this procedure a miniature transducer attached to a small catheter is moved to the artery to be studied. Once it is in the artery, ultrasound images are obtained. The health of the arterial layers is assessed, including the composition, location, and thickness of any plaque. ICUS can evaluate vessel response to treatments such as stent placement and atherectomy, as well as any complications that may have occurred during the procedure (see Chapter 34). Patients most often have ICUS in addition to angiography or a coronary intervention. Thus nursing care is similar to that following cardiac catheterization (see Table 32-6).

Fractional Flow Reserve. Fractional flow reserve (FFR) is a procedure that is done during a cardiac catheterization. It involves using a special wire that can measure pressure and flow in the coronary artery. FFR helps to determine the need to perform angioplasty or stenting on nonsignificant blockages.

Electrophysiology Study

The electrophysiology study (EPS) records and manipulates the heart's electrical activity using electrodes placed inside the heart chambers. It provides information on SA node, AV node, and ventricular conduction. It is particularly helpful in determining the source and treatment of dysrhythmias. Patients with symptomatic supraventricular or ventricular tachycardias may be at risk for sudden cardiac death. Information from an EPS helps to make an accurate diagnosis and guides treatment decisions.

In EPS, catheters are inserted in a manner similar to that used in a right-sided heart catheterization. These catheters are placed at specific anatomic sites within the heart to record electrical activity. Nursing care for patients after EPS is similar to the care of patients after cardiac catheterization. This includes continuous ECG monitoring and frequent assessment of vital signs and puncture site.

CASE STUDY—cont'd

Objective Data: Diagnostic Studies

Jupiterimages/Banana-Stock/Thinkstock

The health care provider orders the following initial diagnostic studies for L.P.:

- 12-lead ECG
- CBC, basic metabolic panel (glucose, electrolytes, BUN, creatinine)
- PTT, PT, INR
- Pro-BNP
- Troponin, CK-MB
- TSH, free T_4
- Chest x-ray

L.P.'s initial troponin and CK-MB levels are within normal limits. The ECG demonstrates atrial fibrillation with a rapid ventricular response. Chest x-ray, CBC, basic metabolic panel, pro-BNP, and coagulation studies are all within normal limits. The health care provider orders IV diltiazem (Cardizem) and heparin to be started in the emergency department. L.P. will be admitted to the progressive care unit and will have a consult with a cardiologist.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient with a tricuspid valve disorder will have impaired blood flow between the
   - **a.** vena cava and right atrium.
   - **b.** left atrium and left ventricle.
   - **c.** right atrium and right ventricle.
   - **d.** right ventricle and pulmonary artery.
2. A patient has a severe blockage in his right coronary artery. Which cardiac structures are most likely to be affected by this blockage *(select all that apply)?*
   - **a.** AV node
   - **b.** Left ventricle
   - **c.** Coronary sinus
   - **d.** Right ventricle
   - **e.** Pulmonic valve
3. The portion of the vascular system responsible for hemostasis is the
   - **a.** thin capillary vessels.
   - **b.** endothelial layer of the arteries.
   - **c.** elastic middle layer of the veins.
   - **d.** smooth muscle of the arterial wall.
4. When a person's blood pressure rises, the homeostatic mechanism to compensate for an elevation involves stimulation of
   - **a.** baroreceptors that inhibit the sympathetic nervous system, causing vasodilation.
   - **b.** chemoreceptors that inhibit the sympathetic nervous system, causing vasodilation.
   - **c.** baroreceptors that inhibit the parasympathetic nervous system, causing vasodilation.
   - **d.** chemoreceptors that stimulate the sympathetic nervous system, causing an increased heart rate.
5. A P wave on an ECG represents an impulse arising at the
   - **a.** SA node and repolarizing the atria.
   - **b.** SA node and depolarizing the atria.
   - **c.** AV node and depolarizing the atria.
   - **d.** AV node and spreading to the bundle of His.
6. When collecting subjective data related to the cardiovascular system, which information should be obtained from the patient *(select all that apply)?*
   - **a.** Annual income
   - **b.** Smoking history
   - **c.** Religious preference
   - **d.** Number of pillows used to sleep
   - **e.** Blood for basic laboratory studies

7. The auscultatory area in the left midclavicular line at the level of the fifth ICS is the best location to hear sounds from which heart valve?
   a. Aortic
   b. Mitral
   c. Tricuspid
   d. Pulmonic
8. When assessing a patient, you note a pulse deficit of 23 beats. This finding may be caused by
   a. dysrhythmias.
   b. heart murmurs.
   c. gallop rhythms.
   d. pericardial friction rubs.
9. When assessing the cardiovascular system of a 79-year-old patient, you might expect to find
   a. a narrowed pulse pressure.
   b. diminished carotid artery pulses.
   c. difficulty in isolating the apical pulse.
   d. an increased heart rate in response to stress.
10. Which nursing responsibilities are priorities when caring for a patient returning from a cardiac catheterization *(select all that apply)?*
    a. Monitoring vital signs and ECG
    b. Checking the catheter insertion site and distal pulses
    c. Assisting the patient to ambulate to the bathroom to void
    d. Informing the patient that he will be sleepy from the general anesthesia
    e. Instructing the patient about the risks of the radioactive isotope injection

1. c, 2. a, b, d, 3. b, 4. a, 5. b, 6. b, c, d, 7. b, 8. a, 9. c, 10. a, b

LEARNING OUTCOMES

1. Relate the pathophysiologic mechanisms associated with primary hypertension to the clinical manifestations and complications.
2. Select appropriate strategies for the prevention of primary hypertension.
3. Describe the collaborative care for primary hypertension, including drug therapy and lifestyle modifications.
4. Explain the collaborative care of the older adult with primary hypertension.
5. Prioritize the nursing management of the patient with primary hypertension.
6. Describe the collaborative care of a patient with hypertensive crisis.

KEY TERMS

blood pressure (BP), p. 710
hypertension, p. 712
hypertensive crisis, p. 726
isolated systolic hypertension (ISH), p. 712
orthostatic hypotension, p. 723
prehypertension, p. 712
primary hypertension, p. 712
secondary hypertension, p. 712
systemic vascular resistance (SVR), p. 710

Hypertension, or high blood pressure (BP), is an important medical and public health problem. There is a direct relationship between hypertension and cardiovascular disease (CVD). As BP increases, so does the risk of myocardial infarction (MI), heart failure, stroke, and renal disease.[1] This chapter discusses the nursing care and collaborative management of patients at risk for or who have hypertension.

One in three adults in the United States has hypertension. Additionally, 30% of adults have prehypertension,[2] and approximately 8% have undiagnosed hypertension.[3] *Healthy People 2020* lists the number of adults with hypertension whose BP is under control as one of the 26 high-priority, leading health indicators for the coming decade.[4] The National Health and Nutrition Examination Survey (NHANES) tracks prevention, treatment, and control of hypertension. Data from NHANES show that most people 20 years of age and older with hypertension (82%) were aware that they had high BP, and 75% were being treated. However, 53% did not have their BP controlled.[2]

The American College of Cardiology Foundation and the American Heart Association (AHA) provide performance measures for hypertension management that address not only treatment, but also control of BP to target goals. To achieve the measures, patients with hypertension must have a BP of less than 140/90 mm Hg or, if their BP is higher, have at least two antihypertensive medications prescribed.[5]

National guidelines are designed to apply to all racial and ethnic groups. However, certain groups have a higher incidence of risk factors[2,6-8] (see boxes on Cultural & Ethnic Health Disparities and Gender Differences).

CULTURAL & ETHNIC HEALTH DISPARITIES

Hypertension

African Americans

- Have the highest prevalence of hypertension in the world.
- Develop hypertension at a younger age than whites.
- Have a higher incidence of hypertension among women than among men.
- Hypertension is more aggressive and results in more severe end-organ damage.
- Have a higher death rate resulting from hypertension than whites.
- Produce less renin and do not respond well to renin-inhibiting drugs. They respond better to calcium channel blockers and diuretics.
- Have a higher risk of angioedema with angiotensin-converting enzyme inhibitors than whites.

Mexican Americans

- Are less likely to receive treatment for hypertension than whites and African Americans.
- Have lower rates of BP control than whites and African Americans.
- Have lower levels of awareness of hypertension and its treatment than whites and African Americans.

GENDER DIFFERENCES

Hypertension

Men

- Before age 45, hypertension is more common in men than in women.

Women

- After age 64, hypertension is more common in women than in men.
- Part of the rise in BP in women is attributed to menopause-related factors such as estrogen withdrawal, overproduction of pituitary hormones, and weight gain.
- Older women (ages 70-79) have very poor control of hypertension compared with women ages 50-69, despite having similar rates of treatment.
- Hypertension is two to three times more common in women who take oral contraceptives than in women who do not.
- A history of preeclampsia may be an early sign of risk for cardiovascular disease.

NORMAL REGULATION OF BLOOD PRESSURE

Blood pressure (BP) is the force exerted by the blood against the walls of the blood vessel. It must be adequate to maintain tissue perfusion during activity and rest. The maintenance of normal BP and tissue perfusion requires the integration of both systemic factors and local peripheral vascular effects. BP is primarily a function of cardiac output (CO) and systemic vascular resistance (Fig. 33-1).

CO is the total blood flow through the systemic or pulmonary circulation per minute. It is described as the stroke volume (amount of blood pumped out of the left ventricle per beat [approximately 70 mL]) multiplied by the heart rate (HR) for 1 minute.

Systemic vascular resistance (SVR) is the force opposing the movement of blood within the blood vessels. The radius of the small arteries and arterioles is the principal factor determining vascular resistance. A small change in the radius of the arterioles creates a major change in the SVR. If SVR is increased and CO remains constant or increases, arterial BP will increase.

The mechanisms that regulate BP can affect either CO or SVR, or both. Regulation of BP is a complex process involving both short-term (seconds to hours) and long-term (days to weeks) mechanisms. Short-term mechanisms, including the sympathetic nervous system (SNS) and vascular endothelium, are active within a few seconds. Long-term mechanisms include renal and hormonal processes that regulate arteriolar resistance and blood volume. In a healthy person these regulatory mechanisms function in response to the body's demands.

Sympathetic Nervous System

The nervous system, which reacts within seconds after a drop in BP, increases BP primarily by activating the SNS. Increased SNS activity increases HR and cardiac contractility, produces widespread vasoconstriction in the peripheral arterioles, and promotes the release of renin from the kidneys. The net effect of SNS activation is to increase BP by increasing both CO and SVR.

Specialized nerve cells called *baroreceptors (pressoreceptors)* are located in the carotid arteries and the arch of the aorta. These cells sense changes in BP and transmit this information to the vasomotor centers in the brainstem. The brainstem sends

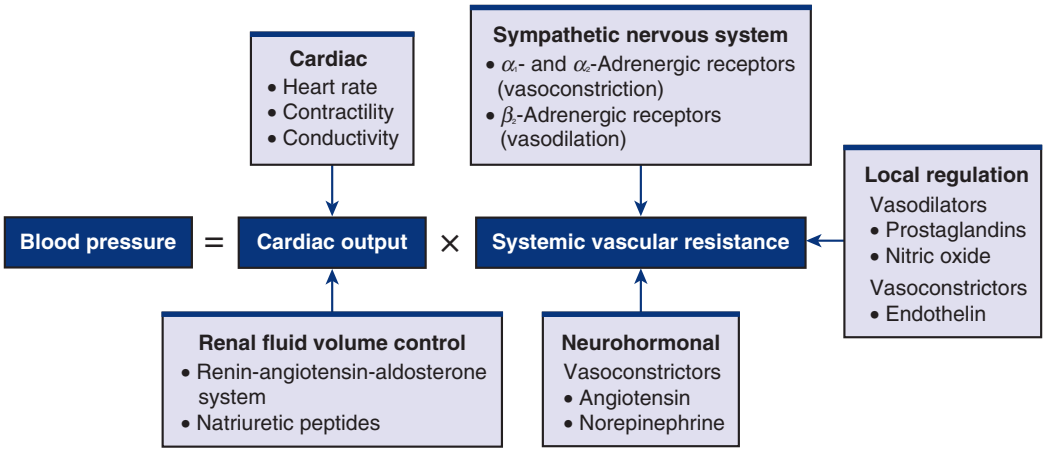

FIG. 33-1 Factors influencing blood pressure (BP). Hypertension develops when one or more of the BP-regulating mechanisms are defective.

this information through complex networks of neurons that excite or inhibit efferent nerves. SNS efferent nerves innervate cardiac and vascular smooth muscle cells. Under normal conditions, a low level of continuous SNS activity maintains vascular tone. BP may be reduced by withdrawal of SNS activity or by stimulation of the parasympathetic nervous system. This decreases the HR (via the vagus nerve) and thereby decreases CO.

The neurotransmitter norepinephrine (NE) is released from SNS nerve endings. NE activates receptors located in the sinoatrial node, myocardium, and vascular smooth muscle. The response to NE depends on the type of receptors present. SNS receptors are classified as α_1, α_2, β_1, and β_2 (Table 33-1). The smooth muscle of the blood vessels has α-adrenergic and β_2-adrenergic receptors. α-Adrenergic receptors located in the peripheral vasculature cause vasoconstriction when stimulated by NE. β_1-Adrenergic receptors in the heart respond to NE and epinephrine with increased HR *(chronotropic),* increased force of contraction *(inotropic),* and increased speed of conduction *(dromotropic).* β_2-Adrenergic receptors are activated primarily by epinephrine released from the adrenal medulla and cause vasodilation (see Fig. 33-1).

The sympathetic vasomotor center interacts with many areas of the brain to maintain normal BP under various conditions. It is activated during times of pain, stress, and exercise. The SNS response causes an appropriate increase in CO and BP to adjust to the body's increased oxygen demands. During postural change from lying to standing, there is a transient decrease in BP. The vasomotor center is stimulated, and the SNS response causes peripheral vasoconstriction and increased venous return to the heart. If this response did not occur, blood flow to the brain would be inadequate, resulting in dizziness or syncope.

Baroreceptors. Baroreceptors have an important role in the maintenance of BP stability during normal activities. They are sensitive to stretching and, when stimulated by an increase in BP, send inhibitory impulses to the sympathetic vasomotor center. Inhibition of the SNS results in decreased HR, decreased force of contraction, and vasodilation in peripheral arterioles.

When a fall in BP is sensed by the baroreceptors, the SNS is activated. The result is constriction of the peripheral arterioles, increased HR, and increased contractility of the heart. In long-standing hypertension the baroreceptors become adjusted to elevated levels of BP and recognize this level as "normal."

TABLE 33-1 SYMPATHETIC NERVOUS SYSTEM RECEPTORS AFFECTING BLOOD PRESSURE

Receptor	Location	Response When Activated
α_1	Vascular smooth muscle	Vasoconstriction
	Heart	Increased contractility (positive inotropic effect)
α_2	Presynaptic nerve terminals	Inhibition of norepinephrine release
	Vascular smooth muscle	Vasoconstriction
β_1	Heart	Increased contractility (positive inotropic effect) Increased heart rate (positive chronotropic effect) Increased conduction (positive dromotropic effect)
	Juxtaglomerular cells of the kidney	Increased renin secretion
β_2	Smooth muscle of blood vessels in heart (e.g., coronary arteries), lungs (e.g., bronchi), and skeletal muscle	Vasodilation
Dopamine receptors	Primarily renal blood vessels	Vasodilation

Vascular Endothelium

The vascular endothelium is a single-cell layer that lines the blood vessels. It produces several vasoactive substances and growth factors. Nitric oxide and prostacyclin help maintain low arterial tone, inhibit growth of the smooth muscle layer, and inhibit platelet aggregation. *Endothelin* (ET) is an extremely potent vasoconstrictor. It also causes adhesion and aggregation of neutrophils and stimulates smooth muscle growth (see Fig. 33-1).

Renal System

The kidneys contribute to BP regulation by controlling sodium excretion and extracellular fluid (ECF) volume (see Chapter 45). Sodium retention results in water retention, which causes an increased ECF volume. This increases the venous return to the heart and the stroke volume. Together, these increase CO and BP.

The renin-angiotensin-aldosterone system (RAAS) also plays an important role in BP regulation (see Fig. 33-1). The juxtaglomerular apparatus in the kidney secretes renin in response to SNS stimulation, decreased blood flow through the kidneys, or decreased serum sodium concentration. Renin is an enzyme that converts angiotensinogen to angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II (A-II). A-II increases BP by two different mechanisms (see Fig. 45-4). First, A-II is a potent vasoconstrictor and increases SVR. This results in an immediate increase in BP. Second, over a period of hours or days, A-II increases BP indirectly by stimulating the adrenal cortex to secrete aldosterone (discussed below).

A-II also acts at a local level within the heart and blood vessels. These effects include vasoconstriction and tissue growth that results in remodeling of the vessel walls. These changes are linked to the development of primary hypertension and also the long-term effects of hypertension (e.g., atherosclerosis, renal disease, cardiac hypertrophy).

Prostaglandins (PGE_2 and PGI_2) secreted by the renal medulla have a vasodilator effect on the systemic circulation. This results in decreased SVR and lowering of BP. (Prostaglandins are discussed in Chapter 12.) The natriuretic peptides (atrial natriuretic peptide [ANP] and b-type natriuretic peptide [BNP]) are secreted by heart cells. They antagonize the effects of antidiuretic hormone (ADH) and aldosterone. This results in *natriuresis* (excretion of sodium in urine) and diuresis, resulting in reduced blood volume and BP.

Endocrine System

Stimulation of the SNS results in release of epinephrine along with a small fraction of NE by the adrenal medulla. Epinephrine increases the CO by increasing the HR and myocardial contractility. Epinephrine activates β_2-adrenergic receptors in peripheral arterioles of skeletal muscle, causing vasodilation. In

TABLE 33-2 CLASSIFICATION OF HYPERTENSION

Category	SBP (mm Hg)		DBP (mm Hg)
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
Hypertension, stage 1	140-159	or	90-99
Hypertension, stage 2	≥160	or	≥100

DBP, Diastolic blood pressure; *SBP*, systolic blood pressure.

TABLE 33-3 CAUSES OF SECONDARY HYPERTENSION*

- Cirrhosis
- Coarctation or congenital narrowing of the aorta
- Drug-related: estrogen replacement therapy, oral contraceptives, corticosteroids, nonsteroidal antiinflammatory drugs (e.g., cyclooxygenase-2 inhibitors), sympathetic stimulants (e.g., cocaine, monoamine oxidase)
- Endocrine disorders (e.g., pheochromocytoma, Cushing syndrome, thyroid disease)
- Neurologic disorders (e.g., brain tumors, quadriplegia, traumatic brain injury)
- Pregnancy-induced hypertension
- Renal disease (e.g., renal artery stenosis, glomerulonephritis)
- Sleep apnea

*List is not all inclusive.

peripheral arterioles with only α_1-adrenergic receptors (skin and kidneys), epinephrine causes vasoconstriction.

A-II stimulates the adrenal cortex to release aldosterone. (Release of aldosterone is also regulated by other factors [see Chapters 48 and 50].) Aldosterone stimulates the kidneys to retain sodium and water. This increases blood volume and CO (see Fig. 45-4).

An increased blood sodium and osmolarity level stimulates the release of ADH from the posterior pituitary gland. ADH increases the ECF volume by promoting the reabsorption of water in the distal and collecting tubules of the kidneys. The resulting increase in blood volume causes an increase in CO and BP.

HYPERTENSION

Classification of Hypertension

Hypertension is defined as a persistent systolic BP (SBP) of 140 mm Hg or more, diastolic BP (DBP) of 90 mm Hg or more, or current use of antihypertensive medication.[1] **Prehypertension** is defined as SBP of 120 to 139 mm Hg or DBP of 80 to 89 mm Hg.

Isolated systolic hypertension (ISH) is defined as an average SBP of 140 mm Hg or more, coupled with an average DBP of less than 90 mm Hg.[9] SBP increases with aging. DBP rises until approximately age 55 and then declines. Control of ISH decreases the incidence of stroke, heart failure, and death.

The classification of BP is based on the average of two or more properly measured BP readings on two or more office visits. Table 33-2 presents the BP classification for people 18 years of age and older.

Etiology

Hypertension can be classified as either primary or secondary.

Primary Hypertension. **Primary** *(essential* or *idiopathic)* **hypertension** is elevated BP without an identified cause, and it accounts for 90% to 95% of all cases of hypertension. Although the exact cause of primary hypertension is unknown, there are several contributing factors. These include increased SNS activity, overproduction of sodium-retaining hormones and vasoconstricting substances, increased sodium intake, greater-than-ideal body weight, diabetes mellitus, tobacco use, and excessive alcohol consumption. Primary hypertension is the major focus of this chapter because of its prevalence and impact on health.

Secondary Hypertension. **Secondary hypertension** is elevated BP with a specific cause that often can be identified and corrected (Table 33-3). This type of hypertension accounts for 5% to 10% of hypertension in adults. Secondary hypertension should be suspected in people who suddenly develop high BP, especially if it is severe. Clinical findings that suggest secondary hypertension relate to the underlying cause. For example, an abdominal bruit heard over the renal arteries may indicate renal disease. Treatment of secondary hypertension is aimed at removing or treating the underlying cause. Secondary hypertension is a contributing factor to hypertensive crisis (discussed later in this chapter).

Pathophysiology of Primary Hypertension

BP rises with any increase in CO or SVR. Increased CO is sometimes found in the person with prehypertension. Later in the course of hypertension, the SVR rises and the CO returns to normal. The hemodynamic hallmark of hypertension is persistently increased SVR. This persistent elevation in SVR may occur in various ways. Table 33-4 presents factors that relate to the development of primary hypertension or contribute to its consequences. Abnormalities of any of the mechanisms involved in the maintenance of normal BP can result in hypertension (see Fig. 33-1).

Genetic Link

Different sets of genes may regulate BP at different times throughout the life span.[2] Genetic abnormalities associated with a rare form of hypertension characterized by excess levels of potassium have been identified. To date, the known contribution of genetic factors to BP in the general population remains very small.[1]

The International Consortium for Blood Pressure Genome-Wide Association Studies is a network of researchers currently working to uncover genetic factors related to hypertension. In practice, you should screen children and siblings of persons with hypertension and strongly advise them to adopt healthy lifestyles to prevent hypertension.

Water and Sodium Retention. Excessive sodium intake is linked to the start of hypertension. Although most people consume a high-sodium diet, only one in three will develop hypertension. When sodium is restricted in many people with hypertension, their BP falls. This suggests that some degree of sodium sensitivity may exist for high sodium intake to trigger the development of hypertension. A high sodium intake may activate a number of pressor mechanisms and cause water retention.

TABLE 33-4 RISK FACTORS FOR PRIMARY HYPERTENSION

Risk Factor	Description
Age	• SBP rises progressively with increasing age. • After age 50, SBP >140 mm Hg is a more important cardiovascular risk factor than DBP.
Alcohol	• Excessive alcohol intake is strongly associated with hypertension. • Patients with hypertension should limit their daily intake to 1 oz of alcohol.
Tobacco use	• Smoking tobacco greatly ↑ risk of cardiovascular disease. • People with hypertension who smoke tobacco are at even greater risk for cardiovascular disease.
Diabetes mellitus	• Hypertension is more common in patients with diabetes. • When hypertension and diabetes coexist, complications (e.g., target organ disease) are more severe.
Elevated serum lipids	• ↑ Levels of cholesterol and triglycerides are primary risk factors in atherosclerosis. • Hyperlipidemia is more common in people with hypertension.
Excess dietary sodium	• High sodium intake can • Contribute to hypertension in some patients • Decrease the effectiveness of certain antihypertensive medications
Gender	• Hypertension is more prevalent in men in young adulthood and early middle age (<55 yr of age). • After age 64, hypertension is more prevalent in women. (See Gender Differences box on p. 710.)
Family history	• History of a close blood relative (e.g., parents, sibling) with hypertension is associated with an ↑ risk for developing hypertension.
Obesity	• Weight gain is associated with increased frequency of hypertension. • The risk is greatest with central abdominal obesity.
Ethnicity	• Incidence of hypertension is 2 times higher in African Americans than in whites. (See Cultural & Ethnic Health Disparities box on p. 710.)
Sedentary lifestyle	• Regular physical activity can help control weight and reduce cardiovascular risk. • Physical activity may ↓ BP.
Socioeconomic status	• Hypertension is more prevalent in lower socioeconomic groups and among the less educated.
Stress	• People exposed to repeated stress may develop hypertension more frequently than others. • People who develop hypertension may respond differently to stress than those who do not develop hypertension.

DBP, Diastolic blood pressure; *SBP,* systolic blood pressure.

In clinical practice, there is not an easy or simple test to identify individuals whose BP will rise with even a small increase in salt intake *(salt sensitive)* versus those who can ingest large amounts of sodium without much change in BP *(salt resistant).* In general, the effect of sodium on BP is greater in African Americans and in middle-aged and older adults.[10]

Altered Renin-Angiotensin-Aldosterone Mechanism. High plasma renin activity (PRA) results in the increased conversion of angiotensinogen to angiotensin I (see Fig. 45-4). This alteration in the RAAS may contribute to the development of hypertension. Any rise in BP inhibits the release of renin from the renal juxtaglomerular cells. Based on this feedback loop, low levels of PRA would be expected in patients with primary hypertension. However, only about 30% have low PRA, 50% have normal levels, and 20% have high PRA. These normal or high PRA levels may be related to excess renin secretion from ischemic nephrons.

Stress and Increased Sympathetic Nervous System Activity. It has long been recognized that BP is influenced by factors such as anger, fear, and pain. Physiologic responses to stress, which are normally protective, may persist to a pathologic degree, resulting in a prolonged increase in SNS activity. Increased SNS stimulation produces increased vasoconstriction, increased HR, and increased renin release. Increased renin activates the RAAS, leading to elevated BP. People exposed to high levels of repeated psychologic stress develop hypertension to a greater extent than those who experience less stress.

Insulin Resistance and Hyperinsulinemia. Abnormalities of glucose, insulin, and lipoprotein metabolism are common in primary hypertension. They are not present in secondary hypertension and do not improve when hypertension is treated. Insulin resistance is a risk factor in the development of hypertension and CVD. High insulin levels stimulate SNS activity and impair nitric oxide–mediated vasodilation. Additional pressor effects of insulin include vascular hypertrophy and increased renal sodium reabsorption.

Endothelium Dysfunction. Endothelium dysfunction may contribute to atherosclerosis and primary hypertension. Some people with hypertension have a reduced vasodilator response to nitric oxide. Others have high levels of ET that produce a pronounced and prolonged vasoconstriction. The role of endothelium dysfunction in the pathogenesis and treatment of hypertension is an area of ongoing investigation.

Clinical Manifestations

Hypertension is often called the "silent killer" because it is frequently asymptomatic until it becomes severe and target organ disease occurs. A patient with severe hypertension may experience a variety of symptoms secondary to the effects on blood vessels in the various organs and tissues or to the increased workload of the heart. These secondary symptoms include fatigue, dizziness, palpitations, angina, and dyspnea. In the past, symptoms of hypertension were thought to include headache and nosebleeds. Unless BP is very high, these symptoms are no more frequent in people with hypertension than in the general population. However, patients with hypertensive crisis (discussed later in the chapter) may experience severe headaches, dyspnea, anxiety, and nosebleeds.[11]

Complications

The most common complications of hypertension are *target organ diseases* occurring in the heart (hypertensive heart disease), brain (cerebrovascular disease), peripheral vessels (peripheral vascular disease), kidneys (nephrosclerosis), and eyes (retinal damage) (Table 33-5).

Hypertensive Heart Disease

Coronary Artery Disease. Hypertension is a major risk factor for coronary artery disease (CAD). The mechanisms by which hypertension contributes to the development of atherosclerosis are not fully known. The "response-to-injury" theory of atherogenesis suggests that hypertension disrupts the coronary artery endothelium (see Fig. 34-1). This results in a stiff arterial wall with a narrowed lumen, and accounts for a high rate of CAD, angina, and MI.

TABLE 33-5 MANIFESTATIONS OF TARGET ORGAN DISEASE

Organ	Manifestations
Cardiac	• Clinical, electrocardiographic, or radiologic evidence of coronary artery disease (e.g., previous myocardial infarction, coronary revascularization) • Left ventricular hypertrophy by ECG or echocardiography • Left ventricular dysfunction or heart failure
Cerebrovascular	• Transient ischemic attack • Stroke
Peripheral vascular	• One or more major pulses in the extremities (except for dorsalis pedis) reduced or absent • Intermittent claudication • Abdominal or carotid bruits or thrills • Aneurysm
Renal	• Serum creatinine ≥1.5 mg/dL (130 µmol/L) • Proteinuria (≥1+) • Microalbuminuria
Retinopathy	• Generalized or focal narrowing of retinal arterioles • Arteriovenous nicking • Hemorrhages or exudates with or without papilledema

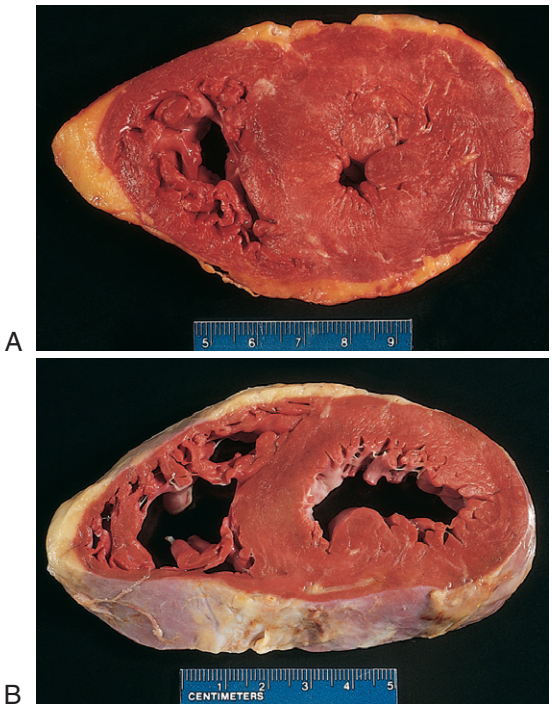

FIG. 33-2 **A,** Massively enlarged heart caused by hypertrophy of the muscle in the left ventricle. **B,** Compare with the thickness of the normal left ventricle. The patient suffered from severe hypertension.

Left Ventricular Hypertrophy. Sustained high BP increases the cardiac workload and produces left ventricular hypertrophy (LVH) (Fig. 33-2). Initially, LVH is a compensatory mechanism that strengthens cardiac contraction and increases CO. However, increased contractility increases myocardial work and oxygen demand. Progressive LVH, especially in the presence of CAD, is associated with the development of heart failure.

Heart Failure. Heart failure occurs when the heart's compensatory mechanisms are overwhelmed and the heart can no longer pump enough blood to meet the body's demands (see Chapter 35). Contractility is depressed, and stroke volume and CO are decreased. The patient may complain of shortness of breath on exertion, paroxysmal nocturnal dyspnea, and fatigue.

Cerebrovascular Disease. Atherosclerosis is the most common cause of cerebrovascular disease. Hypertension is a major risk factor for cerebral atherosclerosis and stroke. Even in mildly hypertensive people, the risk of stroke is four times higher than in normotensive people. Adequate control of BP diminishes the risk of stroke.

Atherosclerotic plaques are commonly found at the bifurcation of the common carotid artery and in the internal and external carotid arteries. Portions of the atherosclerotic plaque or the blood clot that forms with disruption of the plaque may break off and travel to cerebral vessels, producing a thromboembolism. The patient may experience transient ischemic attacks or a stroke. (These conditions are discussed in Chapter 58.)

Hypertensive encephalopathy may occur after a marked rise in BP if the cerebral blood flow is not decreased by autoregulation. Autoregulation is a physiologic process that maintains constant cerebral blood flow despite fluctuations in BP. Normally, as pressure in the cerebral blood vessels rises, the vessels constrict to maintain constant flow. When BP exceeds the body's ability to autoregulate, the cerebral vessels suddenly dilate, capillary permeability increases, and cerebral edema develops. This produces a rise in intracranial pressure. If left untreated, patients die quickly from brain damage. (Chapter 57 discusses cerebral blood flow and autoregulation.)

Peripheral Vascular Disease. Hypertension speeds up the process of atherosclerosis in the peripheral blood vessels. This leads to the development of peripheral vascular disease, aortic aneurysm, and aortic dissection (see Chapter 38). *Intermittent claudication* (ischemic leg pain precipitated by activity and relieved with rest) is a classic symptom of peripheral vascular disease.

Nephrosclerosis. Hypertension is one of the leading causes of chronic kidney disease, especially among African Americans. Some degree of renal disease is usually present in the hypertensive patient, even one with a minimally elevated BP. Renal disease results from ischemia caused by the narrowing of the renal blood vessels. This leads to atrophy of the tubules, destruction of the glomeruli, and eventual death of nephrons. Initially intact nephrons can compensate, but these changes may eventually lead to renal failure. Laboratory indications of renal disease are microalbuminuria, proteinuria, microscopic hematuria, and elevated serum creatinine and blood urea nitrogen (BUN) levels. The earliest manifestation of renal disease is usually nocturia (see Chapter 47).

Retinal Damage. The appearance of the retina provides important information about the severity and duration of hypertension. The blood vessels of the retina can be directly visualized with an ophthalmoscope. Damage to the retinal vessels provides an indication of related vessel damage in the heart, brain, and kidneys. Manifestations of severe retinal damage include blurring of vision, retinal hemorrhage, and loss of vision.

TABLE 33-6 COLLABORATIVE CARE

Hypertension

Diagnostic Studies

History and physical examination, including an ophthalmic examination
Routine urinalysis
Basic metabolic panel (serum glucose, sodium, potassium, chloride, carbon dioxide, BUN, and creatinine)
Complete blood count
Serum lipid profile (total lipids, triglycerides, HDL and LDL cholesterol, total-to-HDL cholesterol ratio)
Serum uric acid
12-lead electrocardiogram (ECG)
Optional:
- 24-hr urinary creatinine clearance
- Echocardiography
- Liver function studies
- Serum thyroid-stimulating hormone (TSH)

Collaborative Therapy

Periodic monitoring of BP
- Home BP monitoring
- Ambulatory BP monitoring (if indicated)
- Every 3-6 mo by health care provider once BP is stabilized

Nutritional therapy (see eTable 33-1)
- Restrict salt and sodium
- Restrict cholesterol and saturated fats
- Maintain adequate intake of potassium
- Maintain adequate intake of calcium and magnesium

Weight management
Regular, moderate physical activity
Tobacco cessation (see Tables 11-4 through 11-6)
Moderation of alcohol consumption
Management of psychosocial risk factors (see Chapter 7)
Antihypertensive drugs (see Tables 33-7 and 33-8)
Patient and caregiver teaching

HDL, High-density lipoprotein; *LDL*, low-density lipoprotein.

Diagnostic Studies

Chapter 32 and the Nursing Management section later in this chapter discuss BP measurement.

Some controversy exists over the diagnostic workup in the initial assessment of a person with hypertension. Because most hypertension is classified as primary hypertension, testing for secondary causes is not routinely done. Basic laboratory studies are performed to (1) identify or rule out causes of secondary hypertension, (2) evaluate target organ disease, (3) determine overall cardiovascular risk, or (4) establish baseline levels before initiating therapy.

Table 33-6 lists basic diagnostic studies performed in a person with hypertension. Routine urinalysis, BUN, and serum creatinine levels are used to screen for renal involvement and to provide baseline information about kidney function. Creatinine clearance reflects the glomerular filtration rate. Decreases in creatinine clearance indicate renal insufficiency. (Chapters 45 and 47 discuss serum creatinine and creatinine clearance.)

Measurement of serum electrolytes, especially potassium, is important to detect hyperaldosteronism, a cause of secondary hypertension. Blood glucose levels assist in the diagnosis of diabetes mellitus. A lipid profile provides information about additional risk factors related to atherosclerosis and CVD. Uric acid levels establish a baseline, since the levels often rise with diuretic therapy. An electrocardiogram (ECG) provides baseline information about cardiac status. It can identify the presence of LVH, cardiac ischemia, or previous MI. If LVH is suspected, echocardiography is often performed. If the patient's age, history, physical examination, or severity of hypertension points to a secondary cause, further diagnostic testing is indicated.

Ambulatory Blood Pressure Monitoring. Some patients have elevated BP readings in a clinical setting and normal readings when BP is measured elsewhere. This phenomenon is referred to as "white coat" hypertension. Self-monitoring of BP is an easy, cost-effective approach that may be chosen before ambulatory BP monitoring (ABPM). ABPM is a noninvasive, fully automated system that measures BP at preset intervals over a 24-hour period. The equipment includes a BP cuff and a microprocessing unit that fits into a pouch worn on a shoulder strap or belt. Tell patients to hold their arm still by their side when the device is taking a reading. Also ask them to maintain a diary of activities that may affect BP. Other potential applications for ABPM include suspected antihypertensive drug resistance, hypotensive symptoms with antihypertensive drugs, episodic hypertension, or SNS dysfunction.

BP demonstrates diurnal variability expressed as sleep-wakefulness difference. For day-active people, BP is highest in the early morning, decreases during the day, and is lowest at night. BP at night (during sleep) usually drops by 10% or more from daytime (awake) BP.[9] Some patients with hypertension do not show a normal nocturnal dip in BP and are referred to as "nondippers." The absence of diurnal variability has been associated with more target organ disease and an increased risk for CVD. The presence or absence of diurnal variability can be determined by ABPM.

Collaborative Care

Table 33-6 summarizes the collaborative care for a patient with hypertension. Goals include achieving and maintaining goal BP, and reducing cardiovascular risk and target organ disease. Lifestyle modifications are indicated for all patients with prehypertension and hypertension.

Lifestyle Modifications. Lifestyle modifications are directed toward reducing the patient's BP and overall cardiovascular risk. Modifications include (1) weight reduction, (2) Dietary Approaches to Stop Hypertension (DASH) eating plan, (3) dietary sodium reduction, (4) moderation of alcohol consumption, (5) regular physical activity, (6) avoidance of tobacco use (smoking and chewing), and (7) management of psychosocial risk factors.

Weight Reduction. Overweight persons have an increased incidence of hypertension and increased risk for CVD. Weight reduction has a significant effect on lowering BP in many people, and the effect is seen with even moderate weight loss. A weight loss of 22 lb (10 kg) may decrease SBP by approximately 5 to 20 mm Hg.[1] When a person decreases caloric intake, sodium and fat intake are usually also reduced. Although reducing the fat content of the diet has not been shown to produce sustained benefits in BP control, it may slow the progress of atherosclerosis and reduce overall CVD risk (see Chapter 34). Weight reduction through a combination of calorie restriction and moderate physical activity is recommended for overweight patients with hypertension (see Chapter 41).

DASH Eating Plan. The DASH eating plan emphasizes fruits, vegetables, fat-free or low-fat milk and milk products, whole grains, fish, poultry, beans, seeds, and nuts. Compared with the typical American diet, the plan contains less red meat, salt, sweets, added sugars, and sugar-containing beverages[12] (see eTable 33-1 on the website for this chapter). The DASH eating plan significantly lowers BP, and these decreases compare with

those achieved with BP-lowering medication.[1] Additional benefits also include lowering of low-density lipoprotein (LDL) cholesterol.[12]

Dietary Sodium Reduction. Healthy adults should restrict sodium intake to less than or equal to 2300 mg/day. African Americans; people middle aged and older; and those with hypertension, diabetes mellitus, or chronic kidney disease should restrict sodium to less than or equal to 1500 mg/day.[10,12] This involves avoiding foods known to be high in sodium (e.g., canned soups, frozen dinners) and not adding salt in the preparation of foods or at meals (see Table 35-8).

Most adults exceed the recommended limits for sodium. Average sodium intake is approximately 4200 mg/day in men and 3300 mg/day in women.[12] The patient and caregiver, especially the person who prepares the meals, need to learn about sodium-restricted diets. Instruction should include reading labels of over-the-counter drugs, packaged foods, and health products (e.g., toothpaste containing baking soda) to identify hidden sources of sodium (see Fig. 35-5). Review the patient's normal diet to identify foods high in sodium.

Sodium restriction may be enough to control BP in some patients. If drug therapy is needed, a lower dosage may be effective if the patient also restricts sodium intake. Further, moderate sodium restriction lessens the risk of hypokalemia associated with diuretic therapy. However, the response differs between patients who are salt sensitive or salt resistant.

The significance of other dietary elements for the control of hypertension is not certain. There is some evidence that greater levels of dietary potassium, calcium, vitamin D, and omega-3 fatty acids are associated with lower BP in the general population and in those with hypertension. People with hypertension should maintain adequate potassium, calcium, and vitamin D intake from food sources. Calcium supplements are not recommended to lower BP. Omega-3 fatty acids found in certain fish oils can contribute to a reduction in BP and triglycerides (see Complementary & Alternative Therapies box).

Moderation of Alcohol Consumption. Excessive alcohol consumption is strongly associated with hypertension. Consumption of three or more alcoholic drinks daily is also a risk factor for CVD and stroke. Men should limit their intake of alcohol to no more than two drinks per day and women and lighter-weight men to no more than one drink per day. One drink is defined as 12 oz of regular beer, 5 oz of wine (12% alcohol), or 1.5 oz of 80-proof distilled spirits. Excessive alcohol consumption that results in cirrhosis is the most frequent cause of secondary hypertension.

Physical Activity. A physically active lifestyle is essential to promote and maintain good health. The AHA and American College of Sports Medicine recommend that adults perform moderate-intensity aerobic physical activity for at least 30 minutes most days (i.e., more than 5 days per week) or vigorous-intensity aerobic activity for at least 20 minutes 3 days a week. The 30-minute goal can be accomplished by performing shorter periods of exercise that last at least 10 minutes. Additionally, combinations of moderate and vigorous activity are acceptable (e.g., walking briskly for 30 minutes on 2 days of the week and jogging for 20 minutes on 2 other days).[13,14]

Separate physical activity guidelines exist for adults age 18 to 65 years, adults over 65 years, and adults age 50 to 64 years with functional limitations. The differences relate to the definition of moderate and vigorous aerobic activity. For adults ages 18 to 65, walking briskly at a pace that noticeably increases the pulse defines moderate-intensity aerobic activity. Jogging at a pace that substantially increases the pulse and causes rapid breathing is an example of vigorous activity for this age-group. For all other adults, individual fitness levels guide aerobic intensity.[13,14]

All adults should perform muscle-strengthening activities using the major muscles of the body at least twice a week. This helps to maintain or increase muscle strength and endurance. Additionally, flexibility and balance exercises are recommended at least twice a week for older adults, especially for those at risk for falls.[14] Moderate-intensity activities can lower BP, promote relaxation, and decrease or control body weight. Regular activity of this type can reduce SBP by approximately 4 to 9 mm Hg.[1]

Generally, physical activity is more likely to be done if it is safe and enjoyable, fits easily into one's daily schedule, and is inexpensive. Many shopping malls open early in the morning and provide a warm, safe, flat area for walking. Some health clubs offer special "off-peak" rates to encourage physical activity among older adults. Cardiac rehabilitation programs offer supervised exercise and education about cardiovascular risk factor reduction.

You can help people with hypertension increase their physical activity by explaining the need for physical activity, describing the different types of physical activities, and assisting in starting an exercise plan. Advise sedentary people to increase activity levels gradually. Individuals with CVD or other serious health problems need a thorough examination and possibly a stress test before beginning an exercise program.

Avoidance of Tobacco Products. Nicotine contained in tobacco causes vasoconstriction and increases BP, especially in people with hypertension. Smoking tobacco is also a major risk factor for CVD. The cardiovascular benefits of stopping tobacco use are seen within 1 year in all age-groups. Strongly encourage everyone, especially patients with hypertension, to avoid tobacco use. Advise those who continue to use tobacco products to monitor their BP during use. (Chapter 11 discusses tobacco use and smoking cessation.)

Management of Psychosocial Risk Factors. Psychosocial risk factors can contribute to the risk of developing CVD, and to a poorer prognosis and clinical course in patients with CVD.

COMPLEMENTARY & ALTERNATIVE THERAPIES

Fish Oil and Omega-3 Fatty Acids

Dietary sources of omega-3 fatty acids include fish oil and certain plant and nut oils. Fish oil contains both docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). Some nuts and vegetable oils contain α-linolenic acid (ALA).

Scientific Evidence

- Reduce blood triglyceride levels
- May cause a small reduction in BP
- May reduce the risk of heart attack, stroke, and death among people with cardiovascular disease

Nursing Implications

- For healthy adults with no history of heart disease, the American Heart Association recommends eating fish at least two times per wk. Fatty fish such as anchovies, bluefish, carp, catfish, halibut, lake trout, mackerel, pompano, salmon, striped sea bass, albacore tuna, and whitefish are recommended.
- Fish oil is generally safe in recommended dosages. Higher doses may result in increased risk of bleeding.

Sources: *www.naturalstandard.com* and *http://nccam.nih.gov/health/omega3/introduction.htm*.

These risk factors include low socioeconomic status, social isolation and lack of support, stress at work and in family life, and negative emotions such as depression and hostility.[15] Frequently, these risk factors are clustered together. For example, rates of depression tend to be higher in individuals with job stress.

Psychosocial risk factors have direct effects on the cardiovascular system by activating the SNS and stress hormones. This can cause a wide variety of pathophysiologic responses, including hypertension and tachycardia, inflammation, endothelium dysfunction, increased platelet aggregation, insulin resistance, and central obesity.[16]

Psychosocial risk factors can contribute to CVD indirectly as well, simply by their impact on lifestyle behaviors and choices. Screening for psychosocial risk factors is important. Make appropriate referrals (e.g., counseling), when indicated. Suggest behavioral interventions such as relaxation training, stress management courses, support groups, and exercise training for individuals who are not in acute psychologic distress.[16]

Drug Therapy. The goal for treating hypertension is a BP less than 140/90 mm Hg. Persons with high risk for CVD (e.g., diabetes mellitus, kidney disease, tobacco use) have the greatest chance of having a cardiovascular event related to uncontrolled hypertension. For these individuals, a lower goal of 130/80 mm Hg may be appropriate. However, specific guidelines for BP goals for high-risk patients will be published when the Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 8) is released.[5]

The drugs currently available for treating hypertension have two main actions: (1) they decrease the volume of circulating blood and (2) they reduce SVR (Table 33-7). The drugs used in the treatment of hypertension include diuretics,

TABLE 33-7 DRUG THERAPY*

Hypertension

Drug	Mechanism of Action	Nursing Considerations
Diuretics		
Thiazide and Related Diuretics		
bendroflumethiazide (Naturetin) chlorothiazide (Diuril) chlorthalidone (Hygroton) hydrochlorothiazide (Microzide, HydroDIURIL) indapamide (Lozol) metolazone (Zaroxolyn)	Inhibit NaCl reabsorption in the distal convoluted tubule. Increase excretion of Na^+ and Cl^-. Initial decrease in ECF. Sustained decrease in SVR. Lower BP moderately in 2-4 wk.	Monitor for orthostatic hypotension, hypokalemia, and alkalosis. Thiazides may potentiate cardiotoxicity of digoxin by producing hypokalemia. Dietary sodium restriction reduces the risk of hypokalemia. NSAIDs can decrease diuretic and antihypertensive effect of thiazide diuretics. Advise patient to supplement with potassium-rich foods.
Loop Diuretics		
bumetanide (Bumex) ethacrynic acid (Edecrin) furosemide (Lasix) torsemide (Demadex)	Inhibit NaCl reabsorption in the ascending limb of the loop of Henle. Increase excretion of Na^+ and Cl^-. More potent diuretic effect than thiazides, but shorter duration of action. Less effective for hypertension.	Monitor for orthostatic hypotension and electrolyte abnormalities. Loop diuretics remain effective despite renal insufficiency. Diuretic effect of drug increases at higher doses.
Potassium-Sparing Diuretics		
amiloride (Midamor) triamterene (Dyrenium)	Reduce K^+ and Na^+ exchange in the distal and collecting tubules. Reduce excretion of K^+, H^+, Ca^+, and Mg^+.	Monitor for orthostatic hypotension and hyperkalemia. Contraindicated in patients with renal failure. Use with caution in patients on ACE inhibitors or angiotensin II blockers. Avoid potassium supplements.
Aldosterone Receptor Blockers		
spironolactone (Aldactone) eplerenone (Inspra)	Inhibit the Na^+-retaining and K^+-excreting effects of aldosterone in the distal and collecting tubules.	Monitor for orthostatic hypotension and hyperkalemia. Do not combine with potassium-sparing diuretics or potassium supplements. Use with caution in patients on ACE inhibitors or angiotensin II blockers. These drugs are also classified as potassium-sparing diuretics.
Adrenergic Inhibitors		
Central-Acting α-Adrenergic Antagonists		
clonidine (Catapres) clonidine patch (Catapres-TTS)	Reduce sympathetic outflow from CNS. Reduce peripheral sympathetic tone, produces vasodilation, decreases SVR and BP.	Sudden discontinuation may cause withdrawal syndrome, including rebound hypertension, tachycardia, headache, tremors, apprehension, sweating. Chewing gum or hard candy may relieve dry mouth. Alcohol and sedatives increase sedation. Transdermal patch may be related to fewer side effects and better adherence.
guanabenz (Wytensin)	Same as clonidine.	Same as clonidine, but not available in transdermal formulation.
guanfacine (Tenex)	Same as clonidine.	Same as clonidine, but not available in transdermal formulation.
methyldopa (Aldomet)	Same as clonidine.	Instruct patient about daytime sedation and avoidance of hazardous activities. Administration of a single daily dose at bedtime minimizes sedative effect.

*An expanded version of this table (eTable 33-2) is available on the website for this chapter.

ACE, Angiotensin-converting enzyme; *AV,* atrioventricular; *CO,* cardiac output; *DBP,* diastolic blood pressure; *ECF,* extracellular fluid; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *SBP,* systolic blood pressure; *SVR,* systemic vascular resistance.

Continued

TABLE 33-7 DRUG THERAPY—cont'd

Hypertension

Drug	Mechanism of Action	Nursing Considerations
Adrenergic Inhibitors—cont'd		
Peripheral-Acting α-Adrenergic Antagonists		
guanethidine (Ismelin)	Prevents peripheral release of norepinephrine, resulting in vasodilation. Lowers CO and reduces SBP more than DBP.	May cause severe orthostatic hypotension. Not recommended for use in patients with cerebrovascular or coronary insufficiency or in older adults. Advise patient to rise slowly and wear support stockings. Hypotensive effect is delayed for 2-3 days and lasts 7-10 days after withdrawal.
guanadrel (Hylorel)	Same as guanethidine	Must be given twice daily. Contraindicated in patients with history of depression. Monitor mood and mental status regularly. Advise patient to avoid barbiturates, alcohol, opioids.
reserpine (Serpasil)	Depletes central and peripheral stores of norepinephrine. Results in peripheral vasodilation (decreases SVR and BP).	
α_1-Adrenergic Blockers		
doxazosin (Cardura) prazosin (Minipress) terazosin (Hytrin)	Block α_1-adrenergic effects, producing peripheral vasodilation (decreases SVR and BP). Beneficial effects on lipid profile.	Reduced resistance to the outflow of urine in benign prostatic hyperplasia. Taking drug at bedtime reduces risks associated with orthostatic hypotension.
phentolamine (Regitine)	Blocks α_1-adrenergic receptors, resulting in peripheral vasodilation (decreases SVR and BP).	Used in short-term management of pheochromocytoma. Also used locally to prevent necrosis of skin and subcutaneous tissue after extravasation of adrenergic drug. No oral formulation.
β-Adrenergic Blockers		
Cardioselective Blockers acebutolol (Sectral) atenolol (Tenormin) betaxolol (Kerlone) bisoprolol (Zebeta) esmolol (Brevibloc) metoprolol (Lopressor) nebivolol (Bystolic)	Cardioselective agents block β_1-adrenergic receptors (see Table 33-1). Reduce BP by blocking β-adrenergic effects. Decrease CO and reduce sympathetic vasoconstrictor tone. Decrease renin secretion by kidneys.	Monitor pulse and BP regularly. Use with caution in patients with diabetes mellitus because drug may depress the tachycardia associated with hypoglycemia. Esmolol is for IV use only. Cardioselective agents lose cardioselectivity at higher doses.
Nonselective Blockers carteolol (Cartrol) nadolol (Corgard) penbutolol (Levatol) pindolol (Visken) propranolol (Inderal) timolol (Blocadren)	Nonselective agents block β_1- and β_2-adrenergic receptors (see Table 33-1). Reduce BP by blocking β_1- and β_2-adrenergic effects.	Same as cardioselective, except nonselective agents may cause bronchospasm, especially in patients with a history of asthma.
Mixed α- and β-Blockers		
carvedilol (Coreg) labetalol (Normodyne, Trandate)	α_1-, β_1-, and β_2-adrenergic blocking properties producing peripheral vasodilation and decreased heart rate (see Table 33-1). Reduce CO, SVR, and BP.	Same as β-adrenergic blockers. IV form available for hypertensive crisis in hospitalized patients. Patients must be kept supine during IV administration. Assess patient tolerance of upright position (severe orthostatic hypotension) before allowing upright activities (e.g., commode).
Direct Vasodilators		
fenoldopam (Corlopam)	Activates dopamine receptors, resulting in systemic and renal vasodilation.	IV use only for hypertensive crisis in hospitalized patients. Use cautiously in patients with glaucoma. Patient should remain supine for 1 hr after administration.
hydralazine (Apresoline)	Reduces SVR and BP by direct arterial vasodilation.	IV use for hypertensive crisis in hospitalized patients. Twice-daily oral dosage. Not used as monotherapy because of side effects. Contraindicated in patients with coronary artery disease.
minoxidil (Loniten)	Reduces SVR and BP by direct arterial vasodilation.	Reserved for treatment of severe hypertension associated with renal failure and resistant to other therapy. Once- or twice-daily dosage.
nitroglycerin (Tridil)	Relaxes arterial and venous smooth muscle, reducing preload and SVR. At low dose, venous dilation predominates; at higher dose, arterial dilation is present.	IV use for hypertensive crisis in hospitalized patients with myocardial ischemia. Administered by continuous IV infusion with pump or control device.

TABLE 33-7 DRUG THERAPY—cont'd

Hypertension

Drug	Mechanism of Action	Nursing Considerations
Direct Vasodilators—cont'd		
sodium nitroprusside (Nipride)	Direct arterial vasodilation reduces SVR and BP.	IV use for hypertensive crisis in hospitalized patients. Administered by continuous IV infusion with pump or control device. Intraarterial monitoring of BP recommended. Wrap IV solutions with an opaque material to protect from light. Stable for 24 hr. Metabolized to cyanide, then thiocyanate. Monitor thiocyanate levels with prolonged use (>3 days) or doses (≥4 mcg/kg/min).
Ganglionic Blockers		
trimethaphan (Arfonad)	Interrupts adrenergic control of arteries, results in vasodilation, and reduces SVR and BP.	IV use for initial control of BP in patient with dissecting aortic aneurysm. Administered by continuous IV infusion with pump or control device.
Angiotensin Inhibitors		
Angiotensin-Converting Enzyme Inhibitors		
benazepril (Lotensin) captopril (Capoten) enalapril (Vasotec) fosinopril (Monopril) lisinopril (Prinivil, Zestril) moexipril (Univasc) perindopril (Aceon) quinapril (Accupril) ramipril (Altace) trandolapril (Mavik)	Inhibit ACE, reduce conversion of angiotensin I to angiotensin II (A-II). Inhibit A-II–mediated vasoconstriction.	Aspirin and NSAIDs may reduce drug effectiveness. Addition of diuretic enhances drug effect. Should not be used with potassium-sparing diuretics. Inhibit breakdown of bradykinin, which may cause a dry, hacking cough. Captopril may be given orally for hypertensive crisis.
enalapril (Vasotec IV)	Inhibits ACE when oral agents not appropriate.	Given IV over 5 min. Monitor BP.
Angiotensin II Receptor Blockers		
candesartan (Atacand) eprosartan (Teveten) irbesartan (Avapro) losartan (Cozaar) olmesartan (Benicar) telmisartan (Micardis) valsartan (Diovan)	Prevent action of A-II and produce vasodilation and increased Na^+ and water excretion.	Full effect on BP may not be seen for 3-6 wk. Do not affect bradykinin levels, therefore acceptable alternative to ACE inhibitors in people who develop dry cough.
Renin Inhibitors		
aliskiren (Tekturna)	Directly inhibits renin, thus reducing conversion of angiotensinogen to angiotensin I.	May cause angioedema of the face, extremities, lips, tongue, glottis, and/or larynx. Not to be used in pregnancy.
Calcium Channel Blockers		
Non-Dihydropyridines		
diltiazem extended release (Cardizem LA, Dilacor XR) verapamil intermediate release (Isoptin, Calan) verapamil long-acting (Covera-HS, Calan SR) verapamil timed-release (Verelan PM)	Inhibit movement of Ca^{2+} across cell membrane, resulting in vasodilation. Cardioselective resulting in decrease in heart rate and slowing of AV conduction.	Use with caution in patients with heart failure. Serum concentrations and toxicity of certain calcium channel blockers may be increased by grapefruit juice; avoid concurrent use. Used for supraventricular tachydysrhythmias. Avoid in patients with second- or third-degree AV block or left ventricular systolic dysfunction.
Dihydropyridines		
amlodipine (Norvasc) clevidipine (Cleviprex) felodipine (Plendil) isradipine (DynaCirc CR) nicardipine sustained release (Cardene SR) nifedipine long acting (Adalat CC, Procardia XL) nisoldipine (Sular)	Cause vascular smooth muscle relaxation resulting in decreased SVR and arterial BP.	More potent peripheral vasodilators. Clevidipine is for IV use only. Use of sublingual short-acting nifedipine in hypertensive emergencies is unsafe and not effective. Serious adverse events (e.g., stroke, acute MI) have been reported. IV nicardipine available for hypertensive crisis in hospitalized patients. Change peripheral IV infusion sites every 12 hr.

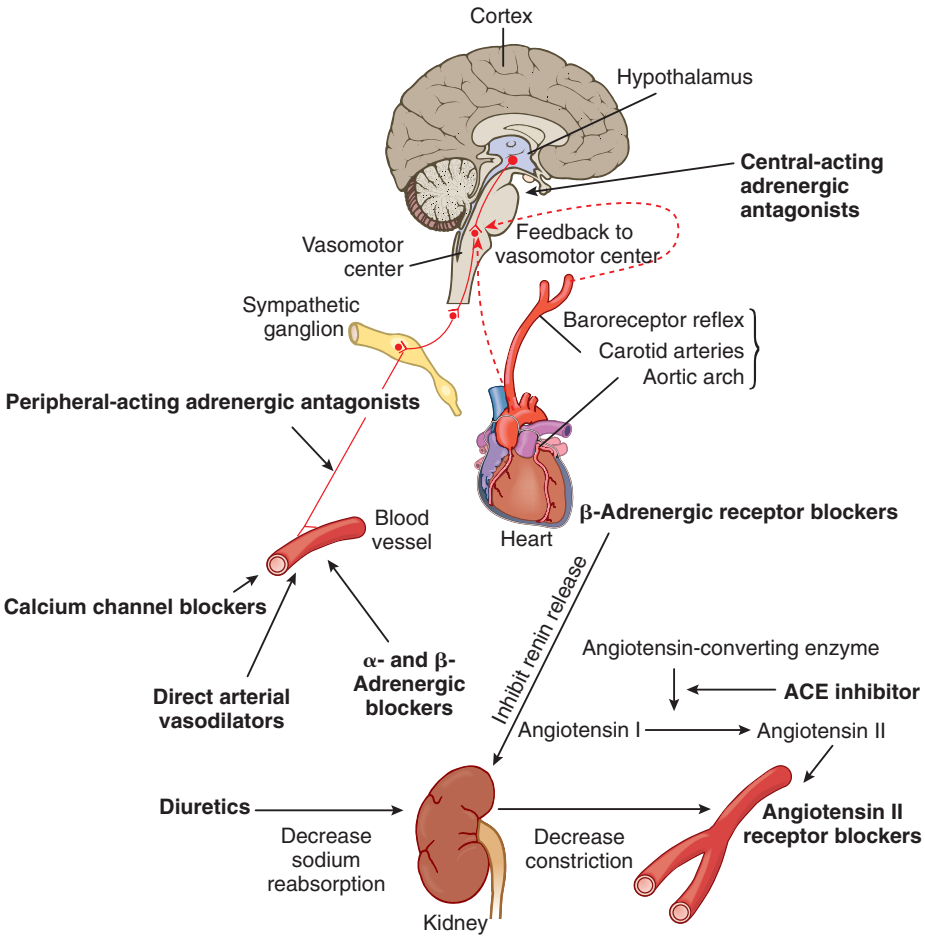

FIG. 33-3 Site and method of action of various antihypertensive drugs *(bold type). ACE,* Angiotensin-converting enzyme.

adrenergic (SNS) inhibitors, direct vasodilators, angiotensin and renin inhibitors, and calcium channel blockers.[17,18] Fig. 33-3 presents the various sites and methods of action of antihypertensive drugs.

Although the precise action of diuretics in the reduction of BP is unclear, it is known that they promote sodium and water excretion, reduce plasma volume, and reduce the vascular response to catecholamines. Adrenergic-inhibiting agents act by decreasing the SNS effects that increase BP. Adrenergic inhibitors include drugs that act centrally on the vasomotor center and peripherally to inhibit NE release or to block the adrenergic receptors on blood vessels. Direct vasodilators decrease the BP by relaxing vascular smooth muscle and reducing SVR. Calcium channel blockers increase sodium excretion and cause vasodilation by preventing the movement of extracellular calcium into cells.

There are two types of angiotensin inhibitors. The first type is angiotensin-converting enzyme (ACE) inhibitors. These prevent the conversion of angiotensin I to A-II and thus reduce A-II-mediated vasoconstriction and sodium and water retention. The second type is A-II receptor blockers (ARBs). These prevent A-II from binding to its receptors in the blood vessel walls.

Most patients who are hypertensive require two or more antihypertensive medications to achieve their goal BP. The addition of a second drug from a different class is started when use of a single drug in adequate doses fails to achieve the goal BP. These can be separate prescriptions or combination therapy (Table 33-8). If a drug is not tolerated or is contraindicated, then a drug from another class is used.

Once antihypertensive therapy is started, patients should return for follow-up and adjustment of medications at monthly intervals until the goal BP is reached. More frequent visits are necessary for patients with stage 2 hypertension or with co-morbidities. After BP is at goal and stable, follow-up visits can usually be at 3- to 6-month intervals. Co-morbidities (e.g., heart failure), associated diseases (e.g., diabetes mellitus), and the need for ongoing monitoring (e.g., laboratory testing) influence the frequency of visits.

Patient and Caregiver Teaching Related to Drug Therapy. Side effects of antihypertensive drugs are common and may be so severe or undesirable that the patient does not adhere to the therapy[17,18] (see Table 33-7). Patient and caregiver teaching related to drug therapy helps them identify and minimize side effects. This may help the patient adhere to therapy. Side effects may be an initial response to a drug and may decrease over time. Informing the patient about side effects that may decrease with time may enable the person to continue taking the drug. The number or severity of side effects may relate to the dosage. It may be necessary to change the drug or decrease the dosage. Advise the patient to report all side effects to the health care provider who prescribes the medication.

A common side effect of several of these drugs is orthostatic hypotension. This condition results from an alteration of the

TABLE 33-8 DRUG THERAPY

Combination Therapy for Hypertension

Combinations	Trade Names
Angiotensin-Converting Enzyme Inhibitors and Diuretics	
benazepril/hydrochlorothiazide	Lotensin HCT
captopril/hydrochlorothiazide	Capozide
enalapril/hydrochlorothiazide	Vaseretic
fosinopril/hydrochlorothiazide	Monopril-HCT
lisinopril/hydrochlorothiazide	Prinzide, Zestoretic
moexipril/hydrochlorothiazide	Uniretic
quinapril/hydrochlorothiazide	Accuretic
Angiotensin II Receptor Blockers and Diuretics	
azilsartan/chlorthalidone	Edarbyclor
candesartan/hydrochlorothiazide	Atacand HCT
eprosartan/hydrochlorothiazide	Teveten HCT
irbesartan/hydrochlorothiazide	Avalide
losartan/hydrochlorothiazide	Hyzaar
olmesartan medoxomil/ hydrochlorothiazide	Benicar HCT
telmisartan/hydrochlorothiazide	Micardis HCT
valsartan/hydrochlorothiazide	Diovan HCT
β-Adrenergic Blockers and Diuretics	
atenolol/chlorthalidone	Tenoretic
bisoprolol/hydrochlorothiazide	Ziac
metoprolol/hydrochlorothiazide	Lopressor HCT
nadolol/bendroflumethiazide	Corzide
propranolol/hydrochlorothiazide	Inderide
timolol/hydrochlorothiazide	Timolide
Centrally Acting Drugs and Diuretics	
methyldopa/hydrochlorothiazide	Aldoril
reserpine/chlorthalidone	Demi-Regroton
reserpine/hydrochlorothiazide	Hydropres
prazosin/polythiazide	Minizide
guanethidine/hydrochlorothiazide	Esimil
clonidine/chlorthalidone	Combipres
Angiotensin-Converting Enzyme Inhibitors and Calcium Channel Blockers	
amlodipine/benazepril	Lotrel
enalapril/felodipine	Lexxel
enalapril/diltiazem	Teczem
trandolapril/verapamil	Tarka
Angiotensin II Receptor Blockers and Calcium Channel Blockers	
telmisartan/amlodipine	Twynsta
valsartan/amlodipine	Exforge
olmesartan/amlodipine	Azor
Diuretics and Diuretics	
amiloride/hydrochlorothiazide	Moduretic
spironolactone/hydrochlorothiazide	Aldactazide
triamterene/hydrochlorothiazide	Dyazide, Maxzide
Angiotensin II Receptor Blocker, Calcium Channel Blocker, and Diuretic	
olmesartan medoxomil/amlodipine/ hydrochlorothiazide	Tribenzor

autonomic nervous system's mechanisms for regulating BP, which are required for position changes. Consequently, the patient may feel dizzy and faint when assuming an upright position after sitting or lying down. Table 33-12 (later in this chapter) presents specific measures to control or decrease orthostatic hypotension.

EVIDENCE-BASED PRACTICE

Applying the Evidence

You are caring for P.N., a 46-year-old man with a history of poorly controlled hypertension and chronic kidney disease. You note that he is taking three antihypertensive medications. He tells you that he can no longer live with the side effects of these drugs (e.g., fatigue, dry mouth, erectile dysfunction). He states that he wants to stop taking the medications. He believes that if he changes his lifestyle by reducing salt from his diet, losing weight, and beginning exercise, he can control his hypertension.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Uncontrolled BP places persons with concurrent risk for cardiovascular disease (e.g., diabetes, kidney disease) at highest risk for a cardiovascular event (e.g., stroke). Most hypertensive patients will need two or more medications to achieve their goal BP in addition to lifestyle changes.	You know that lifestyle changes can help reduce and control BP in many patients. However, patients with poorly controlled hypertension and target organ disease require medications to control BP and prevent further complications.	P.N. wishes to eliminate antihypertensive medications because of unpleasant and unacceptable side effects that are interfering with his quality of life.

Your Decision and Actions

You discuss the role of lifestyle changes and medications in the treatment of hypertension and prevention of (further) target organ disease with P.N. You support his intention to make lifestyle changes and validate his concerns regarding the side effects of the medications. You discuss the side effects that he is experiencing and explain that it may be possible to change some of his medications to eliminate or reduce the unpleasant side effects. However, given the severity of his hypertension and the chronic kidney disease, he will need to be on medications on a long-term basis. Any of his plans to discontinue medications need to be discussed with his physician.

Reference for Evidence

National Heart, Lung, and Blood Institute: Seventh report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7), NIH Publication No. 04-5230, Bethesda, Md, 2004, The Institute. Retrieved from *www.nhlbi.nih.gov/guidelines/hypertension/jnc7full.pdf*.

Sexual problems may occur with many of the antihypertensive drugs and can be a major reason that patients do not adhere to the treatment plan. Problems can range from reduced libido to erectile dysfunction. Rather than discussing a sexual problem with a health care provider, the patient may decide just to stop taking the drug. Approach the patient on this sensitive subject and encourage discussion of any sexual problem that may be experienced. The sexual problems may be easier for the patient to discuss once you explain that the drug may be the source of the problem. Changing to another antihypertensive drug can decrease or remove these side effects. Encourage the patient to discuss sexual issues with the health care provider. If the patient is reluctant to do so, offer to alert the health care provider to the side effects that the patient is experiencing. There are many drug options in treating hypertension. A plan that is acceptable to the patient should be achievable.[19]

Some unpleasant side effects of drugs result from their therapeutic effect, but these can be decreased. For example, diuret-

TABLE 33-9 CAUSES OF RESISTANT HYPERTENSION

Improper BP measurement
Volume overload
- Excess salt intake
- Volume retention from kidney disease
- Inadequate diuretic therapy

Drug-induced or other causes
- Nonadherence
- Illegal drugs (e.g., cocaine, amphetamines)
- Inadequate drug dosages
- Inappropriate combinations of drug therapy
- Nonsteroidal antiinflammatory drugs
- Sympathomimetics (e.g., decongestants, diet pills)
- Oral contraceptives
- Corticosteroids
- Cyclosporine and tacrolimus (Prograf)
- Erythropoietin
- Licorice (including some chewing tobacco)
- Selected over-the-counter dietary or herbal supplements and medicines (e.g., ma huang, bitter orange)

Associated conditions
- Increasing obesity
- Excess alcohol consumption

Identifiable causes of secondary hypertension

Source: National Heart, Lung, and Blood Institute: Seventh report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7), NIH Publication No. 04-5230, Bethesda, Md, 2004, The Institute. Retrieved from www.nhlbi.nih.gov/guidelines/hypertension/jnc7full.pdf.

ics cause dry mouth and frequent voiding. Sugarless gum or hard candy may help ease the dry mouth. Taking diuretics earlier in the day may limit frequent voiding during the night and preserve sleep. Side effects of vasodilators and adrenergic inhibitors decrease if the drugs are taken in the evening. Remember that BP is lowest during the night and highest shortly after awakening. Therefore drugs with a 24-hour duration of action should be taken as early in the morning as possible (e.g., 4 or 5 AM if the patient awakens to void).

Resistant Hypertension. *Resistant hypertension* is the failure to reach goal BP in patients who are taking full doses of an appropriate three-drug therapy regimen that includes a diuretic. Carefully explore reasons why the patient is not at goal BP (Table 33-9). Studies have shown that the use of *renal denervation* (destruction of overactive renal nerves) reduces BP and muscle sympathetic nerve activity in patients with resistant hypertension. The exact mechanisms underlying sympathetic neural inhibition are not clear.[20]

NURSING MANAGEMENT PRIMARY HYPERTENSION

NURSING ASSESSMENT

Table 33-10 presents subjective and objective data to obtain from a patient with hypertension.

NURSING DIAGNOSES

Nursing diagnoses and collaborative problems for the patient with hypertension include, but are not limited to, the following.

- Ineffective self-health management *related to* lack of knowledge of pathology, complications, and management of hypertension
- Anxiety *related to* complexity of management regimen

TABLE 33-10 NURSING ASSESSMENT

Hypertension

Subjective Data

Important Health Information

Past health history: Known duration and past workup of high BP; cardiovascular, cerebrovascular, renal, or thyroid disease; diabetes mellitus; pituitary disorders; obesity; dyslipidemia; menopause or hormone replacement status

Medications: Use of any prescription or over-the-counter, illicit, or herbal medications or products; previous use of antihypertensive drug therapy

Functional Health Patterns

Health perception–health management: Family history of hypertension or cardiovascular disease; tobacco use, alcohol use; sedentary lifestyle

Nutritional-metabolic: Usual salt and fat intake; weight gain or loss

Elimination: Nocturia

Activity-exercise: Fatigue; dyspnea on exertion, palpitations, exertional chest pain; intermittent claudication, muscle cramps; usual pattern and type of exercise

Cognitive-perceptual: Dizziness; blurred vision; paresthesias

Sexual-reproductive: Erectile dysfunction, decreased libido

Coping–stress tolerance: Stressful life events

Objective Data

Cardiovascular

SBP consistently >140 mm Hg or DBP >90 mm Hg, orthostatic changes in BP and pulse; bilateral BPs significantly different; abnormal heart sounds; laterally displaced, apical pulse; diminished or absent peripheral pulses; carotid, renal, or femoral bruits; peripheral edema

Gastrointestinal

Obesity (BMI ≥30 kg/m^2); abnormal waist-hip ratio

Neurologic

Mental status changes

Possible Diagnostic Findings

Abnormal serum electrolytes (especially potassium); ↑ BUN, creatinine, glucose, cholesterol, and triglyceride levels; proteinuria, microalbuminuria, microscopic hematuria; evidence of ischemic heart disease and left ventricular hypertrophy on ECG; evidence of structural heart disease and left ventricular hypertrophy on echocardiogram; evidence of arteriovenous nicking, retinal hemorrhages, and papilledema on funduscopic examination

BMI, Body mass index; *DBP,* diastolic blood pressure; *SBP,* systolic blood pressure.

- Sexual dysfunction *related to* side effects of antihypertensive medication
- Risk for decreased cardiac tissue perfusion
- Risk for ineffective cerebral tissue perfusion
- Risk for ineffective renal perfusion
- Potential complication: stroke
- Potential complication: MI

PLANNING

The overall goals for the patient with hypertension are that the patient will (1) achieve and maintain the goal BP; (2) understand and follow the therapeutic plan; (3) experience minimal or no unpleasant side effects of therapy; and (4) be confident of the ability to manage and cope with this condition.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Primary prevention of hypertension is a cost-effective approach. Current recommendations for primary

prevention include lifestyle modifications that prevent or delay the rise in BP in at-risk people. Following the DASH diet and reducing sodium can lower BP (see eTable 33-1). This diet is recommended for primary prevention in the general population. Dietary changes by the food industry (e.g., reducing the amount of salt in processed foods) may also be effective.

To raise awareness about the dangers of high BP, the National Heart, Lung, and Blood Institute provides web-based educational materials for health care providers, patients, and the public. (See Your Guide to Lowering High Blood Pressure at *www.nhlbi.nih.gov/hbp*.)

Individual Patient Evaluation. Hypertension is usually identified through routine screening for insurance, preemployment, and military physical examinations. You are in an ideal position to assess for the presence of hypertension, identify the risk factors for hypertension and CAD, and teach the patient about these conditions. In addition to BP measurement, a complete health assessment should include such factors as age, gender, and race; diet history (including sodium and alcohol intake); weight patterns; tobacco use; and family history of heart disease, stroke, renal disease, and diabetes mellitus. Note all medications taken, both prescribed and over-the-counter drugs. Finally, ask the patient about a previous history of high BP and the results of treatment (if any) (see Table 33-10).

Blood Pressure Measurement. BP can be measured using the oscillatory or auscultatory method.[21] Initially, take the BP in both arms to note any differences. Atherosclerosis in the subclavian artery can cause a falsely low reading on the side where the narrowing occurs. Use the arm with the highest BP and take at least two readings, a minimum of 1 minute apart (see Table 33-11). Waiting for at least 1 minute between readings allows the blood to drain from the arm and prevents inaccurate readings. Record the average pressure as the value for that visit.

Proper size and correct placement of the BP cuff are critical for accurate measurement. Place the cuff snugly around the patient's bare upper arm with the midline of the bladder of the cuff (usually marked on the cuff by the manufacturer) placed above the brachial artery. Place the patient's arm at the level of the heart during BP measurement. For BP measurements taken in the sitting position, raise and support the arm at the level of the heart. For measurements taken in a supine position, raise and support (e.g., with a small pillow) the arm at heart level. If the arm is resting on the bed, it will be below heart level.

If neither upper arm can be used to measure the BP (e.g., presence of IV lines, fistula), or if a maximum size BP cuff does not fit the upper arm, use the forearm. In this case, position the proper size cuff midway between the elbow and the wrist. Auscultate Korotkoff sounds over the radial artery or use a Doppler device to note SBP. Use of an oscillometric device on the forearm is acceptable. Forearm and upper arm BPs are not interchangeable.[21]

SAFETY ALERT

- If using the forearm for BP measurement, always document the site.
- BP cuffs that are too small or too large will result in readings that are falsely high or low, respectively.
- If bilateral BP measurements are not equal, document this finding and use the arm with the highest BP for all future measurements.

Assess for orthostatic (or postural) changes in BP and pulse in older adults, in people taking antihypertensive drugs, and in patients who report symptoms consistent with reduced BP on standing (e.g., light-headedness, dizziness, syncope). Measure serial BP and pulse with the patient in the supine, sitting, and standing positions. Initially, measure BP and pulse with the patient in the supine position after at least 2 to 3 minutes of rest. Reposition the patient in the sitting position with legs dangling and measure BP and pulse again within 1 to 2 minutes. Finally reposition the patient to the standing position and measure the BP and pulse within 1 to 2 minutes. Usually the SBP decreases slightly (less than 10 mm Hg) on standing, whereas the DBP and pulse increase slightly. A decrease of 20 mm Hg or more in SBP, a decrease of 10 mm Hg or more in DBP, and/or an increase in the HR of 20 beats/minute or more from supine to standing indicates **orthostatic hypotension.** Common causes of orthostatic hypotension include intravascular volume loss and inadequate vasoconstrictor mechanisms related to disease or medications.

DRUG ALERT: Doxazosin (Cardura)

- Use caution with administration of initial dose.
- Syncope (sudden loss of consciousness) occasionally occurs 30 to 90 min after the initial dose, a too-rapid increase in dose, or addition of another antihypertensive agent to therapy.

In the acute care setting, BP measurement is usually performed to evaluate vital signs, volume status, and effects of medications, rather than to diagnose hypertension. Drugs, acute illness, bed rest, and alterations in usual diet all have an impact on BP values. Inform the health care provider of any patient with a persistent increase in BP. These patients

TABLE 33-11 BLOOD PRESSURE MEASUREMENT

The patient should not have smoked, exercised, or ingested caffeine within 30 min before measurement.

1. Seat patient with legs uncrossed, feet on the floor, and back supported. Bare patient's arm and support it at heart level.
2. Begin measurement after patient has rested quietly for 5 min. Ask patient to relax as much as possible and not to talk during the measurement.
3. Measure and record BP in both arms initially.
4. Select the appropriate cuff size, following instructions for fit and placement according to manufacturer's recommendations.
5. Take the BP with a recently calibrated aneroid or mercury sphygmomanometer, or electronic oscillometric device. Accuracy of oscillometric devices may be limited if patients are hypertensive, are hypotensive, or have heart dysrhythmias (e.g., atrial fibrillation).
6. For auscultatory measurement, estimate SBP by palpating the radial pulse and inflating the cuff until the pulse disappears. Inflate the cuff 20-30 mm Hg above this level.
7. Deflate the cuff at a rate of 2-3 mm Hg/sec.
8. Record the SBP and the DBP. Note the SBP when the first of two or more Korotkoff sounds is heard and the DBP when sound disappears.
9. Average two or more readings (taken at intervals of at least 1 min). Obtain additional readings if the first two readings differ by more than 5 mm Hg.
10. Provide the patient (verbally and in writing) with the BP reading, BP goal, and recommendations for follow-up.

DELEGATION DECISIONS

Caring for the Patient With Hypertension

Many members of the health care team obtain blood pressure (BP) readings. In patients with stable hypertension, LPN/LVNs and UAP provide most of the routine BP monitoring. For patients in hypertensive crisis, the RN is responsible for titration of medications and ongoing assessment and evaluation of BP.

Role of Registered Nurse (RN)

- Develop and conduct hypertension screening programs.
- Assess patients for hypertension risk factors, and develop risk modification plans.
- Teach patients about lifestyle management and medication use.
- Evaluate the effectiveness of lifestyle management and medications in decreasing BP to acceptable levels.
- Teach about home BP monitoring, including the correct use of automatic BP monitors.
- Make appropriate referrals to other health care professionals, such as dietitians or stress management programs.
- Monitor for complications of hypertension such as coronary artery disease, heart failure, cerebrovascular disease, peripheral vascular disease, and renal disease.
- Assess the patient with hypertensive urgency or crisis for target organ disease (encephalopathy, renal insufficiency, cardiac decompensation).
- Manage the patient with hypertensive crisis, including administration of medications and evaluation for resolution of the emergency.

Role of Licensed Practical Nurse (LPN)

- Administer antihypertensive medications to stable patients.
- Monitor for adverse effects of antihypertensive medications.
- Reinforce teaching about medications and lifestyle management.

Role of Unlicensed Assistive Personnel (UAP)

- Obtain accurate BP readings in outpatient and inpatient settings.
- Report high or low BP readings immediately to RN.
- Check for postural changes in BP as directed.

should be evaluated for hypertension before discharge, if appropriate, or after discharge.[9]

Screening Programs. Screening programs in the community are widely used to check individuals for high BP. At the time of the BP measurement, give each person a written, numeric value of the reading. If necessary, explain why further evaluation is needed. Effort and resources should focus on the following: (1) controlling BP in persons already identified as having hypertension; (2) identifying and controlling BP in at-risk groups such as African Americans, obese people, and blood relatives of people with hypertension; and (3) screening those with limited access to the health care system.

Cardiovascular Risk Factor Modification. Teaching regarding CVD risk factors is appropriate for all individuals and during targeted screening programs. Modifiable cardiovascular risk factors include hypertension, obesity, diabetes mellitus, tobacco use, and physical inactivity. Discuss lifestyle modifications based on identified risk factors. (Table 34-2 discusses health-promoting behaviors for risk factor reduction.)

AMBULATORY AND HOME CARE

Your primary responsibilities for long-term management of hypertension are to assist the patient in reducing BP and adhering to the treatment plan. Your nursing actions include evaluating therapeutic effectiveness, detecting and reporting any adverse treatment effects, assessing and enhancing adherence, and patient and caregiver teaching (Table 33-12).

TABLE 33-12 PATIENT & CAREGIVER TEACHING GUIDE

Hypertension

When teaching the patient and/or caregiver about hypertension, include the following information.

General Instructions

1. Provide the patient's BP reading and explain what it means (e.g., high, low, normal, borderline). Encourage patient to monitor BP at home and instruct the patient to call health care provider if BP exceeds high or low limits set by health care provider.
2. Hypertension is usually asymptomatic and symptoms (e.g., nosebleeds) do not reliably indicate BP levels.
3. Hypertension means high BP and does not relate to a "hyper" personality.
4. Long-term therapy and follow-up care are necessary to treat hypertension. Therapy involves lifestyle changes (e.g., weight management, sodium reduction, smoking cessation, regular physical activity) and, in most cases, medications.
5. Therapy will not cure, but should control hypertension.
6. Controlled hypertension usually results in an excellent prognosis and a normal lifestyle.
7. Explain the potential dangers of uncontrolled hypertension (e.g., target organ disease).

Instructions Related to Medications

1. Be specific about the names, actions, dosages, and side effects of prescribed medications.
2. Help the patient plan regular and convenient times for taking medications and measuring BP.
3. Do not stop drugs abruptly because withdrawal may cause a severe hypertensive reaction.
4. Do not double up on doses when a dose is missed.
5. If BP increases, the patient should not increase the medication dosage before consulting with the health care provider.
6. Do not take a medication belonging to someone else.
7. Supplement diet with foods high in potassium (e.g., citrus fruits, green leafy vegetables) if taking potassium-wasting diuretics.
8. Avoid hot baths, excessive amounts of alcohol, and strenuous exercise within 3 hr of taking medications that promote vasodilation.
9. Many medications cause orthostatic hypotension. The effects of orthostatic hypotension can be reduced by rising slowly from bed, sitting on the side of the bed for a few minutes, standing slowly, and beginning to move if no symptoms develop (e.g., dizziness, light-headedness). Do not stand still for prolonged periods, do leg exercises to increase venous return, or sleep with the head of the bed raised. Do lie or sit down when dizziness occurs.
10. Many medications cause sexual problems (e.g., erectile dysfunction, decreased libido). Consult with the health care provider about changing drugs or dosages if sexual problems develop.
11. The side effects of medication(s) may decrease with time.
12. Be careful about taking potentially high-risk over-the-counter medications, such as high-sodium antacids, appetite suppressants, and cold and sinus medications. Read warning labels and consult with a pharmacist.

Home BP Monitoring. Most patients with known or suspected hypertension should monitor their BP at home. Home BP monitoring reduces the white coat effect of measurement by a health care provider. The readings are often lower than those taken in the office setting and are a better predictor of CVD risk.[22]

Patient teaching is critical to ensure accuracy. Tell patients to buy an oscillometric BP monitor that uses a cuff for the upper arm. The patient should bring the BP monitor to the office to verify proper cuff size, accuracy of the device, and the patient's technique.

INFORMATICS IN PRACTICE

Monitoring Blood Pressure

- For patients with hypertension who have a smart phone or computer access, encourage them to use applications aimed at helping them manage their care, including BP self-monitoring and appointment tracking.
- Patients enter their SBP and DBP, heart rate, and other information, including the arm measured. They also indicate whether they were standing, sitting, or lying down and time the BP was taken.
- At appointment time, you can review the reports generated from the application to assist you in determining how well the patient's BP has been controlled.

DBP, Diastolic BP; *SBP*, systolic BP.

Teach the patient to obtain a BP according to the steps in Table 33-11. Tell the patient to measure BP in the nondominant arm, or arm with the higher BP if there is a known difference between arms. Advise the patient to measure BP first thing in the morning (if possible, before taking medications) and at night before going to bed. Tell the patient to keep a log of all BP measurements and to bring the log to office visits.

For clinical decision making (e.g., adjustments in dosage, start of new drug), instruct patients to take BP readings as described for 1 week. Stable, normotensive patients should measure morning and evening BP for at least 1 week every 3 months.[22] Devices that have memory or printouts of the readings are recommended to ensure accurate reporting.[9]

Home BP readings may help achieve patient adherence by reinforcing the need to remain on therapy. However, some patients become overly concerned with the BP readings. Discourage too frequent checking of their BP. Generally, home BP monitoring should reassure the patient that the treatment is effective.

Patient Adherence. A major problem in the long-term management of the patient with hypertension is poor adherence with the prescribed treatment plan. The reasons are many and include inadequate patient teaching, unpleasant side effects of drugs, return of BP to normal range while on medication, lack of motivation, high cost of drugs, lack of insurance, and lack of a trusting relationship between the patient and the health care provider. Also assess the patient's diet, activity level, and lifestyle as additional indicators of adherence.

Individually assess patients to determine the reasons why the patient is not adhering to the treatment and develop a plan with the patient to improve adherence. The plan should be compatible with the patient's personality, habits, and lifestyle. Active patient participation increases the likelihood of adherence to the treatment plan. Measures such as including the patient in the development of a medication schedule, selecting medications that are affordable, and involving caregivers help increase patient adherence.

Substituting combination drugs for multiple drugs once the BP is stable may also facilitate adherence. Combination drugs reduce the number of pills the patient has to take each day and may reduce costs.

It is important to help the patient and caregiver understand that hypertension is a chronic illness that cannot be cured. Emphasize that it can be controlled with drug therapy, diet changes, physical activity, periodic follow-up, and other relevant lifestyle modifications.

EVALUATION

The overall expected outcomes are that the patient with hypertension will

- Achieve and maintain goal BP as defined for the individual
- Understand, accept, and implement the therapeutic plan
- Experience minimal or no unpleasant side effects of therapy

GERONTOLOGIC CONSIDERATIONS

HYPERTENSION

The prevalence of hypertension increases with age. The lifetime risk of developing hypertension is approximately 90% for middle-aged (ages 55 to 65) and older (over 65) normotensive men and women.[17] Isolated systolic hypertension (ISH) is the most common form of hypertension in people over 50 years of age. Additionally, older adults are more likely to have white coat hypertension.[9]

The pathophysiology of hypertension in the older adult involves the following age-related physical changes: (1) loss of elasticity in large arteries from atherosclerosis, (2) increased collagen content and stiffness of the myocardium, (3) increased peripheral vascular resistance, (4) decreased adrenergic receptor sensitivity, (5) blunting of baroreceptor reflexes, (6) decreased renal function, and (7) decreased renin response to sodium and water depletion.

In the older adult who is taking antihypertensive medication, absorption of some drugs may be altered as a result of decreased blood flow to the gut. Metabolism and excretion of drugs may also be prolonged.

Careful technique is important in assessing BP in older adults. Some older people have a wide gap between the first Korotkoff sound and subsequent beats. This is called the *auscultatory gap.* Failure to inflate the cuff high enough may result in underestimating SBP (see Table 33-11).

The recommended BP goals are less than 140/90 mm Hg for people 65 to 79 years of age and an SBP of 140 to 145 mm Hg for those 80 years and older. Lower goals are recommended for older adults with diabetes mellitus, kidney disease, or CAD. Preferred antihypertensive drugs are low-dose thiazides, calcium channel blockers, and RAAS blockers. A diuretic should always be the first or second drug ordered for this age-group.[17]

Because of varying degrees of impaired baroreceptor reflexes, orthostatic hypotension often occurs in older adults, especially in those with ISH. Orthostatic hypotension in this age-group is often associated with volume depletion or chronic disease states, such as decreased renal and hepatic function or electrolyte imbalance. To reduce the likelihood of orthostatic hypotension, antihypertensive drugs should be started at low doses and increased slowly. Measure BP and HR in the supine, sitting, and standing positions at every visit.

Older adults experience postprandial drops in BP. The greatest decrease occurs approximately 1 hour after eating. BP returns to preprandial levels 3 to 4 hours after eating. Avoid giving vasoactive medications with meals.[7]

After CVD, arthritis is the second most prevalent disease in older adults. The most frequently taken drugs by older adults are nonsteroidal antiinflammatory drugs (NSAIDs), both prescription and over-the-counter. Nonselective NSAIDs (e.g., ibuprofen [Advil]) and selective NSAIDs (e.g., celecoxib [Celebrex]) have caused loss of BP control and heart failure. Additionally, there is the potential for adverse renal effects and/or hyperka-

TABLE 33-13 CAUSES OF HYPERTENSIVE CRISIS

- Exacerbation of chronic hypertension
- Renovascular hypertension
- Preeclampsia, eclampsia
- Pheochromocytoma
- Drugs (cocaine, amphetamines)
- Monoamine oxidase inhibitors taken with tyramine-containing foods
- Rebound hypertension (from abrupt withdrawal of some hypertensive drugs such as clonidine [Catapres] or β-adrenergic blockers)
- Head injury
- Acute aortic dissection

lemia when NSAIDs are used with ACE inhibitors, ARBs, or aldosterone antagonists.[7]

HYPERTENSIVE CRISIS

Hypertensive crisis is a term used to indicate either a hypertensive urgency or emergency. This is determined by the degree of target organ disease and how quickly the BP must be lowered.

A *hypertensive emergency* develops over hours to days. It is a situation in which a patient's BP is severely elevated (often above 220/140 mm Hg) with clinical evidence of target organ disease. Hypertensive emergencies can cause encephalopathy, intracranial or subarachnoid hemorrhage, acute left ventricular failure, MI, renal failure, dissecting aortic aneurysm, and retinopathy.

Hypertensive urgency develops over days to weeks. This is a situation in which a patient's BP is severely elevated (usually above 180/110 mm Hg), but there is no clinical evidence of target organ disease.[23]

The rate of rise of BP is more important than the absolute value in determining the need for emergency treatment. Patients with chronic hypertension can tolerate much higher BPs than normotensive people. Prompt recognition and management of hypertensive crisis are essential to decrease the threat to organ function and life.

Hypertensive crisis occurs more often in patients with a history of hypertension who have not adhered to their medication regimens or who have been undermedicated. In such cases, rising BP is thought to trigger endothelial damage and the release of vasoconstrictor substances. A vicious cycle of BP elevation follows, leading to life-threatening damage to target organs.

Hypertensive crisis related to cocaine or crack use is a frequent problem. Other drugs such as amphetamines, phencyclidine (PCP), and lysergic acid diethylamide (LSD) can also cause hypertensive crisis that may be complicated by drug-induced seizures, stroke, MI, or encephalopathy. Table 33-13 lists causes of hypertensive crisis.

Clinical Manifestations

A hypertensive emergency is often manifested as *hypertensive encephalopathy*, a syndrome in which a sudden rise in BP is associated with severe headache, nausea, vomiting, seizures, confusion, and coma. The manifestations of encephalopathy are the result of increased cerebral capillary permeability. This leads to cerebral edema and a disruption in cerebral function. On retinal examination, exudates, hemorrhages, and/or papilledema is found[23] (Fig. 33-4).

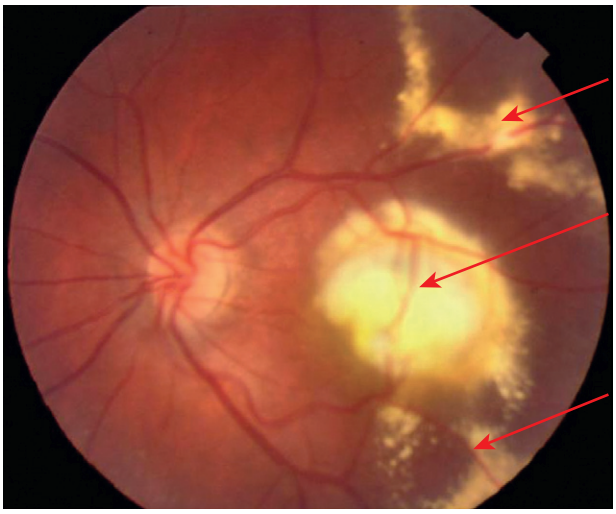

FIG. 33-4 Massive retinal exudates (indicated by *arrows*) from hypertensive retinopathy. To see what a normal retina looks like on ophthalmoscopic examination, see Fig. 21-5 on p. 377.

Renal insufficiency ranging from minor injury to complete renal failure can occur. Rapid cardiac decompensation ranging from unstable angina to MI and pulmonary edema is also possible. Patients can have chest pain and dyspnea. Aortic dissection can develop and will cause sudden, excruciating chest and back pain and possibly reduced or absent pulses in the extremities.

Patient assessment is extremely important. Monitor for signs of neurologic deficits, retinal damage, heart failure, pulmonary edema, and renal failure. The neurologic changes are often similar to those related to a stroke. However, a hypertensive crisis does not show focal or lateralizing signs often seen with a stroke.

NURSING AND COLLABORATIVE MANAGEMENT HYPERTENSIVE CRISIS

BP level alone is a poor indicator of the seriousness of the patient's condition. It is not the major factor in deciding the treatment for a hypertensive crisis. The link between elevated BP and signs of new or progressive target organ disease determines the seriousness of the situation.

Hypertensive emergencies require hospitalization, IV administration of antihypertensive drugs, and intensive care monitoring. In treatment of hypertensive emergencies, the mean arterial pressure (MAP) is often used instead of BP readings to guide and evaluate drug therapy. MAP is calculated as follows:

$$MAP = (SBP + 2\,DBP) \div 3$$

The initial goal is to decrease MAP by no more than 20% to 25%, or to decrease MAP to 110 to 115 mm Hg. If the patient is clinically stable, drugs can be titrated to gradually lower BP over the next 24 hours. Lowering the BP too quickly or too much may decrease cerebral, coronary, or renal perfusion. This could precipitate a stroke, MI, or renal failure.

Special circumstances include patients with aortic dissection. These patients should have their SBP lowered to less than 100 to 120 mm Hg as soon as possible, and if tolerated.[23] Another exception is patients with acute ischemic stroke, in

whom BP is lowered to allow the use of thrombolytic agents. Finally, an elevated BP in the immediate poststroke period may be a compensatory response to improve cerebral perfusion to ischemic brain tissue. There is no clear evidence supporting the use of antihypertensive medications in these patients[1] (see Chapter 58).

IV drugs used for hypertensive emergencies include vasodilators (e.g., sodium nitroprusside [Nitropress], fenoldopam [Corlopam], nicardipine [Cardene]), adrenergic inhibitors (e.g., phentolamine [Regitine], labetalol [Normodyne], esmolol [Brevibloc]), the ACE inhibitor enalapril (Vasotec IV), and the calcium channel blocker clevidipine (Cleviprex)[23,24] (see Table 33-7). Sodium nitroprusside is the most effective IV drug to treat hypertensive emergencies. Oral agents may be given along with IV drugs to help make an earlier transition to long-term therapy.

DRUG ALERT: Labetalol (Normodyne)

- Instruct patient not to discontinue drug abruptly, since this may precipitate angina or heart failure.

Antihypertensive drugs administered IV have a rapid (within seconds to minutes) onset of action. Assess the patient's BP and pulse every 2 to 3 minutes during the initial administration of these drugs. Use an intraarterial line (see Chapter 66) or an automated, noninvasive BP machine to monitor the BP. Titrate the drug according to MAP or BP as ordered. Monitor the ECG for heart dysrhythmias and signs of ischemia or MI. Use extreme caution in treating the patient with CAD or cerebrovascular disease. Measure urine output hourly to assess renal perfusion. Patients receiving IV antihypertensive drugs may be restricted to bed. Getting up (e.g., to use the commode) may cause severe cerebral ischemia and fainting.

Ongoing assessment is essential to evaluate the effectiveness of these drugs and the patient's response to therapy. Frequent neurologic checks, including level of consciousness, pupillary size and reaction, and movement of extremities, help detect any changes in the patient's condition. Monitor cardiac, pulmonary, and renal systems for decompensation caused by the severe elevation in BP (e.g., angina, pulmonary edema, renal failure).

Hypertensive urgencies usually do not require IV medications but can be managed with oral agents. The patient with hypertensive urgency may not need hospitalization, but will require follow-up. The oral drugs most frequently used for hypertensive urgencies are captopril (Capoten), labetalol, clonidine (Catapres), and amlodipine (Norvasc)[23] (see Table 33-7). The disadvantage of oral medications is the inability to regulate the dosage moment to moment, as can be done with IV medications. If a patient with hypertensive urgency is not hospitalized, outpatient follow-up care should be arranged within 24 hours.

Once the hypertensive crisis is resolved, it is important to determine the cause. The patient will need appropriate management and teaching to avoid future crises.

DRUG ALERT: Clonidine (Catapres)

Instruct patient to do the following:

- Change positions slowly to limit orthostatic hypotension.
- Avoid hazardous activities, since the drug may cause drowsiness.
- Do not discontinue the medication abruptly to prevent rebound hypertension.

Not every patient with an elevated BP and no target organ disease will require emergent drug therapy or hospitalization. Allowing the patient to sit for 20 or 30 minutes in a quiet environment may significantly reduce BP. Oral drugs may be started or adjusted. Additional nursing interventions include encouraging the patient to verbalize any concerns or fears, answering questions regarding hypertension, and eliminating any adverse stimuli (e.g., excess noise) in the patient's environment.

CASE STUDY

Primary Hypertension

iStockphoto/Thinkstock

Patient Profile

R.L. is a 45-year-old African American man with no previous history of hypertension. At a screening clinic 2 months ago, his BP was found to be 150/95 mm Hg. His primary care provider has followed him for the past month. During this time he has been taking hydrochlorothiazide 12.5 mg/day. He is here today for a follow-up visit.

Subjective Data

- Father died of stroke at age 60
- Mother is alive but has hypertension and a history of MI
- States that he feels fine and is not a "hyper" person
- Smokes one pack of cigarettes daily for the past 28 yr
- Drinks 1-2 six-packs of beer on most Friday and Saturday nights
- Has heard that BP drugs "make you impotent"

Objective Data

Physical Examination

- Mild retinopathy (retinal arteriolar narrowing on ophthalmoscopic examination)
- BP: 166/108 mm Hg (average of two readings, 1 min apart)
- Sustained apical impulse palpable in the fourth intercostal space just lateral to the midclavicular line

Diagnostic Studies

- ECG: mild left ventricular hypertrophy
- Urinalysis: protein 30 mg/dL (0.3 g/L)
- Serum creatinine level: 1.6 mg/dL (141 mmol/L)

Collaborative Care

- Low-sodium, DASH diet
- Hydrochlorothiazide 25 mg/day PO (dosage increase)
- Nicardipine (Cardene) sustained release 30 mg PO bid (second drug added)

Discussion Questions

1. What risk factors for hypertension does R.L. have?
2. What evidence of target organ disease is present?
3. What misconceptions about hypertension should be corrected?
4. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses and interventions? What are the collaborative problems?
5. ***Evidence-Based Practice:*** R.L. wants to know the most effective nonpharmacologic strategies to lower his BP. What would you tell him?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which BP-regulating mechanism(s) can result in the development of hypertension if defective *(select all that apply)?*
   - **a.** Release of norepinephrine
   - **b.** Secretion of prostaglandins
   - **c.** Stimulation of the sympathetic nervous system
   - **d.** Stimulation of the parasympathetic nervous system
   - **e.** Activation of the renin-angiotensin-aldosterone system
2. While obtaining subjective assessment data from a patient with hypertension, the nurse recognizes that a modifiable risk factor for the development of hypertension is
   - **a.** a low-calcium diet.
   - **b.** excessive alcohol consumption.
   - **c.** a family history of hypertension.
   - **d.** consumption of a high-protein diet.
3. In teaching a patient with hypertension about controlling the condition, the nurse recognizes that
   - **a.** all patients with elevated BP require medication.
   - **b.** obese persons must achieve a normal weight to lower BP.
   - **c.** it is not necessary to limit salt in the diet if taking a diuretic.
   - **d.** lifestyle modifications are indicated for all persons with elevated BP.
4. A major consideration in the management of the older adult with hypertension is to
   - **a.** prevent primary hypertension from converting to secondary hypertension.
   - **b.** recognize that the older adult is less likely to adhere to the drug therapy regimen than a younger adult.
   - **c.** ensure that the patient receives larger initial doses of antihypertensive drugs because of impaired absorption.
   - **d.** use careful technique in assessing the BP of the patient because of the possible presence of an auscultatory gap.
5. A patient with newly discovered high BP has an average reading of 158/98 mm Hg after 3 months of exercise and diet modifications. Which management strategy will be a priority for this patient?
   - **a.** Medication will be required because the BP is still not at goal.
   - **b.** BP monitoring should continue for another 3 months to confirm a diagnosis of hypertension.
   - **c.** Lifestyle changes are less important, since they were not effective, and medications will be started.
   - **d.** More vigorous changes in the patient's lifestyle are needed for a longer time before starting medications.
6. A patient is admitted to the hospital in hypertensive emergency (BP 244/142 mm Hg). Sodium nitroprusside is started to treat the elevated BP. Which management strategy(ies) would be appropriate for this patient *(select all that apply)?*
   - **a.** Measuring hourly urine output
   - **b.** Decreasing the MAP by 50% within the first hour
   - **c.** Continuous BP monitoring with an intraarterial line
   - **d.** Maintaining bed rest and providing tranquilizers to lower the BP
   - **e.** Assessing the patient for signs and symptoms of heart failure and changes in mental status

1. a, c, e, 2. b, 3. d, 4. d, 5. a, 6. a, c, e

LEARNING OUTCOMES

1. Relate the etiology and pathophysiology of coronary artery disease (CAD), angina, and acute coronary syndrome (ACS) to the clinical manifestations of each disorder.
2. Describe the nursing role in the promotion of therapeutic lifestyle changes in patients at risk for CAD.
3. Differentiate the precipitating factors, clinical manifestations, collaborative care, and nursing management of the patient with CAD and chronic stable angina.
4. Explain the clinical manifestations, complications, diagnostic study results, and collaborative care of the patient with ACS.
5. Evaluate commonly used drug therapy in treating patients with CAD and ACS.
6. Prioritize key components to include in the rehabilitation of patients recovering from ACS and coronary revascularization procedures.
7. Differentiate the precipitating factors, clinical presentation, and collaborative care of patients who are at risk for or have experienced sudden cardiac death.

Cardiovascular disease is the major cause of death in the United States. (The leading causes of death are shown in eFig. 34-1, available on the website for this chapter.) Coronary artery disease (CAD) is the most common type of cardiovascular disease and accounts for the majority of these deaths.[1] Patients with CAD can be asymptomatic or develop chronic stable angina (or chest pain). Unstable angina (UA) and myocardial infarction (MI) are more serious manifestations of CAD and are termed *acute coronary syndrome* (ACS).

The American Heart Association (AHA) estimates that 1.1 million Americans have an MI each year. About one fourth of these persons die in an emergency department (ED) or before reaching a hospital. Although the mortality rate from MI has decreased because of advances in treatment, it remains the leading cause of death from all cardiovascular diseases and other conditions in general.[1]

CORONARY ARTERY DISEASE

Coronary artery disease (CAD) is a type of blood vessel disorder that is included in the general category of atherosclerosis. The term **atherosclerosis** comes from two Greek words: *athere,* meaning "fatty mush," and *skleros,* meaning "hard." This combination implies that atherosclerosis begins as soft deposits of fat that harden with age. Consequently, atherosclerosis is commonly referred to as "hardening of the arteries." Although this condition can occur in any artery in the body, the *atheromas* (fatty deposits) prefer the coronary arteries. The terms *arteriosclerotic heart disease, cardiovascular heart disease, ischemic heart disease, coronary heart disease,* and *CAD* all describe this disease process.

Etiology and Pathophysiology

Atherosclerosis is the major cause of CAD. It is characterized by deposits of lipids within the intima of the artery. Endothelial injury and inflammation play a central role in the development of atherosclerosis.

The endothelium (the inner lining of the vessel wall) is normally nonreactive to platelets and leukocytes, as well as coagulation, fibrinolytic, and complement factors. However, the endothelial lining can be injured as a result of tobacco use, hyperlipidemia, hypertension, toxins, diabetes, hyperhomocysteinemia, and infection causing a local inflammatory response[2] (Fig. 34-1, *A*).

C-reactive protein (CRP), a protein produced by the liver, is a nonspecific marker of inflammation. It is increased in many patients with CAD[3] (see Table 32-6). The level of CRP rises when there is systemic inflammation. Chronic elevations of CRP are associated with unstable plaques and the oxidation of low-density lipoprotein (LDL) cholesterol.

Developmental Stages. CAD is a progressive disease that develops over many years. When it becomes symptomatic, the disease process is usually well advanced. The stages of development in atherosclerosis are (1) fatty streak, (2) fibrous plaque, and (3) complicated lesion.

Fatty Streak. *Fatty streaks,* the earliest lesions of atherosclerosis, are characterized by lipid-filled smooth muscle cells. As streaks of fat develop within the smooth muscle cells, a yellow tinge appears.[2] Fatty streaks can be seen in the coronary arteries by age 15 and involve an increasing amount of surface area as one ages. Treatment that lowers LDL cholesterol may reverse this process (Fig. 34-1, *B*).

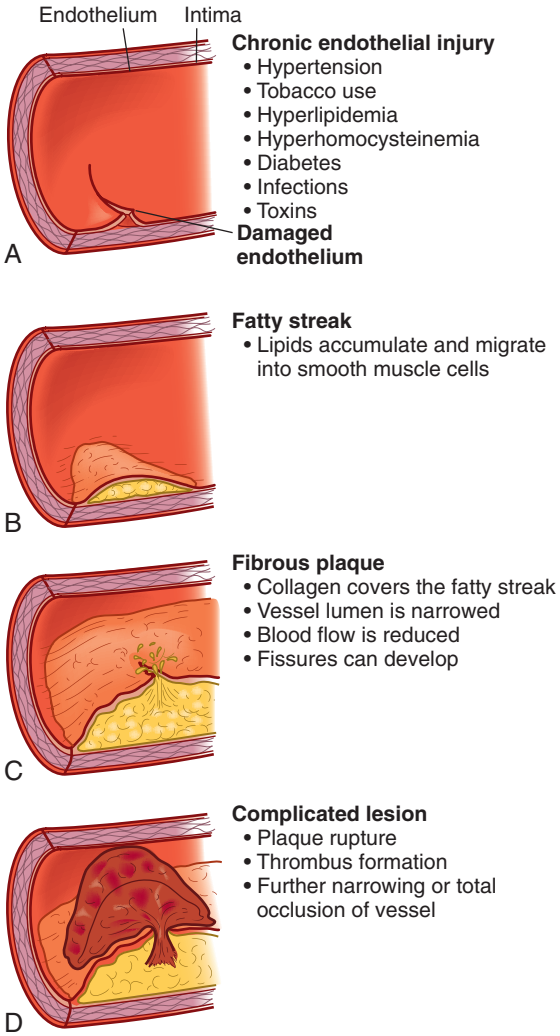

FIG. 34-1 Pathogenesis of atherosclerosis. **A,** Damaged endothelium. **B,** Fatty streak and lipid core formation. **C,** Fibrous plaque. Raised plaques are visible: some are yellow; others are white. **D,** Complicated lesion: thrombus is red; collagen is blue. Plaque is complicated by red thrombus deposition.

Fibrous Plaque. The *fibrous plaque* stage is the beginning of progressive changes in the endothelium of the arterial wall. These changes can appear in the coronary arteries by age 30 and increase with age.

Normally the endothelium repairs itself immediately. This does not happen in the individual with CAD. LDLs and growth factors from platelets stimulate smooth muscle proliferation and thickening of the arterial wall. Once endothelial injury has taken place, lipoproteins (carrier proteins within the bloodstream) transport cholesterol and other lipids into the arterial intima. Collagen covers the fatty streak and forms a fibrous plaque with a grayish or whitish appearance. These plaques can form on one portion of the artery or in a circular fashion involving the entire lumen. The borders can be smooth or irregular with rough, jagged edges. The result is a narrowing of the vessel lumen and a reduction in blood flow to the distal tissues (Fig. 34-1, *C*).

Complicated Lesion. The final stage in the development of the atherosclerotic lesion is the most dangerous. As the fibrous plaque grows, continued inflammation can result in plaque instability, ulceration, and rupture. Once the integrity of the

artery's inner wall is compromised, platelets accumulate in large numbers, leading to a thrombus. The thrombus may adhere to the wall of the artery, leading to further narrowing or total occlusion of the artery. Activation of the exposed platelets causes expression of glycoprotein Ilb/IIIa receptors that bind fibrinogen. This, in turn, leads to further platelet aggregation and adhesion, further enlarging the thrombus. At this stage the plaque is referred to as a *complicated lesion* (Fig. 34-1, *D*).

Collateral Circulation. Normally some arterial anastomoses or connections, termed **collateral circulation,** exist within the coronary circulation. Two factors contribute to the growth and extent of collateral circulation: (1) the inherited predisposition to develop new blood vessels *(angiogenesis)* and (2) the presence of chronic ischemia. When a plaque occludes the normal flow of blood through a coronary artery and the resulting *ischemia* is chronic, increased collateral circulation develops (Fig. 34-2). When occlusion of the coronary arteries occurs slowly over a long period, there is a greater chance of adequate collateral circulation developing, and the myocardium may still receive an adequate amount of blood and oxygen.

However, with rapid-onset CAD (e.g., familial hypercholesterolemia) or coronary spasm, time is inadequate for collateral development. Consequently, a diminished blood flow results in a more severe ischemia or infarction.

Risk Factors for Coronary Artery Disease

Risk factors are characteristics or conditions that are associated with a high incidence of a disease. Many risk factors have been associated with CAD. They are categorized as nonmodifiable and modifiable (Table 34-1). *Nonmodifiable risk factors* are age, gender, ethnicity, family history, and genetics. *Modifiable risk factors* include elevated serum lipids, elevated blood pressure, tobacco use, physical inactivity, obesity, diabetes, metabolic syndrome, psychologic states, and elevated homocysteine level.

Data on risk factors for CAD come from several major studies. In the Framingham study (one of the most widely known), men and women were observed for 20 years. Over time, it was noted that elevated serum cholesterol (greater than 240 mg/dL), elevated systolic blood pressure (BP) (greater than 160 mm Hg), and tobacco use (one or more packs a day) were positively correlated with an increased incidence of CAD.[1]

Nonmodifiable Risk Factors

Age, Gender, and Ethnicity. The incidence of CAD and MI is highest among white, middle-aged men. After age 65, the incidence in men and women equalizes, although cardiovascular disease causes more deaths in women than men. Additionally, CAD is present in African American women at rates higher than those of their white counterparts.[1] (See Cultural & Ethnic Health Disparities box for additional differences in CAD among ethnic groups.)

Heart disease kills almost 10 times more women than breast cancer and is the leading cause of death in women. Yet most women do not consider CAD their greatest health risk.[4] (Cardiovascular disease mortality trends for both men and women are shown in eFig. 34-2, available on the website for this chapter.) On average, women with CAD are older than men who have

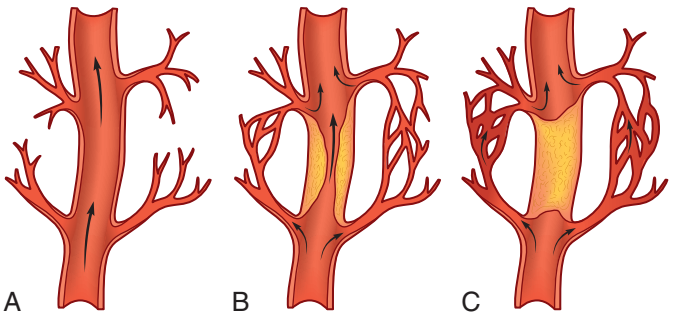

FIG. 34-2 Vessel occlusion with collateral circulation. **A,** Open, functioning coronary artery. **B,** Partial coronary artery closure with collateral circulation being established. **C,** Total coronary artery occlusion with collateral circulation bypassing the occlusion to supply blood to the myocardium.

CULTURAL & ETHNIC HEALTH DISPARITIES

Coronary Artery Disease

Whites
- White, middle-aged men have the highest incidence of coronary artery disease (CAD).

African Americans
- African Americans have an early age of onset of CAD.
- Mortality rates for African Americans ages 35 to 64 are more than twice those of whites of the same age.
- African American women have a higher incidence and death rate related to CAD than white women.

Native Americans
- Native Americans less than 35 yr of age have heart disease mortality rates twice as high as those of other Americans.
- Major modifiable cardiovascular risk factors for Native Americans are tobacco use, hypertension, obesity, and diabetes mellitus.

Hispanics
- Hispanics have lower rates of CAD than either non-Hispanic whites or African Americans.
- Hispanics have lower death rates from CAD than non-Hispanic whites.

TABLE 34-1 RISK FACTORS FOR CORONARY ARTERY DISEASE

Nonmodifiable Risk Factors	Modifiable Risk Factors
Increasing age	**Major**
Gender (more common in men than in women until 65 yr of age)	Serum lipids: • Total cholesterol >200 mg/dL • Triglycerides ≥150 mg/dL* • LDL cholesterol >160 mg/dL • HDL cholesterol <40 mg/dL in men or <50 mg/dL in women*
Ethnicity (more common in whites than in African Americans)	Blood pressure ≥140/90 mm Hg*
Genetic predisposition and family history of heart disease	Diabetes mellitus
	Tobacco use
	Physical inactivity
	Obesity: Waist circumference ≥102 cm (≥40 in) in men and ≥88 cm (≥35 in) in women*
	Contributing
	Fasting blood glucose ≥100 mg/dL*
	Psychosocial risk factors (e.g., depression, hostility, anger, stress)
	Elevated homocysteine levels

*Three or more of these risk factors meet the criteria for metabolic syndrome (as defined by the National Cholesterol Education Program Adult Treatment Panel III). Metabolic syndrome is discussed in Chapter 49.

GENDER DIFFERENCES

Coronary Artery Disease and Acute Coronary Syndrome

Men	Women
Coronary Artery Disease	
• Initial cardiac event for men is more often MI than angina. • Men report more typical signs and symptoms of angina and MI. • Men receive more evidence-based therapies (e.g., aspirin, statins, diagnostic catheterization, PCI) when acutely ill from CAD (e.g., MI) than women. • Mortality rates from CAD have fallen more rapidly for men than women.	• Women experience the onset of heart disease approximately 10 yr later than men. • CAD is the leading cause of death for women, regardless of race or ethnicity. • Initial cardiac event for women is more often angina than MI. • More women than men with MI die of sudden cardiac death before reaching the hospital. • Before menopause, women have higher HDL cholesterol levels and lower LDL cholesterol levels than men. After menopause LDL levels increase.
Acute Coronary Syndrome	
• Incidence of MI is highest among white, middle-aged men. • After age 65, the incidence of MI in men and women equalizes. • Men present more frequently than women with an acute MI as the first manifestation of CAD. • Men develop greater collateral circulation than women. • Men have larger-diameter coronary arteries than women. Vessel diameter is inversely related to risk of restenosis after interventions. • Standard screening for risk of sudden cardiac death (e.g., EP studies) is more predictive in men.	• Women are older than men when seen with first MI and often have more co-morbidities. • Women delay longer in seeking care and are often more ill on presentation than men. • Once a woman reaches menopause, her risk for an MI quadruples. • Fewer women than men manifest the "classic" signs and symptoms of UA or MI. • Fatigue is often the first symptom of ACS in women. • Women experience more "silent" MIs compared with men. • Among those who have an MI, women are more likely to suffer a fatal cardiac event within 1 yr than men. • Women report more disability after a cardiac event than men. • Women who have coronary artery bypass graft surgery have a higher mortality rate and more complications after surgery than men.

ACS, Acute coronary syndrome; *CAD,* coronary artery disease; *EP,* electrophysiology; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *PCI,* percutaneous coronary intervention, *UA,* unstable angina.

CAD, and women are more likely to have co-morbidities (e.g., hypertension, diabetes). Most women have atypical symptoms of angina rather than MI when they experience their first cardiac event[4] (see Gender Differences box).

Genetic Link

Genetic predisposition is an important factor in the occurrence of CAD. Family history is a risk factor for CAD and MI. Most times, patients with angina or MI can name a parent or sibling who died of CAD.

The genetic basis of CAD/MI is complex and, to date, poorly understood. It is estimated that the genetic contribution to CAD/MI is as high as 40% to 60%. This proportion relates mainly to genes that control known risk factors (e.g., lipid metabolism).[5] (Genes known to contribute to CAD risk are listed in eTable 34-1, available on the website for this chapter.) See the Genetics in Clinical Practice box at right.

Major Modifiable Risk Factors

Elevated Serum Lipids. An elevated serum lipid level is one of the four most firmly established risk factors for CAD.[6] The risk of CAD is associated with a serum cholesterol level greater than 200 mg/dL (5.2 mmol/L) or a fasting triglyceride level greater than 150 mg/dL (3.7 mmol/L). (See Table 32-6 for normal serum lipid values.)

For lipids to be used and transported by the body, they must become soluble in blood by combining with proteins. Lipids combine with proteins to form lipoproteins. Lipoproteins are vehicles for fat mobilization and transport, and vary in composition. They are classified as high-density lipoproteins (HDLs), LDLs, and very-low-density lipoproteins (VLDLs).

HDLs contain more protein by weight and fewer lipids than any other lipoprotein. HDLs carry lipids away from arteries

GENETICS IN CLINICAL PRACTICE

Familial Hypercholesterolemia

Genetic Basis
- Autosomal dominant disorder.
- Mutation in low-density lipoprotein receptor *(LDLR)* gene.
- Gene codes for low-density lipoprotein (LDL) receptor that binds to LDLs.
- LDLs are the primary carriers of cholesterol in the blood. By removing LDLs from the bloodstream, the LDL receptors play a critical role in regulating cholesterol levels.
- Exists in both heterozygous (most common) and homozygous forms.

Incidence
- Heterozygotes: 1 in 500
- Homozygotes: rare

Genetic Testing
- Disorder is characterized by elevated serum LDLs.
- Serum lipid profile can be used to measure total cholesterol, triglycerides, LDLs, and high-density lipoproteins (HDLs).
- DNA testing is available.

Clinical Implications
- Common genetic disease.
- High cholesterol levels are a result of defective function of the LDL receptors.
- Plasma levels of LDLs elevated throughout life.
- Develop severe atherosclerosis in early to middle years.
- Xanthomas (fatty deposits under the surface of the skin) can occur (see eFig. 34-4, available on the website for this chapter).
- Treatment strategies include low-fat diet, exercise, and lipid-lowering medications.
- Homozygous familial hypercholesterolemia is much more severe than the heterozygous form. Cholesterol levels may exceed 600 mg/dL in these patients.

and to the liver for metabolism. This process of HDL transport prevents lipid accumulation within the arterial walls. Therefore high serum HDL levels are desirable and lower the risk of CAD.

There are two types of HDLs: HDL_2 and HDL_3. They differ by their density and apolipoprotein composition. Apolipoproteins are found on lipoproteins and activate enzyme or receptor sites that promote the removal of fat from plasma. Several types of apolipoproteins exist (e.g., apo A-I, apo B-100, apo C-I). Women produce more apo A-I than men, and premenopausal women have HDL_2 levels approximately three times greater than men. This is thought to be related to the protective effects of natural estrogen. After menopause, women's HDL_2 levels decrease and quickly near those of men.

In general, HDL levels are higher in women, decrease with age, and are low in persons with CAD. Physical activity, moderate alcohol consumption, and estrogen administration increase HDL levels.

LDLs contain more cholesterol than any of the lipoproteins and have an attraction for arterial walls. VLDLs contain both cholesterol and triglycerides, and may deposit cholesterol directly on the walls of arteries. Elevated LDL levels correlate closely with an increased incidence of atherosclerosis and CAD. Therefore low serum LDL levels are desirable.[6,7]

Certain diseases (e.g., type 2 diabetes, chronic kidney disease), drugs (e.g., corticosteroids, hormone therapy), and genetic disorders have been associated with elevated triglyceride levels. Lifestyle factors that can contribute to elevated triglycerides include high alcohol consumption, high intake of refined carbohydrates and simple sugars, and physical inactivity. When a high triglyceride level is combined with a high LDL level, a smaller, denser LDL particle is formed, which favors deposition on arterial walls. People with insulin resistance often have this pattern.

Guidelines for treating elevated LDL cholesterol are based on a person's 10-year risk for having a nonfatal MI or dying from a coronary event and his or her LDL levels. The following information generates a risk score: (1) age, (2) gender, (3) use of tobacco, (4) systolic BP, (5) use of BP medications, (6) total cholesterol, and (7) HDL cholesterol level.[7] A 10-year risk calculator is available at *http://hin.nhlbi.nih.gov/atpiii/calculator.asp?usertype=prof*.

In general, individuals with no or only one risk factor are considered at low risk for the development of CAD, and the LDL goal is less than 160 mg/dL (4.14 mmol/L). Those at very high risk have CAD and multiple risk factors. The LDL goal for this group is less than 70 mg/dL (1.8 mmol/L).[7]

Hypertension. The second major risk factor in CAD is hypertension, which is defined as a BP greater than 140/90 mm Hg or greater than 130/80 mm Hg if the patient has diabetes or chronic kidney disease.[8] Hypertension increases the risk of death from CAD 10-fold in all people. In postmenopausal women, hypertension is associated with a higher incidence of CAD than in men and premenopausal women.

Blood pressure is classified as (1) normal (BP less than 120/80 mm Hg), (2) *prehypertension* (BP of 120 to 139/80 to 89 mm Hg), (3) stage 1 hypertension (140 to 159/90 to 99 mm Hg), and (4) stage 2 hypertension (BP greater than 160/100 mm Hg).[8] The cause of hypertension in 90% of those affected is unknown, but it is usually controllable with diet and/or drugs. Therapeutic lifestyle changes should begin in people with prehypertension. Those with stage 1 or 2 hypertension often require more than one drug to reach therapeutic goals[8] (see Table 33-7). Teach all people with elevated systolic or diastolic BP the importance of achieving and maintaining target BP goals.

The stress of an elevated BP increases the rate of atherosclerotic development. This relates to the shearing stress that causes endothelial injury. Atherosclerosis, in turn, causes narrowed, thickened arterial walls and decreases the distensibility and elasticity of vessels. More force is required to pump blood through diseased arteries, and this increased force is reflected in a higher BP. This increased workload results in left ventricular hypertrophy and decreased stroke volume with each contraction. Salt intake positively correlates with elevated BP, adding volume and increasing systemic vascular resistance (SVR) to the cardiac workload. (See Chapter 33 for a complete discussion of hypertension.)

Tobacco Use. A third major risk factor in CAD is tobacco use. The risk of developing CAD is two to six times higher in those who smoke tobacco or use smokeless tobacco than in those who do not. Further, tobacco smoking decreases estrogen levels, placing premenopausal women at greater risk for CAD. Risk is proportional to the number of cigarettes smoked. Changing to lower nicotine or filtered cigarettes does not affect risk.

Nicotine in tobacco smoke causes catecholamine (i.e., epinephrine, norepinephrine) release. These neurohormones cause an increased heart rate (HR), peripheral vasoconstriction, and increased BP. These changes increase the cardiac workload. Tobacco smoke is also related to an increase in LDL level, a decrease in HDL level, and release of toxic oxygen radicals. All of these add to vessel inflammation and thrombosis.[2]

Carbon monoxide, a byproduct of combustion found in tobacco smoke, affects the oxygen-carrying capacity of hemoglobin by reducing the sites available for oxygen transport. Thus the effects of an increased cardiac workload, combined with the oxygen-depleting effect of carbon monoxide, significantly decrease the oxygen available to the myocardium. There is also some indication that carbon monoxide is a chemical irritant and causes injury to the endothelium.

The benefits of smoking cessation are dramatic and almost immediate. CAD mortality rates drop to those of nonsmokers within 12 months. However, nicotine is highly addictive, and often intensive intervention is required to assist people to quit. Individual and group counseling sessions, nicotine replacement therapy, smoking cessation medications (e.g., bupropion [Zyban], varenicline [Chantix]), and hypnosis are examples of smoking cessation strategies. (See Chapter 11, Tables 11-4 through 11-6 for information on smoking cessation.)

Chronic exposure to environmental tobacco (secondhand) smoke also increases the risk of CAD.[6] People who live in the same household as the patient should be encouraged to stop smoking. This reinforces the individual's effort and decreases the risk of ongoing exposure to environmental smoke. Pipe and cigar smokers, who often do not inhale, have an increased risk of CAD similar to those exposed to environmental tobacco smoke.

Physical Inactivity. Physical inactivity is the fourth major modifiable risk factor. Physical inactivity implies a lack of adequate physical exercise on a regular basis. An example of health-promoting regular physical activity is brisk walking (3 to 4 miles per hour) for at least 30 minutes five or more times a week.[9]

The mechanism by which physical inactivity predisposes a person to CAD is mostly still unknown. Physically active people

have increased HDL levels. Exercise improves thrombolytic activity, thus reducing the risk of clot formation. Exercise may also encourage the development of collateral circulation in the heart.

Exercise training for those who are physically inactive decreases the risk of CAD through more efficient lipid metabolism, increased HDL production, and more efficient oxygen extraction by the working muscles, thereby decreasing the cardiac workload. For those individuals with CAD, regular physical activity reduces symptoms, improves functional capacity, and improves other risk factors such as insulin resistance and glucose intolerance.

Obesity. The mortality rate from CAD is statistically higher in obese persons. Obesity is defined as a body mass index (BMI) of greater than 30 kg/m^2 and a waist circumference more than 40 inches for men and more than 35 inches for women. BMI is a measure of body fat based on height and weight. It can be calculated online *(http://nhlbisupport.com/bmi/bmicalc.htm)*.
